A sequential switching circuit is a circuit which assumes a number of states, each dependent not only upon the particular input signals, or combination of input signals, applied but also upon the sequence in which these signals appear. In other words, the behavior of a sequential circuit, upon receipt of a given input signal, depends upon its state resulting from previous input signals. This is in contrast to the combinational-type circuits which have just been discussed. The essential difference between these two types of circuit lies in the requirement that the sequential circuit, unlike the combinational circuit, must include some form of memory to make possible a differentiation between similar signals separated in time.

A circuit designed to count a number of identical pulses is a familiar example of a sequential circuit. As pulses are received, the counting circuit passes from one state to another. The state of the circuit at any instant during the process depends upon the number of pulses already received before that time. Therefore, the circuit must be capable of remembering that a given pulse has been received until the next pulse has arrived; that is, the memory facilities must store information of the receipt of the first pulse until the second pulse appears, it must store information of the receipt of the second pulse until the third pulse appears, and so on.

This partial analysis of a counting circuit indicates that the memory capabilities of the circuit must be sufficient to store a number of different pieces or bits of information, the exact number, as will be seen, depending upon the maximum number of pulses to be counted. It is convenient to assume that the required storage facilities consist of 2-valued elements, each capable of remembering one bit of information. Such an element may be a gas tube, semiconductor device, bistable multivibrator, or the like; its basic characteristic consisting of the ability to remain in one state until driven by a signal to a second state. It may then remain in this second, active state until cleared by a second signal or until, after a predetermined time has elapsed, it returns to its original state under its own control. Individual cells on magnetic drums and memory tubes have simi-

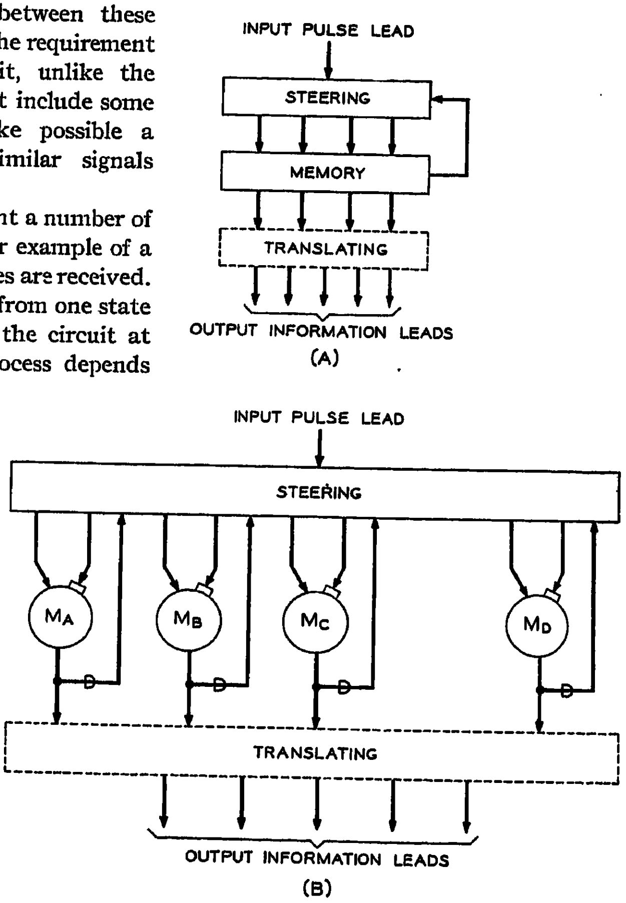

Fig. 13 (right). Block diagrams of counting circuit

lar characteristics, and may also be considered as separate memory elements.

To generalize, a memory element may be indicated in symbolic form as shown in Fig. 12(A). A signal on lead 1 (STORE) causes the element to assume its active state. A signal on lead 2 (CLEAR) clears the element, restoring it to its original passive state. An indication of the state of the element is obtained from lead 3 (READ). It is convenient to assume that this latter information is continuously available, although this is not necessary. Where the element is self-clearing, maintaining an active state for only a limited time, the CLEAR lead is omitted, as in Fig. 12(B).

Returning now to the analysis of the counting circuit requirements, it is clear that if the input pulses are themselves to actuate the various memory elements, some form of steering is necessary between the input pulse lead and the memory elements. If, for example, the first pulse is to actuate a memory element M_A and the second pulse is to actuate a memory element M_B, the first pulse should be directed to the STORE lead of element M_A and the second pulse to the STORE lead of element M_B. This steering function associating the input pulse lead with the memory elements can be under the direct control of these elements since, taken in aggregate, they indicate at any time the number of pulses already received.

Now, if this steering circuit is to be controlled directly from the READ leads of the memory elements, it is necessary to take measures to avoid switching the pulse lead while a pulse is still present on that lead. Where the memory elements are such that there is sufficient delay between the appearance of a STORE or CLEAR signal and the appearance and disappearance, respectively, of the active output signal on the READ lead, the control signals to the steering circuit will cause that circuit to act after the termination of each input pulse. However, if the memory elements are rapid in operation compared to the effective length of the pulses, it is necessary to insert delay elements (for example, a resistance-capacitance network) in the control paths between the READ leads and the steering elements. (This assumes input pulses of a predetermined, and preferably short duration. If pulses are of an undetermined duration, a differentiating network can be placed in the input lead to produce short, constant-duration pulses to actuate the counting circuit.) A delay element is indicated by the symbol D as in Fig. 12(C). It is important to note that this delay is not included in the memory requirements of the over-all circuit, but is necessitated by the steering function between the input pulse lead and the memory elements.

The requisite output indications to be passed to external circuits may be obtained from the memory elements. The output indications may be derived directly from the READ leads of the memory elements, or, if necessary, the READ leads may actuate a translating circuit to provide the count information in the desired form.

The over-all counting circuit may be shown in block form as in Fig. 13(A), to illustrate the required functions to be carried out in the circuit. Separating the memory block into its component parts, the symbolic representation of the circuit is as indicated in Fig. 13(B).

MEMORY REQUIREMENTS

In the design of a circuit capable of counting a certain maximum number of pulses, it is convenient to specify the minimum number of memory elements which must be provided. This may easily be determined from a consideration of the quantity of information which must be stored. Briefly, the circuit at any time must know, or must have remembered, how many pulses have been received. Thus, the circuit must have a capacity for storing a number of independent pieces of information equal to the maximum number of pulses. Thus, if these bits of information are stored in the collection of memory elements on a combinational basis, the number of memory elements, N, which must be provided is given by the expression $P \leq 2^N - 1$, where P is the maximum number of pulses, or by $P \leq 2^N$ if the circuit is to be restored to normal by the Pth pulse. It will be recognized that 2^N is the number of unique combinations of N elements, each of which is either active or inactive. For example, 15 pulses can be counted by a circuit containing 4 memory elements; the 16th pulse may be used to restore the circuit to normal.

It should be noted that this is not in contradication to the expression for the minimum number of relays R, in a relay counter: $2P \leq 2^R - 1$ or $2P \leq 2^R$, depending upon the action of the circuit after the Pth pulse. In the case of relay sequential circuits, both the memory facility and the delay necessitated by the steering function are provided by relays. Thus, the total number of relays which must be employed is greater than the number determined by the memory requirement alone.

In the design of a counting circuit, of course, the number of memory elements may exceed the theoretical minimum. This comes about because, in some cases, the arrangement used to steer the pulse lead may be simplified by the use of additional memory elements.

GENERAL DESIGN ROUTINE

After determining the number of memory elements to be utilized, an operating sequence is specified for these elements. This process corresponds to the formulation of a sequence diagram for a sequential relay circuit. By inspection of this sequence diagram, the requirements for actuating and clearing each memory element may be stated in terms of the input pulses and the states (active or passive) of all the memory elements. These requirements indicate the configuration of a suitable steering arrangement composed of gate elements; this circuit may be designed by the routine method already presented. Finally, if necessary, a translating circuit is similarly designed to provide the requisite output indications.

Although the preceding paragraphs have presented the basis for the design of a circuit for counting pulses, it is evident that the method is applicable to the design of any sequential circuit composed of gate and memory elements. In the general case, the single pulse lead of the diagram of Figure 13(B) is replaced by a number of input signal leads. Sufficient storage capacity is provided in accordance with the output requirements of the circuit, and a steering circuit composed of gate elements is placed between the input signal leads and the memory elements. The output signals may be obtained from the memory elements either directly or through a translating circuit. This translating circuit may be under the control of both the memory elements and the input signals.

THE DESIGN OF A 3-PULSE COUNTING CIRCUIT

Requirements

An electronic counting circuit is to be designed to follow short-duration positive pulses appearing on an input lead. The circuit is to recycle (restore to its normal condition) after a set of 3 pulses have been received. The output signals to be supplied to external circuits are not specified. The memory elements to be utilized have the following characteristics:

1. A positive signal on the STORE lead actuates the element;
2. A positive signal on the CLEAR lead clears the element;

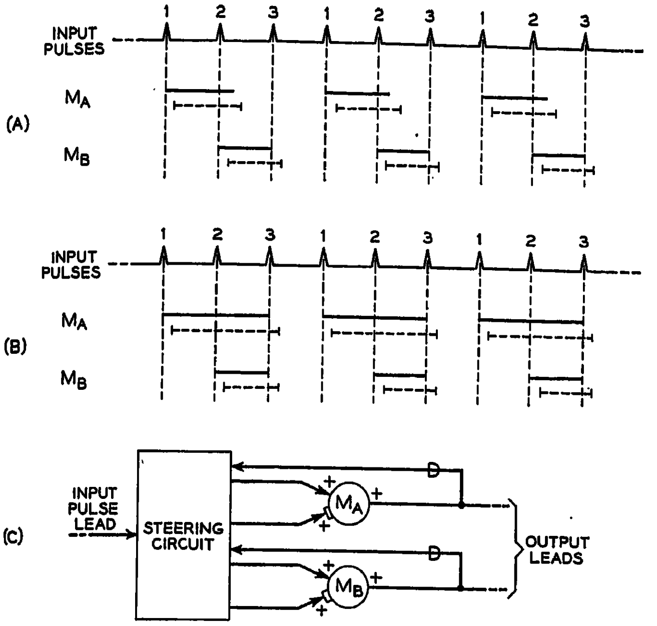

Fig. 14. Preliminary plans for 3-pulse counter

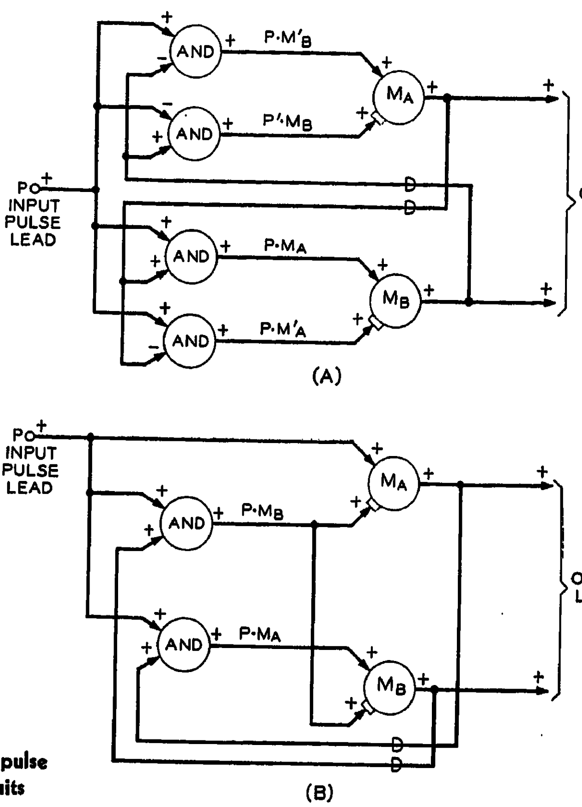

Fig. 15 (right). Three-pulse recycling counting circuits

3. A positive signal on the READ lead indicates that the element is in an active condition.

Solution

Since the number of pulses to be counted, 3, is greater than 2^1 but less than 2^2, it is evident that at least 2 memory elements must be provided. It appears that several sequences for the operation of these elements, M_A and M_B, are possible; two of these are indicated in Figs. 14(A) and 14(B). In both diagrams, the solid lines indicate the periods of activation of the memory elements, and the dotted lines indicate the resultant signals passed to the steering circuit through the delay elements. In the first of these sequences, the counting circuit knows that one pulse has been received if element M_A is actuated, and that two pulses have been received if element M_B is actuated. In the sequence of Fig. 14(B), the receipt of one pulse is indicated by M_A actuated and M_B at rest, and the receipt of two pulses by M_B actuated. In either case, a block diagram of the counting circuit will appear as in Fig. 14(C).

A symbolic circuit for the sequence of Fig. 14(A) is derived first. Evidently, the steering circuit must switch the pulse lead to four points:

1. The STORE lead of M_A;
2. The CLEAR lead of M_A;
3. The STORE lead of M_B;
4. The CLEAR lead of M_B.

Using switching algebra, a steering arrangement is determined by inspection of the sequence diagram, as follows:

Element M_A is actuated by a pulse occurring when both M_A and M_B are unactivated. Thus, the algebraic expression indicating the energization of the STORE lead of M_A is

$$f(M_A)_S=PM_A'M_B' \qquad (12)$$

Element M_A is cleared when M_B is in an activated state and no pulse is present. Therefore

$$f(M_A)_C=P'M_B \qquad (13)$$

Element M_B is actuated by a pulse occurring when M_A is actuated (as indicated on the lead from the READ lead of M_A through the delay D). Therefore, the requirement for energizing the STORE lead of M_B is

$$f(M_B)_S=PM_A \qquad (14)$$

Element M_B is cleared by a pulse occurring when M_A is at rest and M_B is actuated. Thus

$$f(M_B)_C=PM_BM_A' \qquad (15)$$

Further inspection of the diagram of Fig. 14(A) indicates that the above expressions for $f(M_A)_S$ and $f(M_B)_C$ may be simplified. Since the STORE lead of M_A may be energized while M_A is in an actuated state, without affecting the state of M_A, both the first and second input pulses may be placed on the STORE lead of M_A. Therefore

$$f(M_A)_S=PM_B' \qquad (16)$$

Similarly, a signal may be placed on the CLEAR lead of M_B when M_B is unactuated without altering its state; both the first and third pulse may appear on the CLEAR lead of M_B. Therefore

$$f(M_B)_C=PM_A' \qquad (17)$$

Sufficient information is now available for the design of the required switching circuit. By inspection of the algebraic expressions 13, 14, 16 and 17 above, and by translating the algebraic symbolism to the gate-element symbolism, the circuit of Fig. 15(A) may be drawn.

A circuit which operates on the sequence plan of Fig. 14(B) may be derived in a similar manner. Here, by inspection of the diagram

$$f(M_A)_S=P \qquad (18)^*$$

$$f(M_A)_C=PM_B \qquad (19)$$

$$f(M_B)_S=PM_A \qquad (20)$$

$$f(M_B)_C=PM_B \qquad (21)$$

Translating these expressions to the gate symbolism, the circuit of Fig. 15(B) immediately results. This circuit is obviously preferable to that of Fig. 15(A) in that two, rather than four, gates are employed. That this would result might have been anticipated since the sequence diagram of Fig. 14(B) evidently requires a less complicated steering procedure than that of Fig. 14(A).

---

* Note that, in this expression, use is made of the assumption that a CLEAR signal overrides a STORE signal to a memory element. If this cannot be assumed, $f(M_A)_S$ could be PM_A'.

Conclusion

On the basis of the procedures discussed here, it appears that the synthesis of electronic switching circuits constructed of 2-valued gate and memory elements can be carried out in a routine manner using the Boolean algebra and other formal techniques to replace much of the detailed logical analysis employed in circuit design. By means of various manipulations a circuit can easily be altered to a number of equivalent forms. The procedure corresponds almost exactly to that involved in the design of relay circuits.

However, the end result of this process in the present case is a circuit composed of more or less idealized elements. Considerable ingenuity may be necessary to replace these elements with their physical equivalents. Nevertheless, it may be anticipated that as new gates and memory devices appear, this final step in the design of a particular circuit may be accomplished in an almost routine fashion.

Transistors and Their Circuits in the 4A Toll Crossbar Switching System

P. MALLERY
NONMEMBER AIEE

NATION-WIDE dialing is one of the more recent advances in the telephone art and has been the subject of papers presented before the AIEE.[1] The heart of nation-wide dialing is the new no. *4A* toll crossbar switching system. It is this system which, at the various control switching points, receives the digits dialed by the toll operators or by the subscribers. It then automatically determines the routing of the call to any destination in the United States, as well as in Canada, and proceeds to establish the connection to succeeding control switching points or to the local office. In this system it is necessary to translate the digits received into information as to the location of trunks on the switches, the kind of outpulsing required, the number of digits to send forward, and other such instructions.

The translator needed for the no. *4A* system must have a large capacity, for it has to be capable of furnishing the information to route a call to any one of thousands of central offices in the United States and Canada. As frequent changes are made in the routing of calls due to the growth of the system and modifications of central offices, corresponding changes must be made in the routing information at the control-switching points. It is therefore necessary to be able to quickly and economically change the routing information pertaining to any given set of input digits. In short, the translator must perform functions similar in nature to those accomplished by quick reference card files.

In order to meet these requirements it was necessary to develop a new type of translator[2] radically different from any previously used. Its operation is based on selecting a particular card from a stack of cards in accordance with the input digits. It obtains the routing information from the output code registered on the card. To determine this output code the translator depends upon that revolutionary new device, the transistor. The purpose of this paper is to describe the transistor and its circuits, as used in the card translator.

Fig. 1 shows a card with the output information registered on it in the form of enlarged holes. In the translator this card stands in a vertical position, resting on the tabs along its lower edge. When all cards are in their normal position, they line up and the holes in the cards form unobstructed, horizontal tunnels, called channels, through the entire stack. The tabs on the lower edge of the card correspond to the input digits for which this card supplies the routing information. A particular card is selected by automatically lowering the support from under its tabs thus allowing it to drop a distance slightly greater than the height of an unenlarged hole. All channels through the stack of cards will then be blocked by the dropped card except those for which the holes in the card have been enlarged. This results in a pattern of clear channels which represents the output information. Determination of whether a channel is clear or blocked is made by passing light beams through the holes. Fig. 2 illustrates the change from all cards normal to one card dropped.

The Channel Circuit

Fig. 3 is a block diagram of the circuit used to determine whether a particular channel is interrupted by a dropped card or not. Each block, with the exception of the light source, represents a piece of equipment provided individually for each channel. The light source is common to all channels. If the hole in the dropped card for a particular channel has been enlarged, the light will pass completely through the stack of cards and fall on the phototransistor. The phototransistor converts the presence of light into an electrical signal which, after being increased by the transistor ampli-

Paper 53-218, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 17, 1953; made available for printing April 23, 1953.

P. MALLERY is with the Bell Telephone Laboratories, Inc., New York, N. Y.

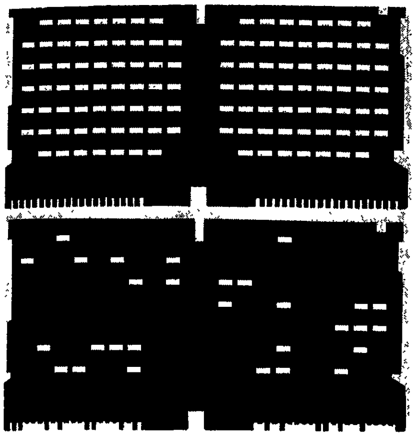

Fig. 2. End view of the stack of cards. The upper section shows all cards normal, the lower shows one card selected and dropped

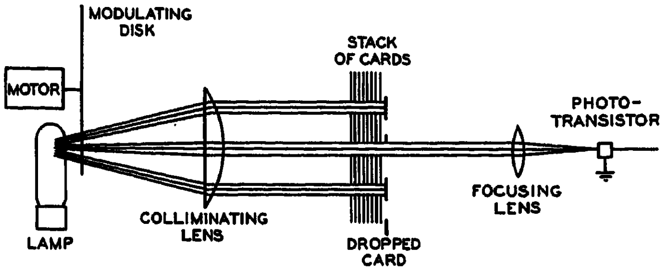
Fig. 4 (right). Optical section of channel circuit



fier, is used to trigger a cold-cathode gas tube. The gas tube, in turn, operates the channel relay. This relay is located in the associated equipment which uses the information supplied by the translator to actually process the call.

In making a detailed examination of the channel circuit it is convenient to break it down into two parts, the optical section and the electrical. The optical section includes everything up to the point where the light falls upon the germanium of the phototransistor. This part of the channel is shown functionally as Fig. 4. The light source is a standard projection-type lamp normally rated at 500 watts. To obtain long life it is operated in the translator at half voltage at which level its input is approximately 170 watts. This type of lamp was chosen because of its high concentration of light in a small plane.

The light from the lamp passes through a motor-driven perforated disk which modulates it with an approximate square wave at a 400-cycle rate. Modulated light is used because it is easier to build a-c than d-c amplifiers, and also, in this manner, the ratio between the light and dark currents of the phototransistor is the important factor rather than the absolute value of either. The modulated light is collimated by a lens to minimize the loss as the beam passes through the holes in the card. Unless interrupted by a dropped card, this light beam will pass through all of the cards and fall on the lens which focuses the light on the sensitive area of the phototransistor. The minimum light intensity at the lens of the phototransistor is 34 foot-candles. This supplies about 12 millilumens to the phototransistor, a figure relatively small when compared to the light intensity required by conventional photoelectric cells. The electrical part of the channel circuits starts with the phototransistor and is shown in Fig. 5. The light acts as the emitter of the phototransistor. The collector is of the conventional type for point-contact transistors.

As is normal in grounded-base transistor circuits, the collector of the phototransistor is biased in the high impedance direction. A variation in the light intensity causes a variation in the collector impedance of the phototransistor. The type used has an impedance of about 10,000 ohms when dark, which is reduced to approximately 3,000 ohms when illuminated. The output of an illuminated phototransistor, when coupled to the amplifier, ranges from 1.3 to 12 volts, positive peak (400 cycles), depending upon the age and condition of the transistor.

Since the discrimination by the channel circuit between a clear or blocked light path depends upon the presence or absence of an a-c output from the phototransistor, noise of sufficient magnitude, if present when the channel is dark, would cause a false indication. To guard against such false operations the Western Electric Company, during the manufacturing process, checks each phototransistor for dark noise. If during a 5-minute interval the dark voltage exceeds 20 millivolts, that phototransistor is rejected.

The phototransistor is coupled to the amplifying transistor by transformer *T1*. This permits convenient matching of impedances and separation of the d-c bias voltage. A voltage-limiting varistor *V* is connected across the input of the transformer to limit surges which might otherwise damage the amplifying transistor. The circuit of the transistor amplifier is a conventional common-base arrangement.

The voltage gain of the amplifier, including the input transformer to the gas tube, ranges from 40 to 100. However when operating in the translator, the phototransistors normally will drive the amplifier to saturation, which limits the output to 160 volts positive peak or less. For the purpose of guaranteeing operation a minimum output voltage of 38.5 has been set as a rejection point for a phototransistor-amplifier combination.

The output of the transistor amplifier is normally sufficient to break down the control gap of the *376B* cold-cathode gas tube. Sufficient current flows in this control gap to insure reliable transfer to the main gap when the output control relay *O* in the associated equipment operates. But to provide greater operating margin, the bias of −24 volts is removed from the control anode just before channel operation is required. The relay *R*, which substitutes ground for the bias voltage is operated by a circuit which checks that the card being dropped is completely down. This down-check circuit utilizes two holes in the card which are never enlarged and employs two photo transistors to detect the presence or absence of light through these holes.

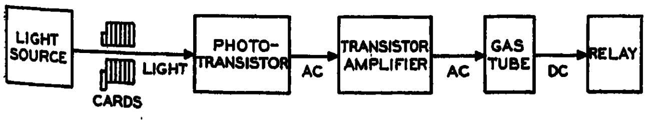


Fig. 3. Block diagram of channel circuit

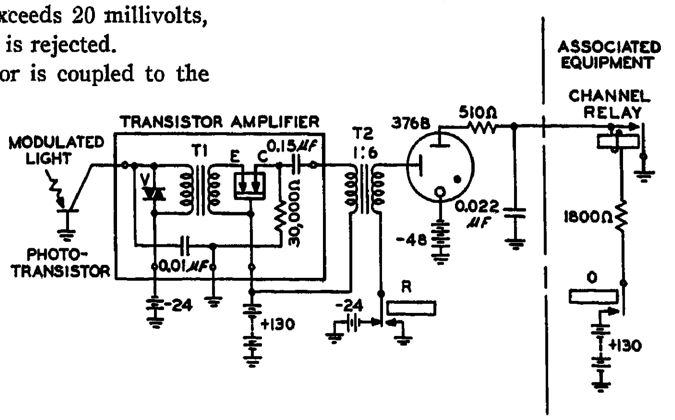

Fig. 5. Electrical section of channel circuit

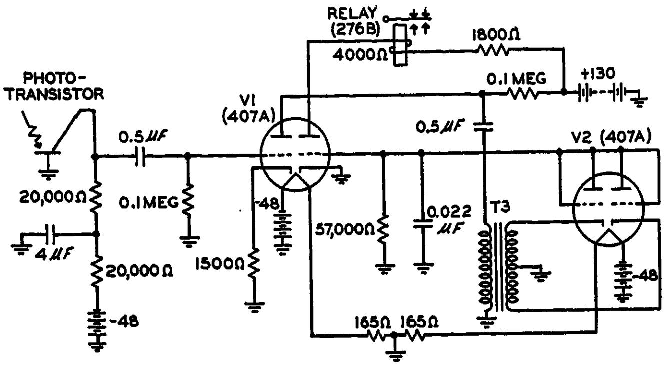

Fig. 6. Card-down check circuit

Fig. 6 shows the card-down check circuit. It differs from the routing-information channel circuits in that the operation of a relay is required when the light is blocked. Therefore the transistor amplifier-gas tube circuit is not applicable. For the down-check channels, the output of the phototransistors is amplified by the first section of a conventional double-triode thermionic-emission tube *V1*. The a-c signal at the plate of *V1* is rectified by a conventional full-wave rectifier consisting of transformer *T3* and tube *V2*. The rectifier voltage is negative with respect to ground and when it is impressed on the grid of the second section of tube *V1*, that section is driven past cutoff. Therefore, as long as light falls on the phototransistor, no current flows through the relay. When the dropped card blocks the light, the negative voltage on the grid disappears and the tube conducts, thus operating the associated relay. While the prime purpose of this down-check is to signal the associated equipment that the card is in position for recording its output code, advantage is also taken of this circuit's ability to distinguish between a light and dark phototransistor at any time to provide alarms in the event of a lamp or modulating disk failure.

After the card has been checked down and the associated equipment is ready to accept the output of the card, that equipment connects a positive 130-volt battery through its channel relays to the main anodes of the gas tubes. All gas tubes associated with illuminated channels will have their control gaps broken down and will transfer to the main gaps. This operates the corresponding channel relays in the associated equipment. The relays, in operating, lock to ground and thereby extinguish the main gap discharges, thus increasing the life of the gas tubes. Those channels which have been blanked out will not have the control gaps of the gas tubes broken down. Therefore when the 130 volts is applied, the relays associated with the darkened channel will not operate. The operation or nonoperation of the relays in the associated equipment completes the function of the channel circuits.

The capacitor and resistor network at the main anode of the tube is to prevent transients due to the operation of other channels from falsely breaking down the main gap of a dark channel.

Channel Packages

The phototransistor is mounted in a tube along with a lens which focuses the colliminated light on the transistor. Fig. 7 is a cutaway view of the *3A* phototransistor showing the relationship of the lens to the transistor. To mount in the translator, the tube is slipped into an accurately positioned hole and clamped in place, using the slotted ear. This mechanical fastening is also the ground connection. The output lead from the collector is attached with the use of a slip-on connector.

The amplifying transistor, transformer *T1*, varistor *V*, the resistor, and two capacitors of the amplifier are packaged as a convenient plug-in unit. Fig. 8 shows these transistor amplifiers. As shown the transistor is mounted under a removable cap on the package so that it may be conveniently replaced if necessary.

The gas tube, transformer *T2*, and the associated resistor and capacitor are also assembled as a packaged unit.

Transistor Performance Tests and Data

Like all classes of devices, transistors have certain characteristics which determine their suitability for any given application. In the card translator, the size advantage as compared to electron tubes was, of course, valuable. However, their ability to work at very low power levels and their relatively long life were the most important factors in their selection. Exactly how sensitive they were and what was their life had to be determined. Also transistors are not free from noise and, in addition, they are known to be affected by temperature. The effects of both these parameters on the ultimate performance of the card translator also had to be evaluated.

The reliability of the transistor circuit was the first and most important question to be answered. To test for this, three card translators were installed in the laboratory and equipped with a total of 272 channel circuits. These translators were connected in the normal service manner to standard associated *4A* crossbar system equipment. Then call after call was sent through the system. In all, 28,000,000 translations were made, each translation requiring the operation of many channels. Only one failure to operate occurred during these translations which might be ascribed to a failure of a channel circuit. The reliability of the circuit was thereby well established.

During the time the tests for reliable operation were continuing, the effect of the internal noise of the two types of transistors was being investigated. Noise produced by the phototransistor would be the more critical of the two as it would be amplified. If the noise was great enough, false operation of a channel relay would result. No false operations due to transistor noise were observed. To obtain data on whether there was margin against the

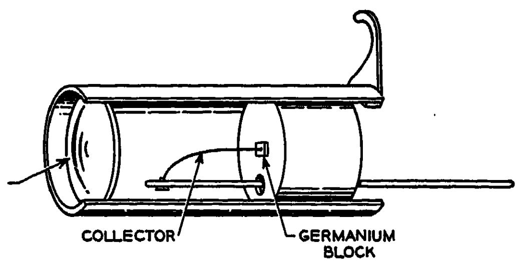

Fig. 7 (left). Cutaway view of phototransistor

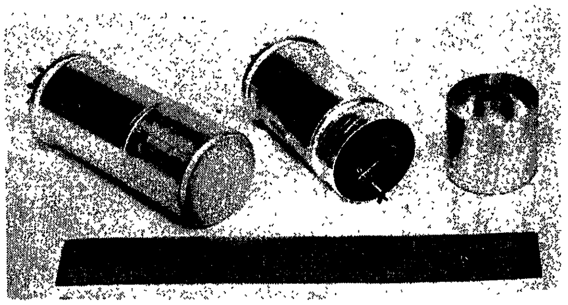

Fig. 8 (right). Transistor amplifiers

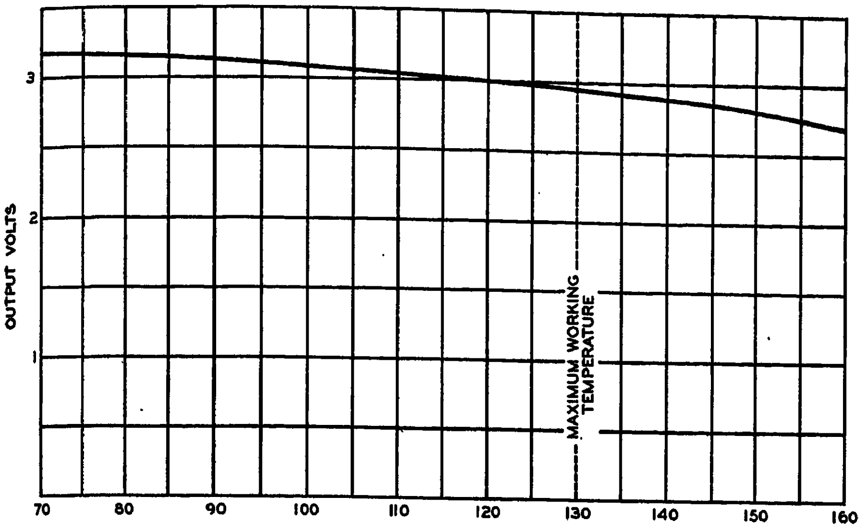

Fig. 9. Average temperature-output voltage characteristic of a phototransistor

effect of noise, several phototransistors which normally would be rejected by the Western Electric Company because of their noise voltage were installed in the translator. There was no adverse effect.

Temperature is one of the important parameters which affects the performance of transistors. Since the translator has powerful electromagnets working in close proximity to the phototransistors, there is a distinct heat rise, which had to be carefully considered. The *3A* phototransistor has an upper limit for reliable operation of 130 degrees Fahrenheit. This is not necessarily typical of other phototransistors and is lower than the temperature limit applying to the amplifying transistors. Fig. 9 graphs the change in output voltage of the *3A* phototransistor with respect to temperature. The output voltage of the transistor amplifier has approximately the same percentage change over the same temperature range. Tests for reliable operation were made on 96 of the channel circuits under temperature conditions corresponding to the maximum expected in service, and were found completely satisfactory.

While the reliable operation of the channel circuits under all conditions which might be encountered in service was of prime importance, the life of the transistors will have great effect on the cost of the apparatus and maintenance. Therefore 96 channels were subjected to a series of measurements designed to determine the effect of aging on the transistor elements. For this purpose a test set was used which was arranged to place the worst circuit condition on the transistor equipment that will occur in service. It was equipped to make output voltage measurements of the phototransistors and the transistor amplifiers.

The results of the series of output voltage measurements were subjected to the usual statistical analyzation method. This showed that the performance with age of the transistor elements fits the normal distribution curve. Fig. 10 is an average curve of the output voltage of a group of 96 phototransistors as they change with time. The months in operation represent the total integrated elapsed time during which the phototransistors were exposed to light with all voltages applied. The first group of points on the curve and the group ranging from the 6-month point on were obtained from two separate groups of phototransistors. The two solid lines are curves based on actual measurements. The dashed portion of the curve is based on the assumption that both groups age in the same manner.

The output voltage measurements of the amplifiers were the outputs of particular phototransistor-amplifier combinations. The average change of a group of 96 pairs in the output voltage with time is shown in Fig. 11. Again the first and last groups of points represent two different lots of transistor equipment.

Maintenance in Service

Although every effort has been made to insure the reliability of operation of the card translator and its associated equipment, it is not considered enough in the Bell System to depend solely on the reliability of equipment. It is important to determine, in advance of service failure, whether any element is becoming weak and to take corrective action before actual failure occurs. This is particularly true when devices which approach their end of life gradually are used. The transistor is such a device.

In the card translator this philosophy of preventing service troubles is carried out by periodically making a marginal test of the channel circuits. To accomplish this test the intensity of the light falling on the phototransistors is reduced and the associated equipment is used to check for channel operation. No card is dropped for this test; therefore no channel is blocked off and every channel relay should operate. A record is made by means of the associated equipment showing the channels which operated.

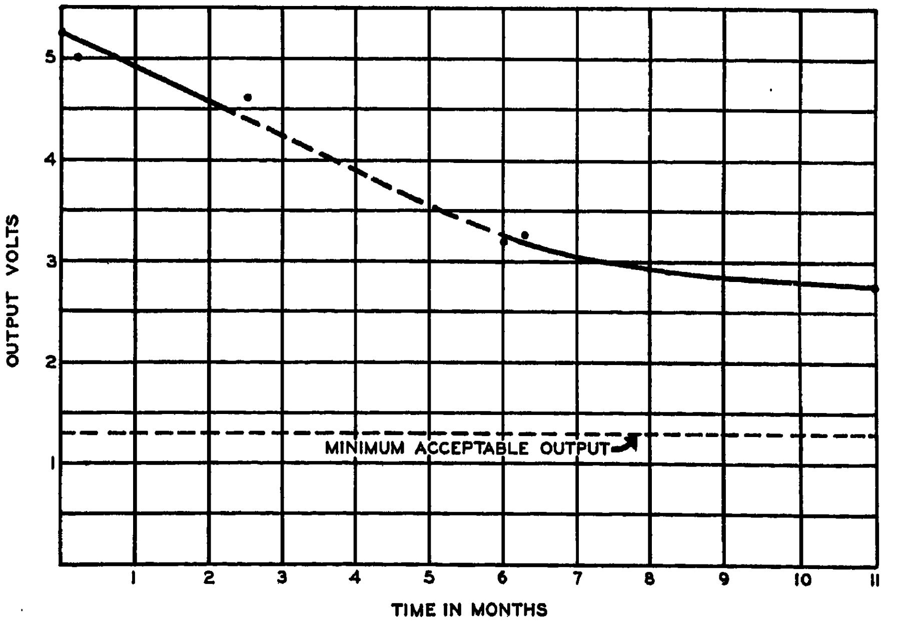

Fig. 10. Average output voltage of 96 phototransistors

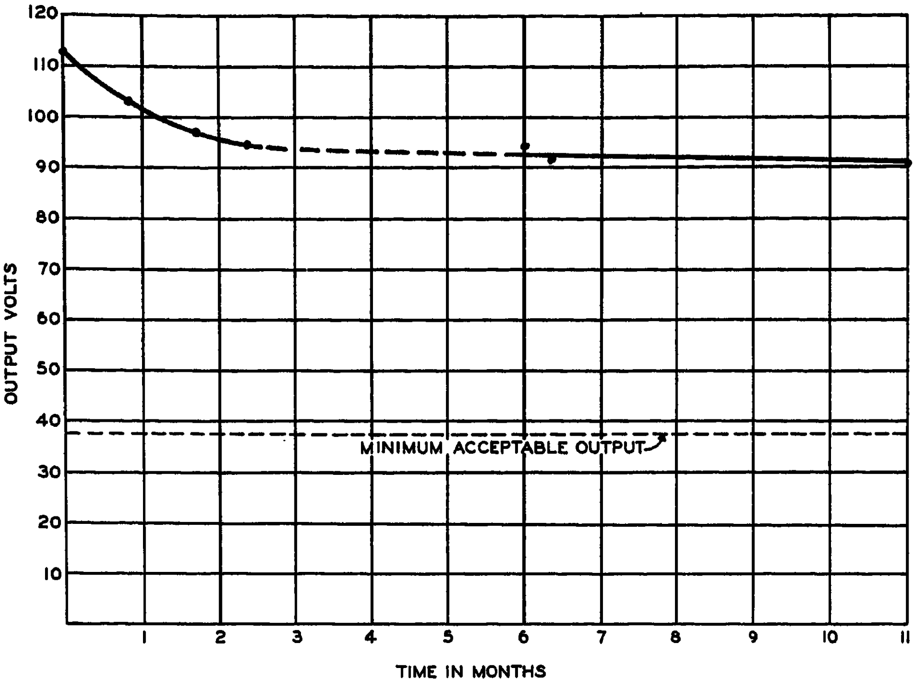

Fig. 11. Average output voltage of 96 phototransistor-amplifier combinations

An examination by the testman of this record will disclose any failure under this test condition.

Although this marginal test will disclose any channel approaching end of life gradually, there always remains the possibility of a sudden failure of some component during service operation. Such a failure will automatically cause a card record to be made of the conditions existing at the time of failure. If this record is caused by maloperation of a channel circuit, it will disclose which one failed thus permitting prompt corrective action to be taken. In the event this trouble occurred on a service call, the system is so arranged that the call will be completed using alternate equipment.

To determine which element has failed when an unsatisfactory channel is detected, the output voltages of the phototransistor and the amplifier are checked against the minimum values permitted and the weak unit can thus be isolated.

Conclusion

The test results show that the transistors and their circuits as used in the card translator are reliable. In addition, their service life appears to be satisfactory. The combination of these two characteristics is a vital factor, especially in view of the key function that translators perform in the *4A* toll switching system. The confidence with which this circuit is regarded is indicated by the fact that over one hundred translators will have been shipped to jobs by June 1, 1953. These installations represent the first commercial application of transistors in the Bell System.

An Automatic Control System with Provision for Scanning and Memory

N. H. YOUNG
NONMEMBER AIEE

Synopsis: This paper describes a system for adjusting a control element to produce a maximum or minimum value of a resulting parameter. The control element is scanned through its entire range of adjustment and returned to the position resulting in the desired maximum or minimum effect. In a system where several maxima or minima are present, the tuning equipment reliably selects the largest. The apparatus required is simple and easily understood and maintained by relatively unskilled personnel.

IN AUTOMATIC control systems, it is frequently desired to adjust a control element to produce a maximum value of a resulting effect. (A minimum value may also be used; throughout this paper only the maximum will be used for simplicity of expression.) Systems sensitive to the slope of the effect are common, where the sensitive element of the system examines the slope of the curve at the point where it happens to be resting when the tuning cycle begins, and adjusts the control element to increase the result. Such systems reliably determine the peak of any curve having only one maximum, and having no points of such low slope that the system cannot determine the proper direction of motion to correct.

In the system described in this paper, these limitations are not present. The system will accommodate response curves having more than one peak; in such cases the system will adjust the control element to the highest peak within the range. In addition, the system will operate correctly with curves having long, relatively flat sections within which the slope, if any, is so small as to be indeterminate. Curves of this type are often found in tuning radio transmitters and receivers. Secondary responses are occasionally produced by harmonics or image responses, and in receivers the system may be used to select

the strongest of several competing signals, where desired.

The sequence of operation is exactly like the operations performed by a careful human operator in tuning an equipment having the type of response described. Such an operator, when asked to readjust the system to tune to a new response point, would adjust the control element throughout its entire range, noting the amplitude of any peaks observed, then returning the control to the position producing the highest response. The automatic system proposed, which is called the "memory-scanning" system, follows exactly this procedure.

The elements of this system are shown in Fig. 1. The postulated response curve of the controlled device is shown as the solid line in Fig. 2. The input to the sensitive element of the control system is assumed to be a unidirectional voltage of varying magnitude. When a tuning cycle is initiated, the controlled element is moved to one end of its range (say, position 100 in Fig. 2). During this time the switch *S* in the system shown in Fig. 3 is in position no. 1, shorting the memory capacitor *C*. When the controlled element has reached the end of its range, a limit switch is operated, causing the switch *S* to go to position no. 2, and causing the motor to move the controlled element through its entire range (say, to position zero in Fig. 2). During this scan, the signal representing the response of the controlled element is being impressed through a diode *D* on the memory capacitor *C*. The potential on this condenser will rise when the input signal rises, but will not be able to drop when the input signal drops because of the unidirectional conducting properties of the diode *D*. Thus, the potential on the memory condenser will follow the dotted lines in Fig. 2, and at the end of this memory scan, will be equal to the highest potential the input signal had reached during the scan.

At the end of this scan, another limit switch operates, causing the switch *S* to be advanced to position no. 3. In this position, the memory capacitor is connected to one of a balanced pair of tubes, while the instantaneous input signal from the controlled element is applied to the other tube of the pair. The motor is also caused to begin to return the controlled element to the other end of its range. At the instant that the potential delivered by the controlled element equals the remembered potential stored in the memory capacitor *C*, the signals applied to the two tubes will be equal, and their plate potentials will be equal. (Necessary adjustments to affect such balance initially are assumed). A sensitive relay connected from plate to plate will thus release just at the time this balance is achieved. This relay is arranged to stop the motor moving the controlled element. Thus the controlled element is stopped just at the point giving the maximum value of the desired effect.

Practical design points affecting the accuracy of the foregoing statement are

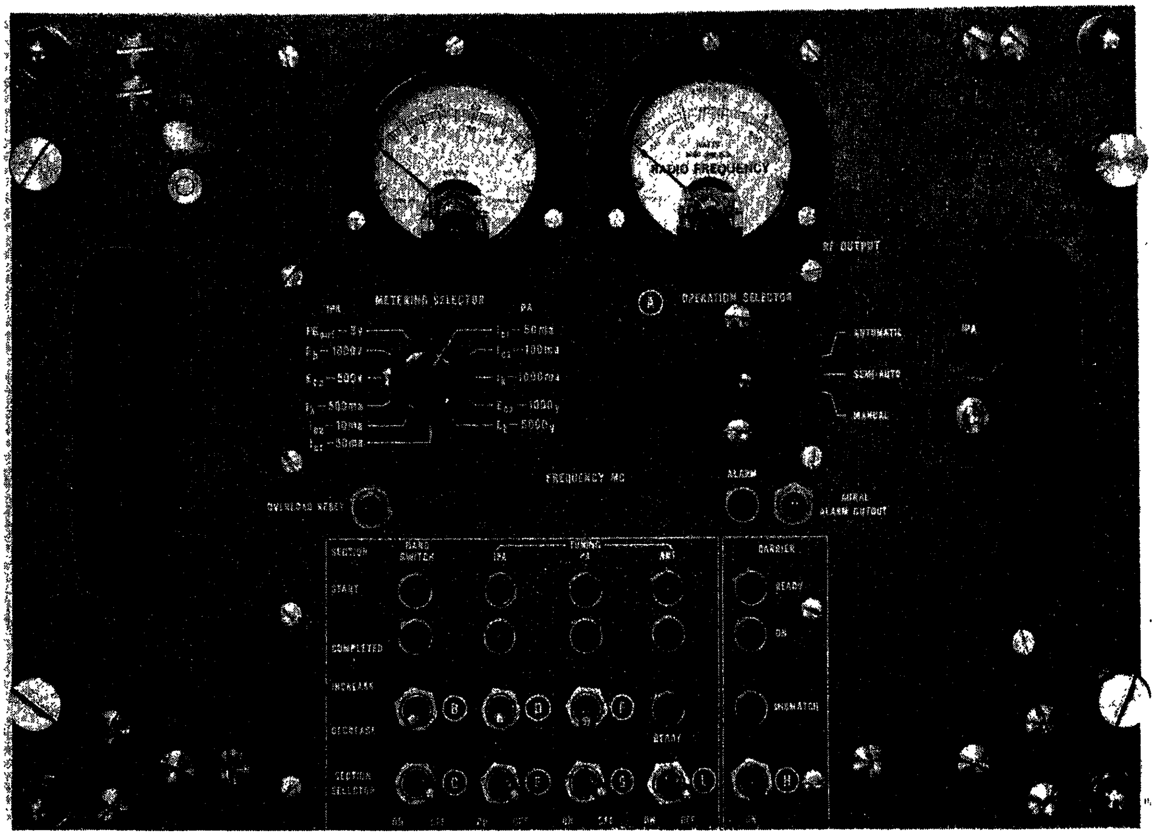

Fig. 4. Front panel of radio-frequency amplifier of transmitter embodying the system

evident by examination of the system. In the first place, if exact matching of potentials is required to effect stopping of the motor, even a minor change in sensitivity of the system between the memory scan and the final tuning scan might prevent the motor from stopping. Secondly, if the motor-stopping impulse was initiated at the moment of perfect tuning, there would inevitably be some overshooting of the moving parts of the system, introducing errors of setting. Fortunately, these two effects may be balanced against each other to a degree which depends principally on the speed of tuning operation required. For example, if it is possible to take a long time for the final scanning operation, the time of action of the relays involved and the time to operate an electromagnetic brake to clamp the motor shaft will be negligibly short. In this case, almost exact matching of potentials will be desirable. If instabilities of the phenomenon being adjusted make accurate match difficult, it may be desirable to cause the system to stop when the instantaneous voltage is equal to only 0.8 of the remembered voltage, and possibly introduce an intentional time lag in the application of the braking force, so that the normal stopping position of the system will be very near the peak. In other cases, where the time available for the tuning cycle is very limited, it may be necessary to anticipate the point of balance, as indicated in the foregoing, especially in order to allow time for the motor-stopping action. If necessary, the motor speed may be reduced for the final scan to increase the accuracy of adjustment. By suitable choice of design factors, a wide range of applications may be accommodated.

One of the principal advantages of this system is the simplicity of the theory of operation, and its similarity to the actions of a human operator. This makes it possible for the usual technicians to understand fully what is going on, and to feel confident in maintaining and trouble-shooting the equipment. No knowledge of the effects of phase on servomotors is required. No vacuum tube amplifiers are needed. The drive motors may be of conventional types, either a-c or d-c, with no unusual problems of checking torque or maintaining slip rings. There is no direct limit to the size of drive motors or the power that may be applied to the controlled element. (Some inertia problems will become apparent in larger sizes of apparatus.)

One embodiment of this principle that has reached production is the automatic tuning of the amplifier stages of a radio transmitter after the exciting frequency has been determined. One important advantage of this system over older systems having mechanical memory of the positions of shafts is in the indefinitely large number of predetermined channels that may be tuned. Any input frequency may be used, without regard to whether it has ever been set up before. Once the input is provided, the automatic system will resonate each of the amplifier stages to the proper frequency quickly and accurately.

The front panel of the radio-frequency amplifier section of this transmitter is shown in Fig. 4. It will be noticed that there are no tuning controls in the usual sense. The knobs shown are for switching the panel meter to the proper circuits, and for limiting the fully automatic action of the tuning system to slow down its tuning cycle for simpler analysis of troubles and for corrective maintenance. Jog switches are also provided to tune the circuits if the automatic system should fail, but they are not normally used. Two separate cycles of the above automatic tuning procedure are employed in this application. One motor drives the two low-level amplifier stages, which are ganged to a common shaft, while another motor drives the output amplifier, which supplies approximately 500 watts to a special automatic antenna resonating system. (The final amplifier cannot be ganged to the low-level stages because of the reaction of the antenna system on its resonance point.) The tuning cycle for the smaller unit, driving the low-level stages, requires approximately 6 seconds, while that of the higher-powered stage requires from 8 to 14 seconds, depending on the frequency band in which the equipment is being operated.

The system described leads to simple, easily maintained equipment, capable of setting any adjustable control to the point in its range producing a maximum (or minimum) of the effect desired. It is capable of an indefinitely large number of settings, depending on the input conditions. If the phenomenon being adjusted is susceptible to drift with time, repeating the tuning cycle will readjust to the new correct position. Its low cost and applicability to a wide range of effects makes it a valuable tool in the automatic adjustment of complex equipment.

Synopsis: The *L3* coaxial system is a new broad-band facility for use with existing and new coaxial cables. It makes possible the transmission of 1,860 telephone channels or 600 telephone channels and a television channel in each direction on a pair of coaxial tubes. The principal system design problems and the methods used in their solution are described. The over-all system is described in terms of its components and their location in the system.

THE *L3* coaxial carrier system is a new broad-band transmission system capable of transmitting either 1,860 telephone message channels or 600 message channels and a 4.2-megacycle broadcast television channel, in each direction, on a pair of coaxials. The system is designed so that signals transmitted over any of these channels will meet high quality Bell System objectives after 4,000 miles of transmission.

The system is composed of auxiliary or line repeaters spaced at approximately 4-mile intervals along the cable route and connecting terminal or dropping repeaters where telephone or television signals are translated to or from the *L3* frequency band. Equalization equipment, power generating and power transmission equipment, and maintenance equipment are required at 100- to 200-mile intervals.

Planning and exploratory development for the system was started late in 1945 with the objective of designing a trunk route system which would provide the maximum channel capacity on the existing coaxial cable consistent with the state of the repeater art. At that time and for the next 4 years a large amount of new cable employing the 600-channel 3-megacycle *L1* coaxial carrier system was being installed or projected.[1]

Since a major field for the use of the *L3* system was to replace the *L1* system on existing routes, the design of the *L1* system, the cable, and the cable route layouts presented the *L3* system with a definite plant framework. Fig. 1 shows the present-day network of *L1* coaxial systems. There are about 8,000 route miles of cable installed of which about 70 per cent consists of eight coaxials, the remainder consisting of six and four coaxials. About 70 per cent of this cable uses coaxials with a 3/8-inch-diameter outer conductor, the present-day standard. The remainder uses the older 0.27-inch-diameter coaxials. All but a few miles of this cable is plowed into the ground or placed in underground conduit. Fig. 2 shows a piece of a typical 8-coaxial cable. Normally, the coaxials are included in a lead sheath with interstitial pairs, which are used for control purposes. In many cases additional quads are included in the cable for other types of transmission systems.

The broad objectives of the *L3* system planning were:

1. The existing cable was to be reused. Thus, the cable loss and its variation with temperature, the cable irregularities resulting from manufacturing and splicing, and the power transmission capabilities of the cable became basic restrictions on the design of the *L3* system.

2. The *L1* telephone terminal equipment was to be reused. This equipment involves channel banks, group and supergroup equipment, and carrier supplies.[2] This limited the system planning to the use of frequency division multiplex on a single side-band carrier suppressed basis.

3. It would be desirable to reuse existing *L1* repeater locations and buildings. The *L1* auxiliary repeaters are spaced at 8-mile intervals and housed in 6-foot by 9-foot concrete block huts. The *L1* main repeaters are spaced at 40-to-160-mile intervals largely dictated by geographical and power transmission considerations.

4. Sufficient bandwidth should be provided so that a black-and-white television signal of at least 4-megacycle quality could be transmitted simultaneously with 600 message signals, the message capacity of the *L1* system. Alternatively, as many massage channels as possible should be transmitted when there is no need for television service.

5. The channels should meet Bell System high quality signal-to-noise and equalization objectives after 4,000 miles of transmission.

The principal system design problems and methods used in solving these problems are described; then the components of the system, their locations, and their functions are given.

Transmission Design

With a given cable loss, the line repeaters determine in large measure the bandwidth and quality of transmission and the economics of the system. The basic system plan therefore evolves from a consideration of the signal-to-noise and equalization performance—that is, the transmission stability—that can be designed into the repeaters. This leads to the development of broad signal-to-noise and equalization analyses which guide and co-ordinate the system design.

SIGNAL-TO-NOISE DESIGN

Simply stated, the signal-to-noise problem is to adjust the repeater spacing and

Many Bell Laboratories departments co-operated in developing the complex *L3* system. In a period of 7 years, over 100 engineers and technicians contributed to its design. In the system planning aspects covered in this paper, particularly large contributions were made by L. G. Abraham, C. H. Bidwell, and S. E. Miller. The section on "Automatic Switching" was written by P. T. Sproul, and the section on "Terminals" by C. G. Arnold.

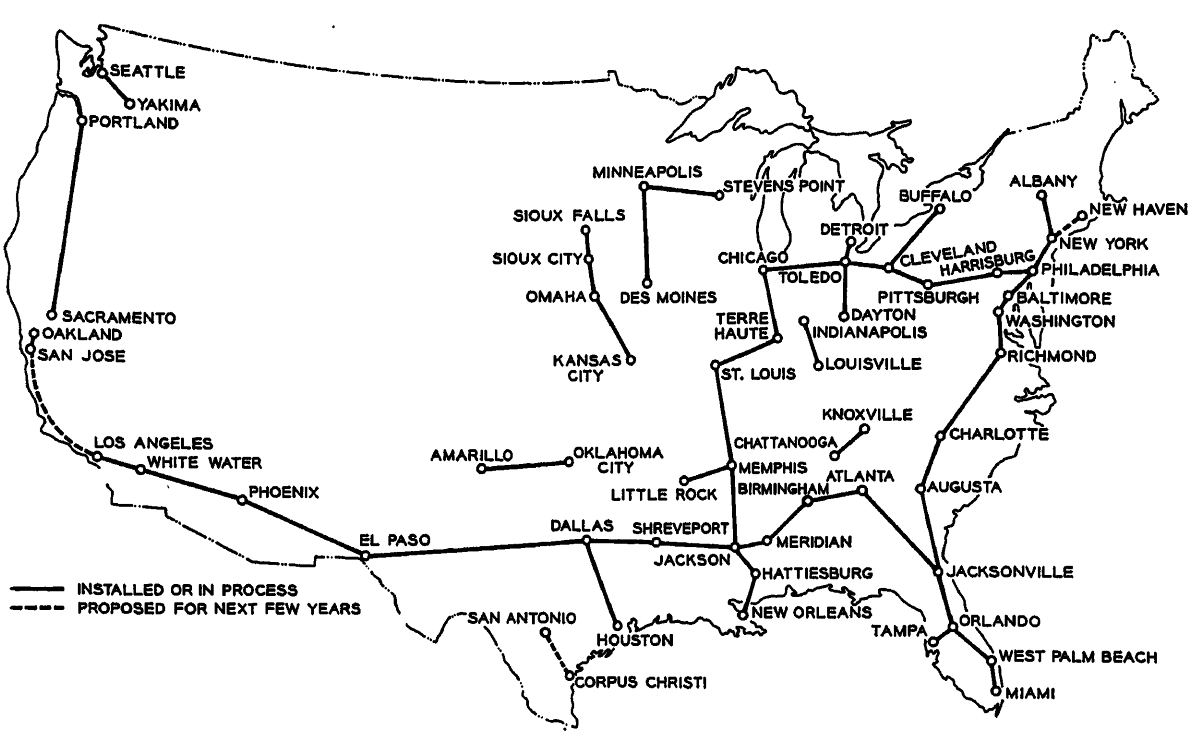

Fig. 1. Coaxial cable routes

bandwidth of the system so that channel objectives can be met with the repeater noise, linearity, and gain performance that the electron tube and circuit art permit. In detail this means the following:

1. translating the broad transmission objectives on message and television channels into detailed requirements on noise, specific modulation products, and compression;
2. analyzing the amount of these interferences that result from various repeater design choices;
3. determining the effect of signal wave form and frequency allocations on both the channel requirements and the repeater performance; and
4. integrating these studies into a specific system design plan that meets the objectives.

Telephone Channel Interference Objectives

The amount of noise, tone interferences, or crosstalk that is considered tolerable in telephone channels is generally determined by judgments involving the subjective reactions of representative observers to specific interferences on typical transmitted signals, and by the cost of providing a given grade of service. The broad objectives for message channels stem from early unpublished work on transmission standards. The interference and load capacity requirements for transmission systems involving large numbers of message channels were developed by Dixon, Holbrook and Bennett.[3,4] In effect, they provide techniques for translating channel objectives into linearity and power-handling requirements on repeaters, taking into account the statistical properties of individual and multichannel speech. Based on the data and techniques in these articles, the requirements on individual channels shown in Table I can be derived. These requirements in themselves form an important basis for the signal-to-noise design of the system. However, in a highly refined system design, it is necessary to extend our notions of requirements somewhat further.

In the *L3* signal-to-noise design the message channel requirements of Table I were used as the initial basis for study. However, when specific interferences of a complex nature were found to be limiting, the wave forms and the probability of their occurrence were examined in detail. As a result of these studies, two distinctive types of interferences were found to be important when the system is used to carry message and television signals simultaneously. The first of these, due to both second- and third-order modulation involving multifrequency key pulse signals and components of the television signal, has the characteristics of intermittent musical tones. The second, due to the second-order difference products generated by the television signal components, produces tones in the message channels which vary in amplitude and frequency as the television signal changes with picture content. Both types of interference were generated in the laboratory and recorded on tapes. From these tapes, records were cut and then used in a series of subjective tests which were made to determine the maximum permissible magnitudes consistent with other important message circuit objectives.

Television Channel Interference Objectives

The amount of noise and single-frequency interference that can be tolerated in a commercial grade of television channel again depends on judgments involving the subjective reactions of observers and the cost of providing a given grade of service. The broad objectives are based on subjective measurements by Mertz and Baldwin.[5–7] From this work it has been determined that 95 per cent of the observers consider a signal-to-noise ratio of 40 decibels (composite signal to rms noise) tolerable, providing the noise has a frequency characteristic that rises about 11 decibels across the video band. Likewise the tolerable single-frequency interference can be set at −70-decibel (peak sine wave below composite signal) if the interference falls below about 1 megacycle. However, the requirement becomes more lenient for interferences falling in the upper part of the band.

Again, for a refined system design, more detailed account must also be taken of the requirements on short duration interferences, the probability of interference occurring, and the exact frequency in the television spectrum at which an interference occurs.

In the *L3* signal-to-noise design the broad television channel objectives outlined in the preceding were used except when a specific complex interference was

Table I. Summary of Message Circuit Objectives

Allowable Zero Level Interference in 3-Kc Band

Source of Interference	Type of Interference	Dba, Message Weighting	Decibels below 1 Milliwatt,* Unweighted
Terminals	Largely spillover between channels, cross-modulation, and crosstalk	+32	50†
Line	Noise and multichannel modulation	+36	46†
Line	Unintelligible crosstalk and babble	+24	58†
Line	Tones	+24	61‡
Total	All sources	+38	44†

* The translations from dba to decibels below 1 milliwatt are effected by noting that a 3,000-cycle band of flat noise with 1 milliwatt of power equals +82 dba and that 1 milliwatt of 1,000-cycle single frequency is equal to +85 dba.

† Interference assumed evenly distributed over 3,000-cycle band.

‡ Tones assumed to be at 1,000 cycles.

found to be limiting. For complex interferences, three additional types of requirement data were used: 1. Tests were made to determine visual thresholds relative to steady tones of short bursts of energy such as occur in the television channel as a result of switchhook "bang-up"; and multifrequency key-pulsing signals in the message channels. Fig. 3 shows the relation between the steady-state and transient requirement. 2. Advantage was taken from the fact that interferences falling between the 15.75-kc line scan multiples of the television signal would be less interfering than unwanted energy falling directly at the line scan multiples. 3. A judgment was used that the tolerability of an interference depends on its probability of occurrence. The judgment was not made on a quantitative basis but when an interference was found to exceed its requirement by a few decibels two or three times a day it was ignored in the signal-to-noise design.

Frequency Allocations

The final frequency allocations shown in Fig. 4 are a result of the signal-to-noise design. The principal features were determined on rather general grounds. When the system is arranged for combined television-message transmission, the television channel is placed above the message channels so that the second harmonic of the television carrier and its immediately adjacent side bands will fall at the top edge of the band where the requirement is more lenient. Likewise the line repeater noise tends to rise with frequency as does the amount of noise that the television channel can tolerate. Details of the frequency allocations shown in Fig. 4 will be discussed later.

Pilot frequencies, indicated in Fig. 4, are transmitted to control the transmission characteristic of the system as described in a companion paper.[8] The frequencies, and the power at which the tones are transmitted, were selected on two bases:

1. Where possible, frequencies used for similar purposes in the *L1* system were selected for possible economies in pilot supply design and manufacture; these are the 556-, 2,064- and 3,096-kc pilots.
2. The transmission of these pilots should not materially degrade the signal-to-noise or load capacity performance of the system.

The latter requirement led to a careful study of cross-modulation products involving the pilot frequencies to assure that message and television objectives would be met.

Repeater Performance

The details of the amplifier design and the factors which determine its performance are covered in a companion paper.[9] For purposes of the signal-to-noise design it is sufficient to know the noise power versus frequency characteristic, the second- and third-order modulation coefficients of the repeater as functions of frequency, and the overload performance of the repeaters. These factors depend on the repeater spacing and cable loss characteristic, electron tube parameters, achievable feedback, and the bandwidth to be transmitted. Thus, in the design procedures the dependence of these properties on repeater gain and bandwidth are determined and used in adjusting the system parameters for a final compatible design. Figs. 5 and 6 show the noise and linearity properties of the final *L3* repeater. The 4-mile repeater spacing requires a repeater gain shown on Fig. 7.

Signal Mechanisms

A signal-to-noise plan which contemplates transmitting the complex wave form of the combined telephone and television channels through 1,000 auxiliary amplifiers and about 200 flat amplifiers with performance factors that are variable with frequency will depend very strongly on the detailed analysis of the interactions between the signals and the repeater system characteristics. In developing this aspect of the signal-to-noise design four related phenomena had to be examined in detail.

Intermodulation Between Signals in Different Parts of Band. In the classical multichannel modulation theory for a large number of message channels, the modulation noise generated by interaction of the speech signals owing to the nonlinear characteristics of the amplifier is shown to be equivalent in interfering effect to random noise. In addition to this type of interference in message channels, cross-modulation between components of the message and television signals result in a host of specific individual modulation products which have been examined by determining their amplitude, duration, and probability of occurrence, and then relating them to the requirements previously discussed. Approximately 400 different products or groups of products were studied in the design of the *L3* system. All but about thirty of these were found to be of negligible importance for the signal levels and frequency allocations being given serious consideration. On final analysis six of these thirty products were

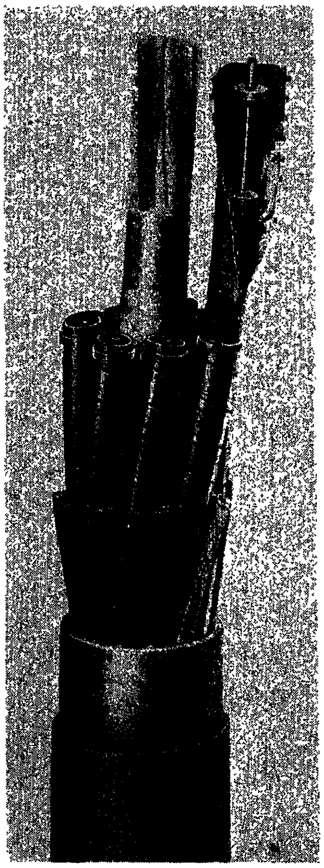

Fig. 2. An 8-coaxial cable

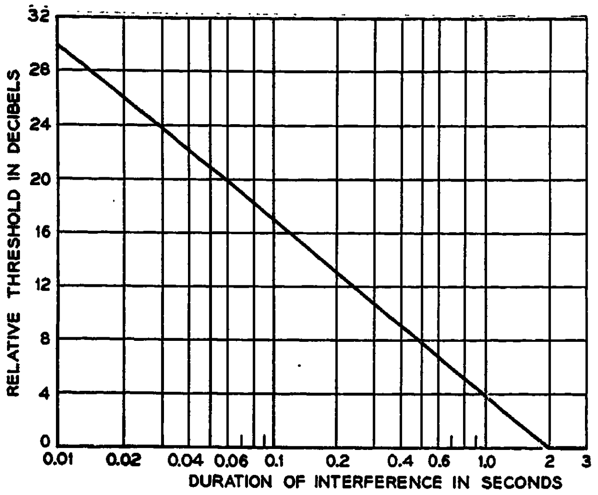

Fig. 3. Television bar pattern threshold versus duration

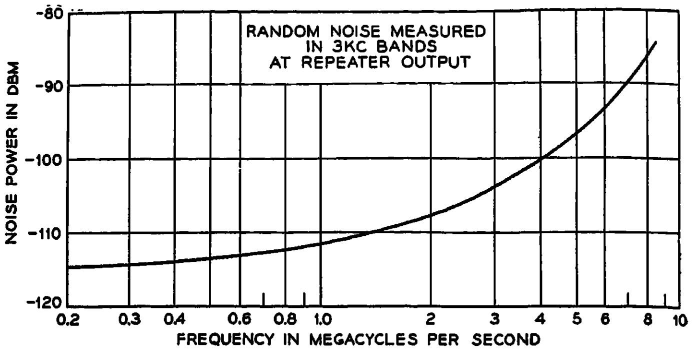

Fig. 5. L3 auxiliary repeater noise characteristic

found to be controlling in establishing system levels. Fig. 8 shows the generating signals and the products they form for the six most critical products. The exact way in which the critical products entered into the determination of signal levels and frequency allocation will be discussed later.

Location of Television Carrier Relative to Telephone Channel Carriers. Among the important modulation product types is one formed by difference frequencies involving components of the telephone and television signals, see Fig. 8(D). These interferences fall back into the telephone band and are of different magnitudes depending, among other things, on which components of the television signal produce them; those produced by the television carrier and adjacent line scan multiples are by far the strongest.

The energy in a disturbing telephone channel tends to be concentrated near the 1,000-cycle point in the voice frequency band. By careful choice of the television carrier frequency, the difference products produced by cross-modulation between telephone signals and the high-magnitude television signal components can be made to fall at frequencies such that the high-energy portions of these products are greatly attenuated by the cutoff characteristics of channel filters.

The message channels are spaced at 4-kc intervals controlled by carrier frequencies which are multiples of 4 kc. To obtain the maximum advantage from the channel filter cutoff characteristic as described, it was found desirable to set the television carrier frequency 1 kc below a 4-kc multiple. A direct result of this allocation is a gain of 12 decibels in television signal-to-noise performance over what could be realized if the carrier had been set at a 4-kc multiple. Such an allocation would have required a 12-decibel lower magnitude of television signal in order to meet the message channel objectives.

Addition of Modulation Products Along the Line. It has been established by analysis and experiment, that in a multi-repeater system second-order modulation products tend to accumulate on a power basis while certain third-order products tend to add on a direct or voltage basis. This direct addition of third-order products depends on the slope of the phase curve being the same over small frequency intervals from repeater to repeater. In multichannel telephone systems, the locations of channels in the frequency band are shifted at intervals along the line to avoid this direct addition of third-order products. In the combined telephone-television application of the *L3* system the $A+B-C$ product illustrated in Fig. 8(G) is formed. Since the B and C components are television line scan multiples which cannot be shifted in location, certain components of this type of product would add directly in a 4,000-mile system. If this were allowed to take place, the requirements would be exceeded by many decibels. However, by placing the delay distortion equalization only in the television band at approximately 200-mile intervals, the phase of these products can be shifted so that rms addition of products accumulated over several 200-mile links of the system may be assumed.

Wave Form of Transmitted Television Signal. Early studies of *L3* led to the

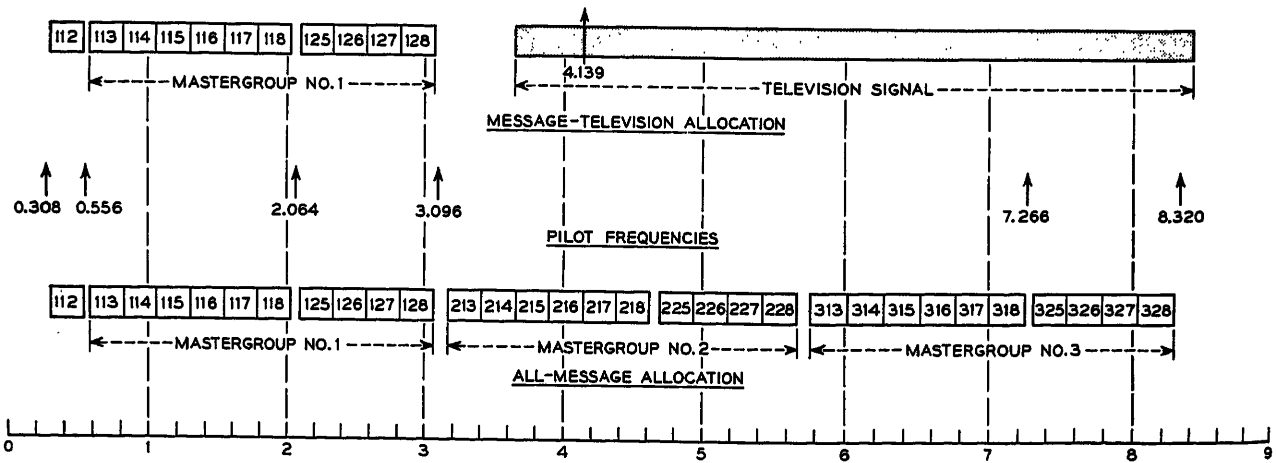

Fig. 4. L3 frequency allocations

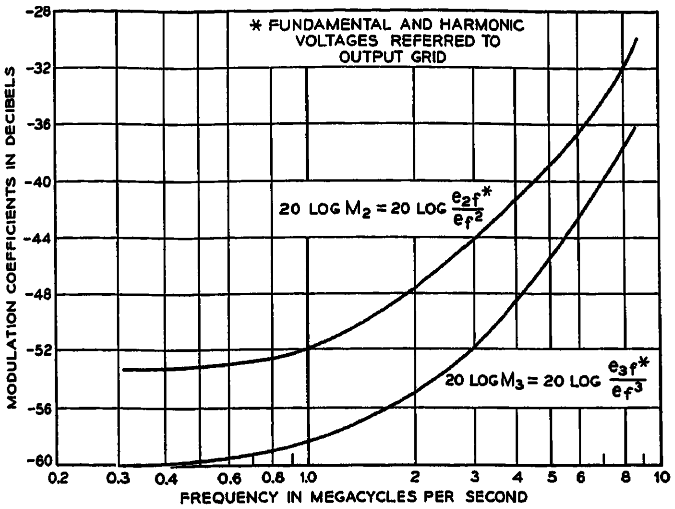

Fig. 6. L3 amplifier modulation coefficients

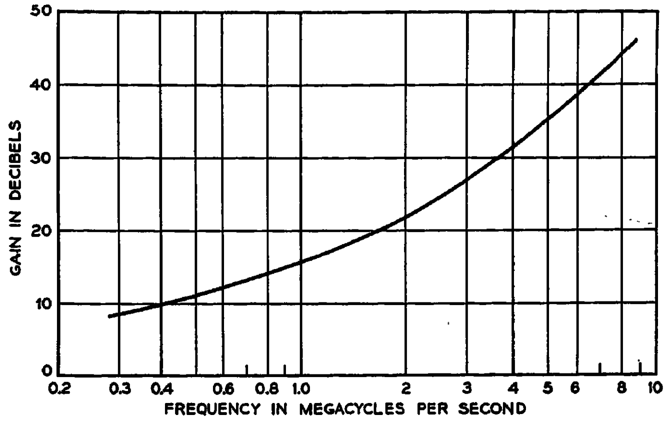

Fig. 7. L3 repeater gain characteristic

conclusion that the most economical method of transmitting the television signal would be by amplitude modulation of a carrier with one side band partially suppressed, that is, vestigial side-band transmission. There remained, however, three major problems for detailed study:

1. the transmission of d-c components of the video signal;
2. the per-cent modulation of the carrier which for convenience is defined in terms of excess carrier ratio, the ratio of the peak (white) signal to the peak-to-peak composite signal as measured in the carrier frequency envelope; and
3. the sign or sense of modulation, that is, whether increasing or decreasing brightness should correspond to increasing signal voltage on the high-frequency line.

Typical wave forms illustrating the alternatives are given in Fig. 9.

The solution to each of these problems required an understanding of how the various alternatives would be affected by the system noise and linearity performance and an understanding of representative television-viewing tube performance with respect to susceptibility to different types of interference. In analyzing the effect of system performance on these problems, it was found that nonlinearity (cross modulation) would produce interferences in the television band which, while they are very complex electrically because of the effect of cross modulation involving line scan components of the signal, would produce the same effect on viewing tubes as single-frequency interferences, that is, bar patterns. Further simplifications were made in the analysis when it was found that such interferences were most visible in relatively large areas of television pictures having essentially constant brightness. During the time intervals corresponding to such areas, the video frequency voltage of the television signal is essentially constant and therefore, in the cases of interest, it could be assumed that the magnitude of the television carrier would also be constant during such intervals. Thus, to compute the magnitude of any modulation product which falls into the television band and which has as one of its components the television signal itself, it is found convenient to use in the computation the magnitude of the television carrier corresponding to either black or white portions of a picture signal. (The reason for intermediate shades of gray being less susceptible than either black or white will be discussed.)

To evaluate the effect of television-viewing tubes on wave form problems, a number of tests were made to determine blank field threshold values of single-frequency interference as a function of frequency for typical viewing tubes. Furthermore, judgments were made as to what might be expected of future viewing tubes with respect to achievable high light brightness, contrast ratio, and operating characteristics. As a result of these tests and judgments, a series of requirements were derived on the basis of long-range objectives to be met for these projected characteristics. The results of these tests and judgments are summarized as follows:

Television viewing tube characteristics assumed for *L3* signal-to-noise analyses.

1. Brightness-grid voltage characteristic of viewing tubes follows 5/2 power law

$B \propto e_g^{5/2}$

2. Maximum high light brightness of viewing tubes will be 150-foot lamberts.
3. Contrast ratio of viewing tubes will be 150 to 1.
4. Viewing tubes will have interference sensitivities which vary with brightness in accordance with the characteristic of Fig. 10.
5. The visibility of bar patterns will decrease with frequency in accordance with the characteristic of Fig. 11.
6. Deviations from the Weber-Fechner law may be assumed to follow the curve of Fig. 12. This law states that "the minimum change in stimulus necessary to produce a perceptible change in response is proportional to the stimulus already existing."

Using the parameters and methods of analysis outlined in the preceding paragraphs, the relative system performance achievable with each of the carrier frequency wave forms of Fig. 9 was computed or determined by observation. For example, these wave forms are all drawn to the same peak-to-peak amplitude. If we assume that the coaxial system is limited only by the peak amplitude transmitted, we may use Fig. 9 to determine relative signal-to-noise performance directly by measuring the peak-to-peak magnitude of the composite signal voltage (sync tip to white) transmitted.

Fig. 9 may also be used to obtain relative modulation performance. For this purpose, the following factors must be considered:

1. the magnitude of the signal generating the interference ("black" or "white" carrier magnitude);
2. whether the interference is proportional directly or to the square of the carrier magnitude;
3. relative interference sensitivity in black or white portions of the picture; and
4. deviations from the Weber-Fechner law as the brightness is varied over its full range.

The relationships among these factors were used to establish that for all cases of interest, bar patterns caused by cross-modulation are always more interfering in either black or white portions of a picture than in an intermediate gray area.

Table II shows the relative system performance for the five carrier frequency wave forms of Fig. 9. For comparison purposes, the signal-to-noise and signal-to-bar pattern ratios are all related to Fig. 9(F).

It is obvious from Table II that the signal is transmitted most efficiently at an excess carrier ratio (ECR) of one half. The wave form of Fig. 9(F), which illustrates excess carrier of one-half, is the one used in *L3*. Television terminal circuit problems arising from this choice of carrier frequency wave form are discussed in another paper.[10]

Signal Levels and Repeater Spacing

In a broad-band system like *L3*, the problem of determining the repeater spacing is made complex by the large number of parameters that must be considered. The approach to this problem that has been used to advantage in the *L3* design is to assume several reasonable values of repeater spacing and determine for each the system performance achievable with various combinations of important parameter values. This method also permits evaluation of the effects on repeater spacing caused by variations in parameters so that it is possible to form judgments as to the most economic design.

One of the important factors in setting repeater spacing is the magnitudes at which signals are transmitted in the system and the relation between these magnitudes and signal-to-noise and repeater overload performance. In the all-telephone system (1,860 channels), the telephone levels (decibels with respect to the transmitting toll test board) were set to optimize signal-to-noise performance. To avoid penalizing the channels in the upper part of the band, where random noise tends to be much higher than at low frequencies, the levels of the three mastergroups are staggered. At the output of any repeater in the high-frequency line, the nominal level of mastergroup 1 is −21 decibels, that of mastergroup 2 is −16 decibels, and that of mastergroup 3 is −11 decibels. As a consequence of setting levels in this way, the random noise in the message channels is approximately 2 decibels higher on the average than modulation noise. It can be shown that with both second- and third-order modulation products contributing, and with third-order somewhat predominant, this relation between random noise and modulation noise produces optimum signal-to-noise performance. With these levels, and 1,860 channel telephone system has approximately a 6-decibel margin against repeater overload which, for *L3* purposes, has been defined as the point at which the repeater modulation coefficients just depart from their constant small-signal values. The signal-to-noise objective of +29 decibels adjusted at the −9-decibel level is met with about a 2-decibel margin.

When the system is used to transmit television and message signals simultaneously, the level of the telephone channels in mastergroup 1 at the repeater output is the same as that of mastergroup 1 in the all-telephone application, −21 decibels. The most convenient measure of the television signal is the power of the unmodulated carrier at the output of a repeater. Its value is 6 decibels above 1 milliwatt. Due to the interrelations between the two signals, the limitations on achievable maximum transmission levels or magnitudes arise from certain types of second-order modulation products

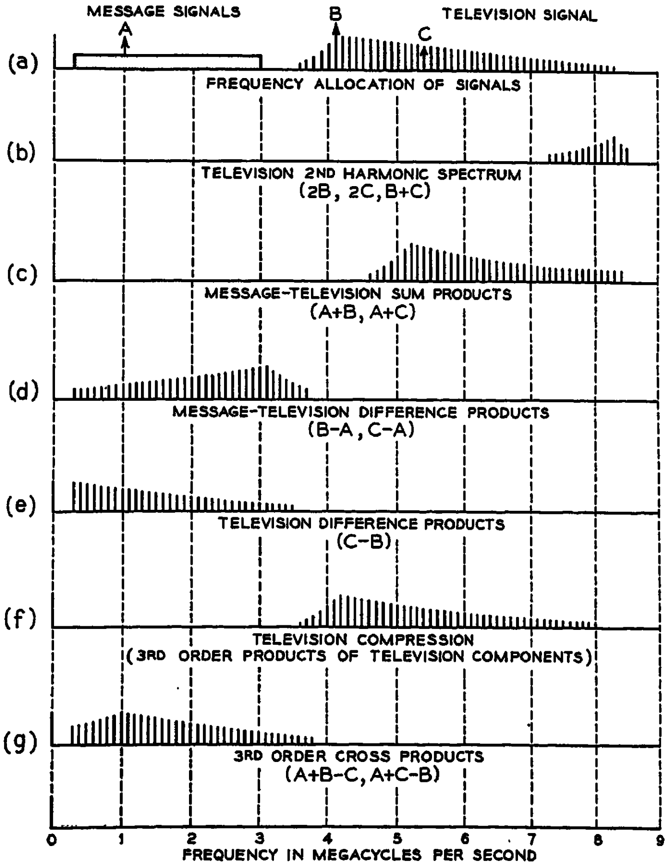

Fig. 8. L3 coaxial system—critical modulation products in combined-message-television application

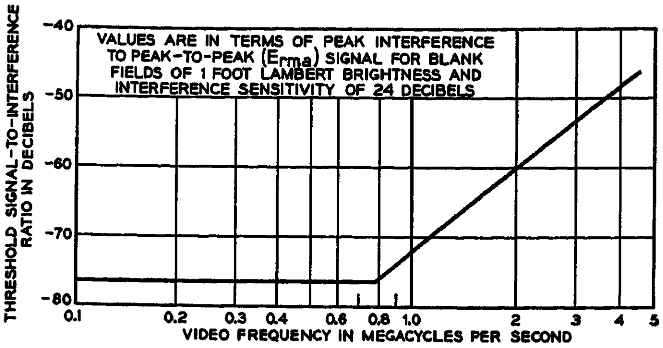

Fig. 11. Threshold values for bar patterns

rather than from optimizing signal-to-noise performance as in the all-telephone application. One of these types consists of sum products of cross-modulation between telephone and television signal components. These form bar patterns and, in so far as signal-to-interference ratio is concerned, are independent of the television signal magnitude. Thus, adjusting such products to equal the appropriate requirement has the effect of setting the maximum permissible magnitude or level of the telephone signal. The second type of limiting product is due to difference frequencies formed by cross modulation among the television signal components. These fall into the telephone channels and, after the telephone level has been set as described, permit calculation of the maximum permissible television signal magnitude.

With signals set at a −21-decibel level for telephone and 6 decibels above 1 milliwatt unmodulated carrier for television, all of the critical products discussed in the preceding section and illustrated in Fig. 8 have adequate margin. The 40-decibel signal-to-noise objective for 4,000-mile television transmission is met with about a 2-decibel margin, and long haul (4,000-mile) message channels meet the +29 decibels adjusted at the −9-decibel level objective with about a 5-decibel margin. A margin of about 5 decibels is also realized with respect to repeater overload performance.

The single-frequency pilots are adjusted to have the following values of power at the output of a transmitting amplifier:

7,266 kc	16 decibels below 1 milliwatt
8,320 kc	26 decibels below 1 milliwatt
all others	36 decibels below 1 milliwatt

With these values, modulation products produced by cross-modulation among the pilots, as well as message signals and television signals, meet the appropriate objectives.

Frogging of Message Circuits

When signals, either message or television, are transmitted over long distances through many amplifiers in tandem the accumulation of modulation products along the line becomes an important system problem for two reasons:

1. The accumulation of certain types of third order products tends to follow a direct or in-phase law.
2. The distribution of modulation products over the band produces more modulation noise in certain parts of the band than in others.

Both of these cumulation problems are alleviated if, at intervals along the line, the signals are shifted with respect to one another in the band, a process known as frogging.

In the *L3* system, signal-to-noise performance is substantially improved by frogging the supergroups at intervals of about 800 miles. In the 1,860 channel all-message application, the busy-hour signal-to-noise performance of 4,000-mile circuits is alike to within 2 decibels with all channels meeting the objective of +29 decibels adjusted at the −9-decibel level. In contrast, if frogging were not specified, a substantial number of circuits, or (10 to 20 per cent) would fail to meet the objectives, while the performance of other channels would be better than required by 6 decibels or more.

When the system is used for combined message-television signals, the message circuits are frogged in supergroup blocks at approximate 800-mile intervals except for supergroups 113 and 114, which must be frogged at 400-mile intervals. This procedure is necessary to prevent second-order sum and difference products of message and television signal components from cumulating excessively, especially those products which involve television signal components close to the television carrier. Frogging these supergroups more frequently than others results in a 3-decibel improvement in television signal-to-noise performance.

Special Services Transmission

During the early design stages, requirements based on the transmission of message and television signals were used to set repeater spacing, to determine the bandwidth and frequency allocations, and to fix important design parameters of the amplifiers. Concurrently, the objectives for the transmission of telegraph, program, and telephotograph signals were studied, and, before the system design crystallized, analyses were made to assure that these special services objectives would be met.

In a few instances it was found that the special services objectives tended to dominate and the system requirements and design were adjusted accordingly. For the most part, however, channels which meet message circuit objectives are satisfactory for special services transmission. In *L3*, telegraph and telephotograph signals may be transmitted without restriction provided the proportion of

† All values referred to ECR=1/2. Group 1 products are those whose magnitudes are directly proportional to the carrier magnitude. Group 2 products are those whose magnitudes are proportional to the square of the carrier magnitude.

these signals does not materially exceed the proportion now installed in the plant. Program signals may be transmitted in the 1,860 all-message arrangement without restriction but, when television transmission is provided, program circuits are restricted to supergroups 113 and 114. This restriction is due to the fact that program circuits are usually more than 4 kc wide; interferences of high magnitude which normally fall between 3,300 and 4,000 cycles or below 300 cycles in message channels of supergroups other than 113 and 114 would fall close to 4,000 cycles in a program circuit where there is high susceptibility to interference.

Uncertainties

In the early stages of system design, firm decisions have to be made on such matters as repeater spacing, bandwidth, and component characteristics. These decisions must be based on a detailed signal-to-noise analysis which in turn involves many judgments of repeater performance parameters, tolerable system requirements, and the effects of signal mechanisms on system performance. It would be easy and safe to engineer the system to provide enough signal-to-noise margin to cover the uncertainties in each of these judgments. Conservative engineering of this type could easily have justified a repeater spacing of 3 miles instead of the 4 miles actually chosen. Instead, an effort was made to estimate a mid-range, or most probable, value for each performance, requirement, or mechanism factor entering into the signal-to-noise design. In addition, a probable uncertainty was estimated for each critical parameter. This was usually taken as one-third of the maximum foreseeable error in the estimate. Finally, these uncertainties in electron tube modulation, realizable feedback, network impedances, channel requirements, interaction laws between signals, and a myriad of other factors were all translated by the signal-to-noise analysis into their effect in decibels on the television channel signal-to-noise performance. On this basis, the probable uncertainties were summed on an rss basis to find the probable uncertainty in the over-all design. Whereas the direct addition of the probable uncertainties gave a figure of about 20 decibels uncertainty in the design, the rss addition indicated about 6 decibels uncertainty. It was then argued that during the ensuing years of development the probability of finding all the judgements to be wrong in the same sense was extremely small. On the other hand, it was deemed reasonable to provide enough margin so that there would be perhaps a 75-per-cent chance of not exceeding the margin. Six decibels of margin was therefore provided, half by clear margin and half by having available economically feasible changes in system design such as a decrease in the telephone channel frogging interval. Any further error in judgment would then have to be taken up by degrading performance below the desired objectives. As the system design proceeded, the early judgments were changed in considerable measure. Likewise numerous additional system parameters were introduced. However, at no point in the system planning was the balance of factors such that there was less than 3 decibels clear margin.

Margin handled in this way becomes a carefully husbanded asset of the whole system. In designing or analyzing a part of the system, a major effort must be made to achieve the performance introduced into the initial determination of repeater spacing and bandwidth. The design of each individual part of the system cannot be allowed a margin which can be used up as the individual designer chooses.

EQUALIZATION DESIGN

The term equalization is used to describe the process of obtaining flat gain and delay characteristics for the system transmission. The system and equipment designs to accomplish this function represent two of the major engineering features of the *L3* system. In an over-all sense, equalization includes:

1. determining deviation objectives for the gain and delay characteristics of the system and its component parts;
2. designing the auxiliary repeater so that the most economical over-all system equalization is obtained; and
3. specifying the location, form, and control methods for the mop-up equalizers that are used at intervals along the system.

Equalization and its related process, regulation, are the subject of a companion paper;[8] therefore in this paper only those aspects of equalization will be covered which are necessary for an appreciation of the over-all system design.

Transmission Objectives

The requirements on the gain characteristic of a band used for multichannel telephony depend on two message channel objectives. One of these is that the gain of a message channel must not vary by more than 2 decibels over the 4-kc band. To meet this requirement, broad changes in the transmission characteristic of the message band are held to less than 0.5 decibel for 150-mile links. The second objective stems primarily from the need to transmit telephotograph signals. Since these signals are relatively intolerant of level changes, the transmission characteristics of working lines and protection lines are made alike to within ±0.25 decibel.

The requirements on the gain and delay characteristics of the television band are based on the subjective determination that an echo delayed by about 2 microseconds or more in a representative picture is considered tolerable by 95 per cent of the viewers when the peak-to-peak voltage of the echo signal is 39 decibels below the peak-to-peak signal voltage.[11] The translation of this echo objective to allowable variations in the gain and delay characteristics is straight forward if idealized sinusoidal deviations extending across the whole band are assumed.

In practice, the characteristics of the transmission deviations in a long repeatered system are very complex and therefore, the idealized objectives are only a tentative guide in system design. Since we do not have a thoroughly satisfactory method of evaluating complex echo patterns, the exact nature of the final television mop-up arrangements will be determined after subjective tests have been made on the interfering effects of echoes resulting from the complex transmission deviations of representative links of the system.

The Mop-up Plan

The deviations from ideally flat gain and delay transmission characteristics may be classified in three broad categories: 1. fixed deviations; 2. slowly varying deviations; and 3. rapidly varying deviations. The distinction made between slow and rapid in the last two categories relates to the frequency of adjustment needed to meet system objectives. Those variations which require adjustment more often than once a week are considered rapid, and those requiring adjustment at longer intervals are considered slow.

Corresponding to each of the three classifications of deviations is a set of equalizers, fixed, manually adjustable, or automatic under control of the pilot or a temperature sensitive element. Networks capable of fulfilling the functions of each are distributed along the line according to carefully prepared rules which enable system objectives to be economically met. The locations of these equalizers, their functions, and general characteristics, are illustrated in Fig. 13.

Fixed Equalizers. To the extent that the auxiliary repeater is designed so that its nominal gain compensates for the loss of 4 miles of coaxial, it may be considered as the first step of fixed equalization. In addition to the amplifier, the auxiliary repeaters are equipped with artificial lines, which are used to build out the loss of short sections to the equivalent of 4 miles of cable, and basic equalizers which provide for differences in the loss characteristics of different types of cable.

The second and final step of fixed gain equalization is known as a design deviation equalizer. Its function is to correct accumulated deviations caused by the failure of the average auxiliary repeater to compensate exactly for cable loss. These equalizers will be used at every mop-up point, at 40- to 120-mile intervals.

When television is transmitted, fixed delay equalizers are used at approximately 150-mile intervals. These equalizers compensate for the delay distortion introduced by the cutoffs of the auxiliary repeater sections.

Manually Adjustable Equalizers. The manually adjustable gain equalizers consist of networks whose loss-frequency characteristics are related to one another by a Fourier series type of representation. The number of terms of the series required to meet system objectives varies with different types of mop-up points, and depends on the system application being provided for, all-message or combined message-television service. Equalizers of this type are used in mop-up points at 40- to 120-mile intervals along the line.

Manually adjustable delay equalizers are provided at approximately 150-mile intervals when television signals are transmitted. These equalizers supplement the fixed delay equalizers described here and are needed to trim the delay characteristic of the line in finer detail than is possible with fixed equalizers.

Automatic Equalizers. The first step of automatic-gain equalization is provided at each auxiliary repeater. The nominal gain characteristic of the repeater is designed to match the loss characteristic of the coaxial at 55 degrees Fahrenheit. The cable loss varies with changes in temperature; the variations, however, have a predictable characteristic, being very closely proportional in decibels to the square root of frequency. To compensate for these changes, the gain characteristic of the amplifier at auxiliary repeaters is adjustable and follows the loss of the cable under the control of a thermistor. Two types of circuits are used to control the current fed to the thermistor as described in a later section.

In the second step of automatic gain equalization, networks are provided to match system gain variations caused by electron tube aging and by changes in repeater hut temperatures. The loss characteristics of these equalizers are controlled by thermistors, which in turn are controlled by the 308-kc and the 2,064-kc pilots. These equalizers are used every 40 to 120 miles.

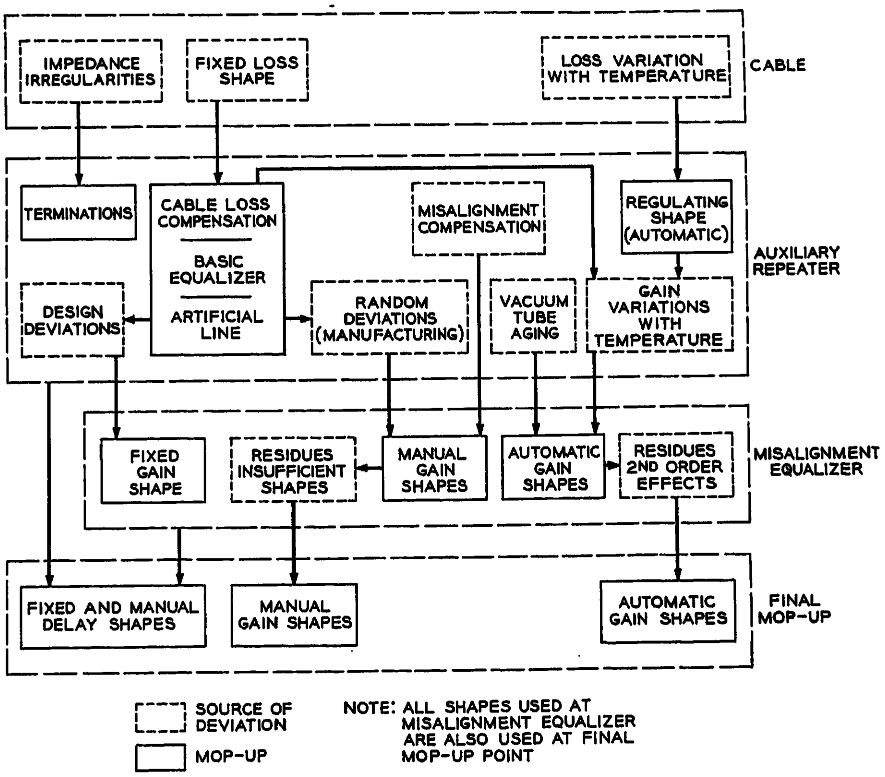
In the final step of automatic gain equalization, networks are provided to compensate for second-order effects of the first three rapid variations described above, namely, cable loss variations, and repeater gain variations caused by hut temperature changes and electron tube aging. The loss characteristics of these networks are under control of thermistors acted on by the 556-kc, 3,096-kc, and 8,320-kc pilots. These equalizers are located at approximately 150-mile intervals.

The thermistors which control the loss-frequency characteristics of automatic equalizers are driven by regulators through a simple form of analogue computer. The design and operation of this circuit is described in a companion paper.[8]

There is no automatic control of the delay characteristic in the system except that provided by the automatic gain equalizers. Every effort is made to have these equalizers match the transmission changes outside the band so that resulting delay changes in the band are minimized.

Equalization System Considerations

Whether the system is being equalized for telephone or television, it is im-



NOTE: ALL SHAPES USED AT MISALIGNMENT EQUALIZER ARE ALSO USED AT FINAL MOP-UP POINT

Fig. 13. L3 coaxial system-equalization plan

mediately apparent that the channel requirements described earlier, which were applied after 4,000 miles of transmission imply that, with no equalization, stability of the transmission characteristics of the individual repeaters would have to be of the order of a few ten thousandths of a decibel. Obviously, stabilities of this magnitude with changes caused by temperature, electron tube aging, and manufacturing processes cannot be achieved. Therefore, the equalization system design must be based on an economical balance between the cost of achieving repeater accuracy and stability and the cost of providing and maintaining an elaborate system of fixed, manual, and automatic equalizers.

The equalization problem involves so many variables that no attempt has been made to evolve a unified theoretical basis for evaluating the factors entering into this economic balance. However, in planning and designing the *L3* system a number of principles and points of view have been developed which have guided the equalization planning.

Misalignment. The transmission objectives described above are determined on the basis of delivering satisfactorily equalized signals at terminals. In addition to this function, the equalizers must limit the signal excursions along the line so that excessive noise or modulation is not accumulated in the repeater system. The amount of signal misalignment that can be allowed to accumulate before the first mop-up equalizer depends of course on the signal-to-noise allowance that has been made for this purpose. The amount of signal-to-noise performance allotted to misalignment must represent a balance between the reduced repeater spacing and increased complexity of equalizers that it costs and the increased spacing between mop-up equalizers and increased repeater deviations that it allows.

The engineering method for arriving at this balance represents an interesting example of system design by successive approximations. For example, the total gain area available over an infinite frequency range, in a coupling network is inversely proportional to the capacity across the network and one of the important design choices is the extent to which one tries to utilize this area in the transmitted frequency band. The degree to which the available gain is concentrated in-band is called the resistance integral efficiency. In the very early stages of the amplifier design it was necessary to choose resistance integral efficiencies and frequency characteristics for the coupling networks. In a definite but complicated way these parameters are related to the sensitivity of the networks to element variations. Efficient networks give improved signal-to-noise performance but also increase the sensitivity to element changes. By examining deviation curves for a number of specific network designs, tentative choices were made of 50-per-cent resistance integral efficiency for the coupling networks and an allocation of about half the cable slope to the pair of coupling networks and the remainder to the feedback network. With an amplifier employing these networks a detailed study was made of the noise and modulation penalties at two frequencies resulting from misalignment in several lengths of line. This study indicated that with certain refinements in the repeater design the misalignment in 20 or more auxiliary repeater sections could be tolerated with a signal-to-noise penalty of about 2 decibels which was judged to be a reasonable allotment for this purpose. In addition, this study brought out: 1. that randomizing the variations of an element between its normal manufacturing limits resulted in a 4-to-1 reduction in the required misalignment allowance as compared with accepting large numbers of elements at one extreme of their limit; and 2. that a small amount of gain adjustment at each repeater in the vicinity of the high magnitude television carrier would reduce the required misalignment allowance by about 2-to-1. Refinements on this plan for handling misalignment had to wait until the signal-to-noise and repeater design were crystallized. However, this study provided a powerful tool for evaluating proposed element deviations during the design period.

characteristics and final element deviations were determined, it became possible to make a refined study of misalignment in terms of the noise and modulation impairment associated with specific signals and distortion products. At this point, performance margins associated with specific interferences could be used to allow more or less misalignment of the particular signal components forming the interference. Likewise, amplifier deviations with specific frequency characteristics could be evaluated exactly in terms of their effect on the number of repeaters between mop-up equalizers. By studies of this type it was determined that the *A* or misalignment equalizers could be spaced at intervals not to exceed 32 auxiliary repeater sections.

Distribution of Element Deviations. The methods of statistical quality control used to monitor the process of manufacture provided the necessary techniques for obtaining the desired randomization of deviations. In the techniques that were developed to apply the broad field of knowledge on quality control to the specific needs of the *L3* system, the most important point to be appreciated is that the control of the process of manufacture (as well as the end electrical requirements) of individual elements is being used as a basic factor in the design of the system.[12]

Repeater Accuracy. In developing the equalization plan, it is a logical and straight forward operation to provide shapes and ranges in the equalizers that will compensate for the random variations of known elements. Likewise, real but indeterminate parasitic elements can be taken into account by specifying the final characteristics of the line amplifier feedback network and the equalizer fixed shapes (design deviation equalizers) on the basis of measurements on a rigidly controlled group of amplifiers that are deemed to be representative of the final product. However, having once specified the equalization on this basis, the design elements and indeterminate parasitic elements must be held to the values and ranges upon which equalizer location, shapes, and ranges are specified. This point of view has led to rigid mechanical control and the omission of component adjustments in the line amplifier which represent a departure from other transmission systems. These features are discussed in detail in a companion paper on amplifiers.[9]

NEW YORK-PHILADELPHIA TRIAL

The first installation of *L3* has been made between New York and Philadelphia. Since the middle of 1952, this installation has been used to test components, to verify values of important system parameters used in system analyses, and to gather data for the further design and development of equalizers.

Random noise measurements have confirmed theoretical values, Fig. 5, to an accuracy of better than 2 decibels. In general, the measurements have indicated that the theoretical values have been conservative.

Measurements of system modulation performance, made with single frequency tones, also confirm the theoretical values used in the analyses. Third order modulation measurements are in almost complete agreement with theory while second-order measurements have been generally two to three decibels more favorable than the analytic values used.

Transmission measurements have confirmed that equalizer networks designed so far are satisfactory for systems to be installed in the near future. Further measurements are required to determine automatic equalizer shapes to correct for

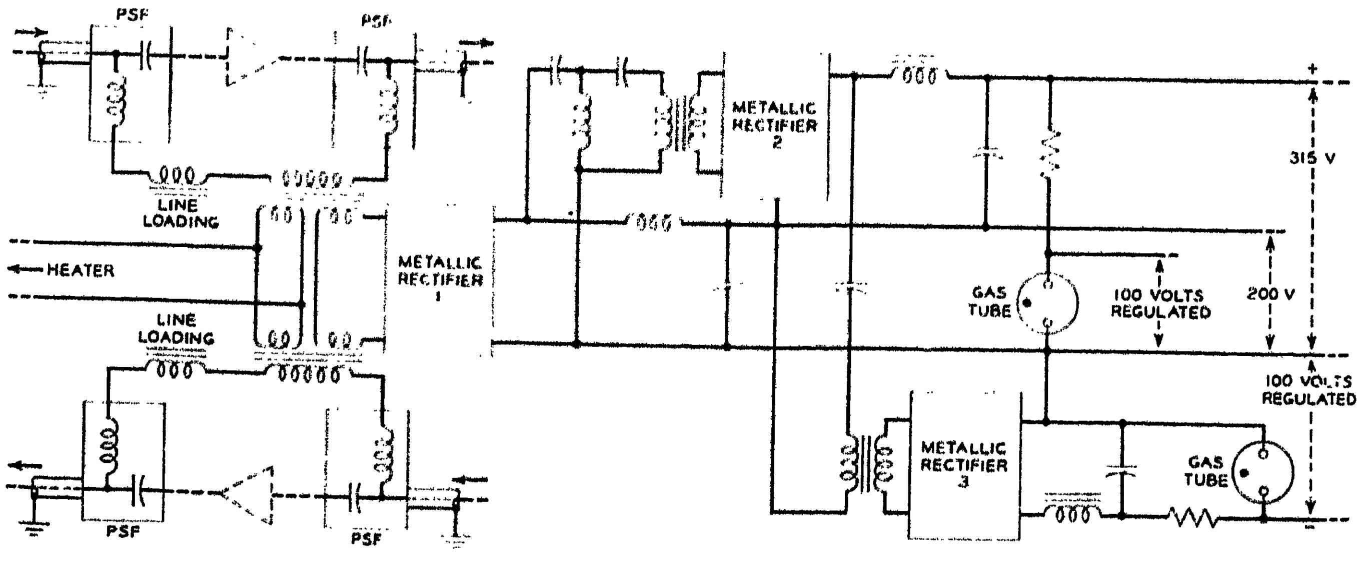

Fig. 16. Auxiliary repeater power supply

the second-order effects of temperature changes and electron tube aging. Also under active study are the problems associated with final mop-up for long television systems.

System Description

GENERAL

In the preceding sections on system design the functions of the auxiliary repeaters and the need for additional repeaters with varying amounts of equalization have been brought out. Fig. 14 shows the transmission layout of a typical *L3* system. The auxiliary repeaters contain amplifiers and regulating equipment to compensate for the basic cable loss and its variation with temperature. Since such repeaters are dependent on the cable for their primary source of power, they are called auxiliary repeaters.

At points in the system where additional first-order equalization is required to reduce misalignment the complexity of the repeater equipment increases and such repeaters receiving power over the cable are called equalizing auxiliary repeaters.

The distance which power may be transmitted over the cable to the auxiliary repeaters is limited; therefore, repeaters at specified intervals must be capable of supplying power to the cable. These are called main repeaters. They may be equalizing main repeaters where only first-order equalization is required or switching main repeaters where lines are switched or circuits dropped.

AUXILIARY REPEATER

Transmission Circuit

This repeater is the basic unit of the system and its design determines to a great extent the performance and economics of the system. A block diagram of such a repeater for transmission in two directions on two coaxials is shown in Fig. 15. The power separation filter (PSF) is a 6-terminal high-pass-low-pass filter designed to separate the high-frequency transmission signals on the coaxial from the low-frequency current transmitted on the center conductor to furnish primary power to the repeater power equipment. At the input to the repeater, the low-frequency current is diverted to a power supply while the high-frequency current follows a path through passive networks to the input of the amplifier. At the output, the signal from the amplifier and the low frequency current from the power supply are recombined in the power separation filter for transmission to the next repeater.

The power separation filters are basically simple designs, but the realization of the theoretical design was complicated by the following: 1. the components in the low-frequency section must pass currents of about 1.5 amperes without change in characteristics, and must withstand potentials as high as 2,000 volts rms without generating corona noise, and 2. the components in the high-frequency section must be such that the loss over the transmission band (300–8,350 kc) is small and stable and of such a shape that it is easily equalized. To meet these requirements, stable inductors and capacitors with a minimum of parasitic resonances in the band were designed.

The artificial line shown preceding the input to the amplifier is a passive network to build out the loss-frequency characteristic of a short cable section to be equivalent to the loss-frequency characteristic of 4.0±0.2 miles of 0.375-inch cable or 2.87±0.15 miles of 0.27-inch cable. These lines are provided in several different sizes so that, where it is impossible physically to locate the repeater within the specified accuracy of 0.4 mile, this accuracy can be obtained electrically. The design of the network is such that an accurate and stable characteristic is obtained with a minimum number of components.

The equalizer is a means for compensating for small variations in the transmission characteristics of coaxial cables which are caused by variations in the physical construction of the cable. In the case of the most generally used cable, this equalizer inserts only a small flat loss.

The amplifier is of the feedback type whose gain-frequency characteristic is closely equivalent to 4.0 miles of 0.375-inch coaxial cable plus the loss of the other passive elements in the repeater. This unit is demountable without tools for maintenance and is sealed in a die cast housing as protection against moisture and dust. The detailed electrical and mechanical design are covered elsewhere.[9]

The regulator may be one of two types. The first, called the auxiliary regulator, adjusts the gain-frequency shape of the amplifier in accordance with the magnitude of the 7,266-kc pilot transmitted along the line. The second type, called the thermometer regulator, adjusts the gain-frequency shape of the amplifier under control of an element representing an average value of cable temperature. This element is a thermistor buried in the ground near the cable. Such a control is, obviously, not as accurate as pilot-controlled regulation, but it is adequate for use at one-half of the auxiliary repeaters and its simplicity results in considerable saving in first cost and power requirements. The regulators are demountable units similar to the amplifiers. Their detailed electrical and mechanical design are covered in another paper.[8]

The pilot alarm unit is provided with auxiliary regulators to indicate pilot deviations beyond a predetermined limit. Its operation will be described later in connection with the discussion of alarm and control arrangements for the entire system.

Power Supply

Primary a-c power for the auxiliary repeater is supplied on a constant current basis from the main repeater over the center conductors of the two associated coaxials. Power generating and control equipment used at the main repeater will be discussed under "Power Generation and Transmission." At the auxiliary repeater, power supply equipment is required to convert the primary power to suitable voltages for heater, plate, and bias use as shown in Fig. 16. Half of the input to the power supply is taken from each center conductor and the output of the power supply is used to power the entire 2-way repeater.

The heater voltages are obtained by simple transformation which is complicated only by the fact that accurate and low-loss transformers are required and that the primaries of these transformers must withstand high a-c potentials without generating corona noise which might be transmitted through the power separation filter to the input of the amplifier. Two separate transformers are used to split the load between the two center conductors, even though the secondaries are connected together to feed the repeater. This arrangement eliminates one crosstalk path at low frequencies where it is difficult and expensive to design power separation filters to meet the system requirements.

The d-c plate and bias supply voltages for amplifiers and regulators could be obtained by conventional rectifier circuits except for one complication which such arrangements introduce. This complication is caused by the fact that a rectifier terminated in a low-pass filter, or conventional ripple filter, reflects a highly distorted current wave into the primary circuit. If the primary current is so distorted the various power supplies in the series circuit will be fed with other than a sine wave of current and will supply different voltages depending on

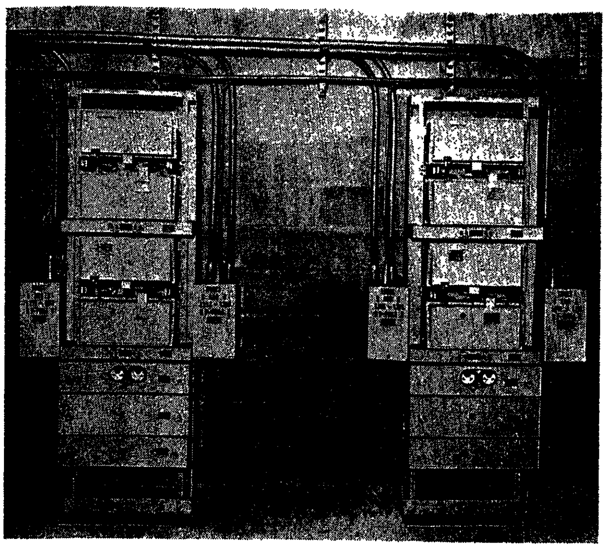

Fig. 17 (above). Typical auxiliary repeater in concrete block hut

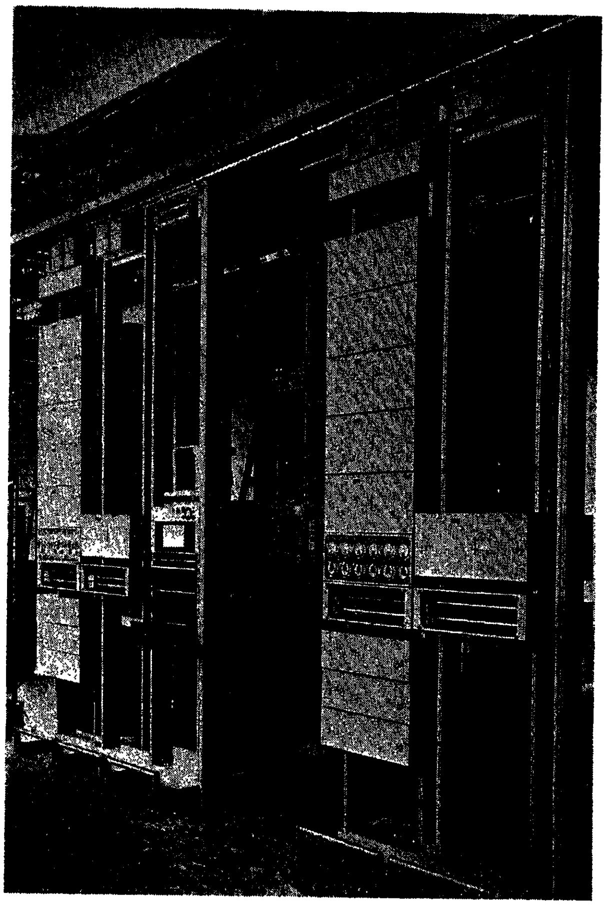

Fig. 18 (right). Typical main repeater installation

the wave form. Since the heater power depends on the rms value of current while the d-c output depends on the peak value of voltage, it is easily seen that the relationship between these two will change with the wave form of the applied current. Furthermore, the line loading to be discussed later must be calculated on the basis of a pure sine wave; appreciable harmonics in the line current tend to make it impossible to predetermine the loading to any reasonable degree of accuracy.

It was found that these problems could be avoided and the power factor of the power supply made very nearly unity if the rectifier (RECT 1) was terminated in a constant resistance load rather than a low-pass filter. This was provided by paralleling the conventional low-pass filter with a high-pass section terminated in the proper resistance load. To avoid wasting the power in this load, a second rectifier was added (RECT 2). The d-c output of this circuit is used in series with the main d-c supply to provide the higher voltage required for the output stage of the amplifier. This rectifier must also be terminated resistively although its effect on the main current wave is less than that of the first rectifier, and the power dissipated is smaller. Since there was a further use for a small amount of power for bias in the regulators, RECT 3 was added to produce a regulated voltage in conjunction with a conventional gas tube circuit. This rectifier and its load provide the termination for the high-pass section of the filter circuit for RECT 2. A second gas tube circuit is used to obtain a regulated bias supply for amplifiers and regulators from the 315-volt source. The loads on both gas tube circuits are fixed so that regulation for variation in input voltage only is required. For this reason a low-current highly stable gas tube could be used.

Power Loading

The power transmission circuit of a power loop is essentially a resistance-capacity network at the power frequency. The line and the power supply resistance are the resistance component, and the line and power separation filter capacity to ground make up the shunt capacity. If the circuit were used in this form, the primary current at each repeater would be different since it would be the vector sum of the current in the succeeding section and the current in the shunt capacitance. This is undesirable as the objective is to make all power supplies alike. A familiar solution is applied to this problem by inserting an inductive reactance in series with the line. A value of this reactance is chosen for each repeater to compensate for the current through the effective shunt capacitance, and thus make the currents through each of the power supplies as nearly alike as possible.

To simplify the loading adjustment in the *L3* system, a continuously variable loading inductor was developed. This arrangement allows more accurate adjustment of loading without the complications of changing wiring taps in a high-voltage circuit. The design of such an inductor presented formidable obstacles, as a large range of variation was desired (20 to 120 millihenrys) and relatively high currents and voltages involved. The device used consists of two inductors which may be rotated with respect to each other, so that the coupling between their magnetic circuits varies ideally between zero and 100 per cent. One inductor is inserted in each side of the power circuit and a net result is obtained which is equivalent to varying each inductor.

Physical Description

The type of auxiliary repeater generally used is shown in Fig. 17. It consists of a 6-foot cable duct framework upon which the component panels are mounted. It is completely wired in the factory. The lower third of the bay contains the power supply equipment while the upper part contains two transmission panels. One panel is provided for each direction of transmission and all of the transmission components of the circuit are found on these panels. The demountable units, amplifier, regulator, and pilot alarm unit are interconnected with plugs and jacks so that they may be removed for maintenance. The other units are interconnected by screw-type terminals and cable as it is expected that they will seldom require maintenance.

Other types of repeaters will be available to meet special conditions such as manholes where sealed apparatus cases will be required to prevent damage due to water submersion, or telephone offices where standard 11-foot 6-inch frameworks are usually desired.

EQUALIZING AND SWITCHING REPEATERS

Components

The equalizing auxiliary and main repeaters use the same general types of transmission equipment as the auxiliary repeater except for the equalizers. They differ principally in the quantity of equalization equipment provided, and the bay arrangements. Table III lists a summary of the basic transmission units in each repeater.

At these repeaters a line amplifier is used as a receiving amplifier to compensate for the previous section of cable. Flat amplifiers are used as transmitting amplifiers and to compensate for the loss introduced by the equalizers. They have a flat gain-frequency characteristic and no provision for pilot control of their gain. Their design is very similar to that of the line amplifier.[9]

The functions of the fixed, the manual, and the pilot-controlled equalizers are noted in the section on "The Mop-up Plan" of this paper and are discussed in detail elsewhere.[8]

Equalizing Auxiliary Repeaters

This type of repeater will be found after a maximum of 32 auxiliary repeaters provided power feed to the cable, dropping, or switching is not required, see Fig. 14. The major components provided are covered in Table III. In addition to these items, power separation filters, basic equalizers and artificial lines identical with those in auxiliary repeaters are used. A pilot alarm unit is also included to monitor each of the three regulators and transmit an alarm when any one of the controlling pilots has deviated beyond a given limit.

Power for these repeaters is obtained from the cable just as in the case of the auxiliary repeater, and much of the same type of equipment is used. However, because of the larger amount of power required, and the layout of the repeater, the auxiliary repeater power units have been repackaged to provide the optimum arrangements for leads carrying high current or critical bias supply circuits.

The design of panels used in this repeater was dictated by the general scheme conceived for the switching main repeater where the maximum amount of equipment is required. This arrangement involves the use of both sides of a duct-type frame. A single panel, again called the transmission panel, is used, but an amplifier is mounted on one side and a regulator on the other. This requires access to both sides of the bay, but results in an over-all saving in the number of bays and over-all floor space.

All of the transmission components and a heater and bias supply unit are mounted in one 7-foot bay for each coaxial. The plate and primary a-c power for two of these bays is mounted in another 7-foot bay.

Equalizing Main Repeater

This repeater contains exactly the same transmission equipment as the equalizing auxiliary repeater; see Table III. It differs in the function noted before, that is, it is equipped to feed power to the cable. The equipment to perform this function will be described later. Since the repeater can feed power to the cable, it can also supply the power for its own operation. This power is derived from the primary a-c supply used for the line by means of conventional metallic rectifiers for d-c circuits and transformers for the a-c heater supplies. These power supplies are not a part of the power loop containing auxiliary repeaters, so no special arrangements are required to obtain good waveform or high power factor.

The equipment arrangement uses the same units as the equalizing auxiliary repeater, but here conventional 11-foot 6-inch frames are used.

Switching Main Repeater

Usually this type of repeater is supplied at the point where circuits are dropped or terminated. To permit switching from a working line to a spare line in case of trouble, (see the section entitled "Automatic Switching") more complex equalization is required so that the lines will be as nearly alike as possible when the switch takes place. Furthermore, the signal delivered to the terminal must meet equalization limits that will result in a satisfactory grade of service.

Where the repeater is part of a system required to transmit only message circuits the basic equipment shown in Table III (telephone only case) is required. In addition to these units, facilities are provided which indicate and alarm pilot levels and provide for patching and other maintenance arrangements. Since this repeater always feeds power to the cable, it uses the same power arrangements as the equalizing main repeater.

Where the system is being used for the combined telephone and television signal this repeater is the same as the all-telephone system repeater except that it has additional equalization equipment to adjust the system for the more stringent television requirements. Furthermore, line-connecting equipment consisting of branching filters and additional equalization is required. Branching filters are used to separate the telephone and television bands so that they can be transmitted to their respective terminal equipment. These are combined high-pass–low-pass structures complicated by strict requirements on stability of the gain-frequency and delay-frequency characteristics. Delay equalization for the line sections must also be provided in the television branch and a large part of this is combined with the branching filters. Other components required for long television systems are adjustable gain and delay equalizers and associated amplification.

The same type of equipment is used as that described for the other repeaters except that a number of additional transmission panels are required to mount the additional amplifiers and regulators associated with the equalizers. Two 11-foot 6-inch bays are used to contain the equipment for one through coaxial. One bay contains the receiving equipment which precedes the line switch. The other bay contains the transmitting equipment

Table III. Summary of High-Frequency Line Equipment at Repeater Stations

	Auxiliary	Equalizing Auxiliary	Auxiliary Main	Switching Main (Telephone Only)	Switching Main Telephone-Television

(transmitting amplifier and hybrid) and any line connecting equipment for combined systems. Fig. 18 shows a typical main repeater installation.

Automatic Switching

To preserve transmission in the event of the failure of a component of the system and for transmission maintenance purposes, one coaxial in each direction is operated as a stand-by. An automatic switching system is provided to permit substitution of the stand-by line for any of the working lines. The lines are switched at the input to the transmitting amplifier and at the output of the receiving amplifiers and equalizers as shown in Fig. 14.

At the receiving end of a switching section, equipment is provided whose function is to recognize failure of a working line and initiate the switching circuits. Information as to the transmission conditions of the system exists in the pilot regulators, the output of which controls a sensitive relay with high- and low-limit contacts. The operation of one of these relays provides the switching system with the information that transmission has failed or been seriously impaired. It is necessary to make a switch as rapidly as possible in the case of a total failure in order to reduce the effect upon the transmission circuits. As the relays take appreciable time to operate, the receiving switch equipment is designed to operate directly from the d-c output of the regulator associated with the 7,266-kc line pilot. This permits complete switch operation in about 15 milliseconds.

Upon receipt of information from the regulators that one or more of the pilots have gone out of limits, the switch initiator signals the transmitting switch control equipment at the transmitting end of the switching section as to which line has failed. Signalling is accomplished by the use of tones in the 280- to 296-kc range which are transmitted over all coaxials in parallel in the reverse direction. Use of the coaxials for transmission of these signals obtains maximum speed of operation of the switch. All paths are used in parallel to preclude failure of the switch if one channel in the opposite direction would be inoperative.

The transmitting switch control equipment causes the transmitting end of the stand-by line to be switched in parallel with the line in trouble and then signals the switch initiator that this has been done. This verifier tone actuates the line switch at the receiving end to complete the switch.

When the trouble clears, the switch is released as the initiator checks every minute to see if service on the working line can be restored. In the event of prolonged trouble, the switch can be locked manually and the initiator will no longer attempt to restore to normal. Release of the switch is accomplished by the transmission of a release tone to the transmitting end while a checking tone returned by the transmitting end indicates completion of release and readies the switch initiator for further switching.

For maintenance purposes, manual operation of the switching equipment is provided. In effect, manual switches are made by simulating a failure. Alarm features are provided to indicate to the operating personnel failure of the coaxial system or failure of the switching equipment. Care has been taken in the design to insure that failure of the switching equipment in no way affects transmission except by removing the protection afforded by the presence of the switching facility.

One 11-foot 6-inch bay is required for the switch control equipment for each direction of an 8-coaxial system. The

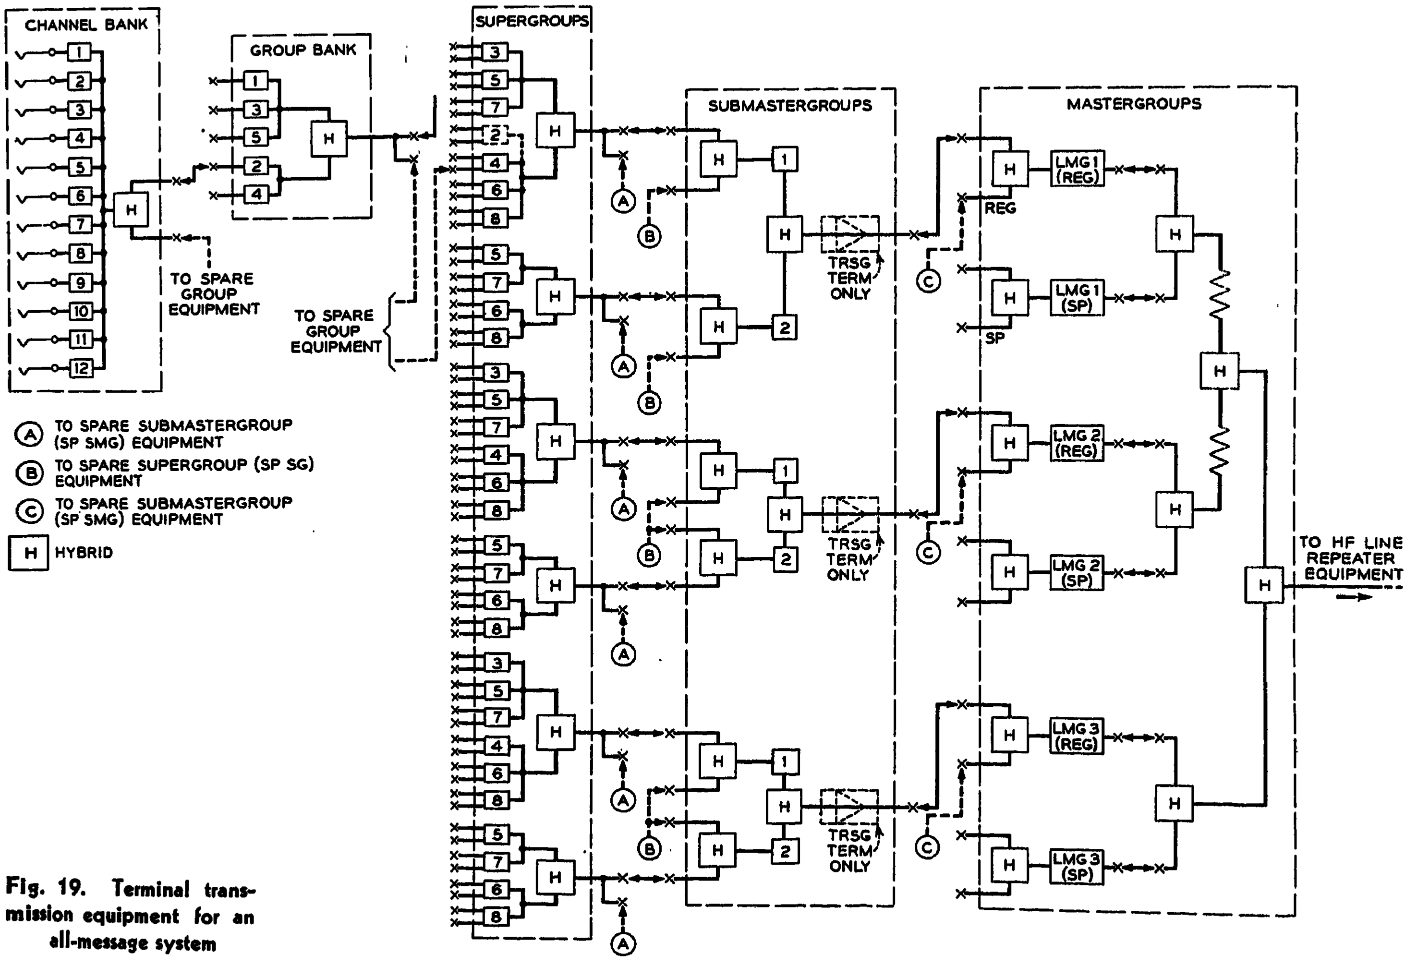

Fig. 19. Terminal transmission equipment for an all-message system

line switches are mounted in the miscellaneous bay of the main repeater lineup.

TERMINALS

Television terminal equipment, which is required to modulate the video frequency signals to and from the high-frequency line, is described in a companion paper[10] and therefore will not be discussed here.

The telephone terminals consist of modulators (and related transmission equipment) and carrier and pilot generating equipment. The transmission components of a terminal for an all message system are shown in Fig. 19. The channel, group, and supergroup equipment are designs previously used in the *L1* system. The designs of the submastergroup and mastergroup units employ circuit arrangements similar to those used in the super group equipment. The greater bandwidths, higher frequencies, and more severe stability requirements demanded new components and improved circuit and layout techniques.

Fig. 20 shows the modulation steps and location in the frequency spectrum of the supergroups, submastergroups, and mastergroups when the *L3* system is used for telephone and television or all telephone. Mastergroup 1 comprises the first ten 60-channel supergroups. This mastergroup is placed directly on the line in the 564 to 3,084-kc frequency band for both the telephone-television and all-telephone cases. When the system is used entirely for telephone, two additional mastergroups are formed by modulating mastergroup 1 up into the desired frequency bands.

Mastergroup 1 is subdivided into two submastergroups. The lower six supergroups, comprising submastergroup 1, are modulated directly up from the basic supergroup located in the 312 to 552-kc band. The modulation and carrier supply equipment for these supergroups are the same units that are employed in the *L1* system. The upper four supergroups comprising submastergroup 2 are obtained by modulating four supergroups located in the same frequency range as the top four supergroups in submastergroup 1 into the top part of mastergroup 1.

The supergroup numbering system used for *L3* has been adopted for easy identification of supergroups in their high-frequency positions. Each supergroup is given a 3-digit number. The first digit identifies the mastergroup, the second digit identifies the submastergroup, and the third digit identifies the *L1* supergroup from which it was originally derived.

In the 1,860-channel all-telephone allocation, supergroup 112, which corresponds to the basic *L1* supergroup 2, may be used for high-quality, long-haul message circuits. When the system is used for telephone and television, supergroup 112 is restricted to circuits under 200 miles in length because of intolerable second-order cross-modulation between these signals and the television signal.

With these groupings of channels, new modulating and carrier supply equipment is required for submastergroup 2 and mastergroups 2 and 3. The frequency allocation and modulation steps shown in Fig. 20 were chosen so that good performance could be obtained with relatively inexpensive filters used for suppressing unwanted side bands and to develop lower side-band signals appearing right side up for transmission over the high-frequency line. The carrier frequencies used in the modulation steps were chosen so that some of the same filters could be used in submastergroup 2 and mastergroup 2 and 3 modulators. The clear bands between the submastergroups and the mastergroups were chosen to permit the use of economical blocking filters at repeaters where circuits are to be dropped from the high-frequency line and to provide frequency space for the line pilots.

It will be noticed in Fig. 19 that facilities are provided for patching spare equipment into service for maintenance reasons or in the event of a failure in working units. Alarm features are in-

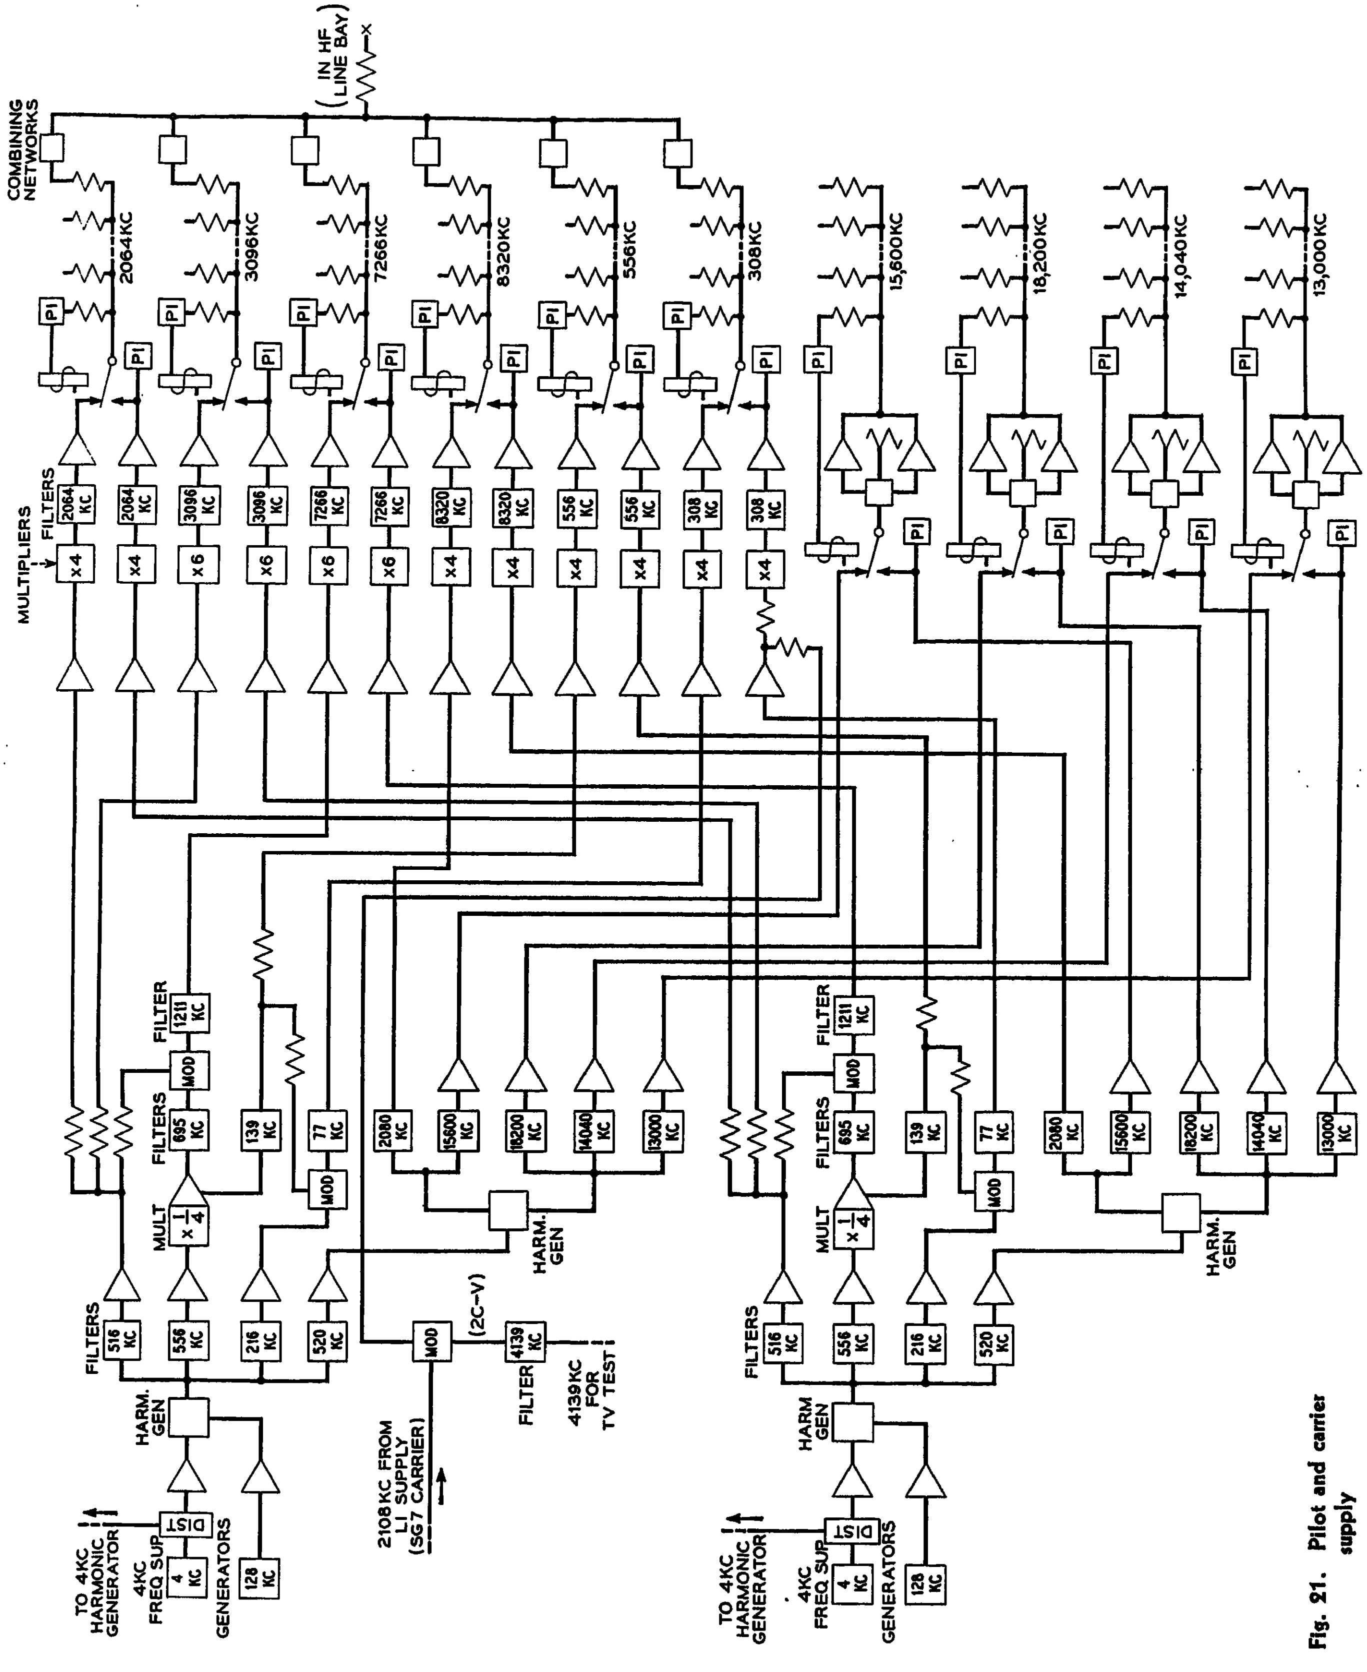

Fig. 21. Pilot and carrier supply

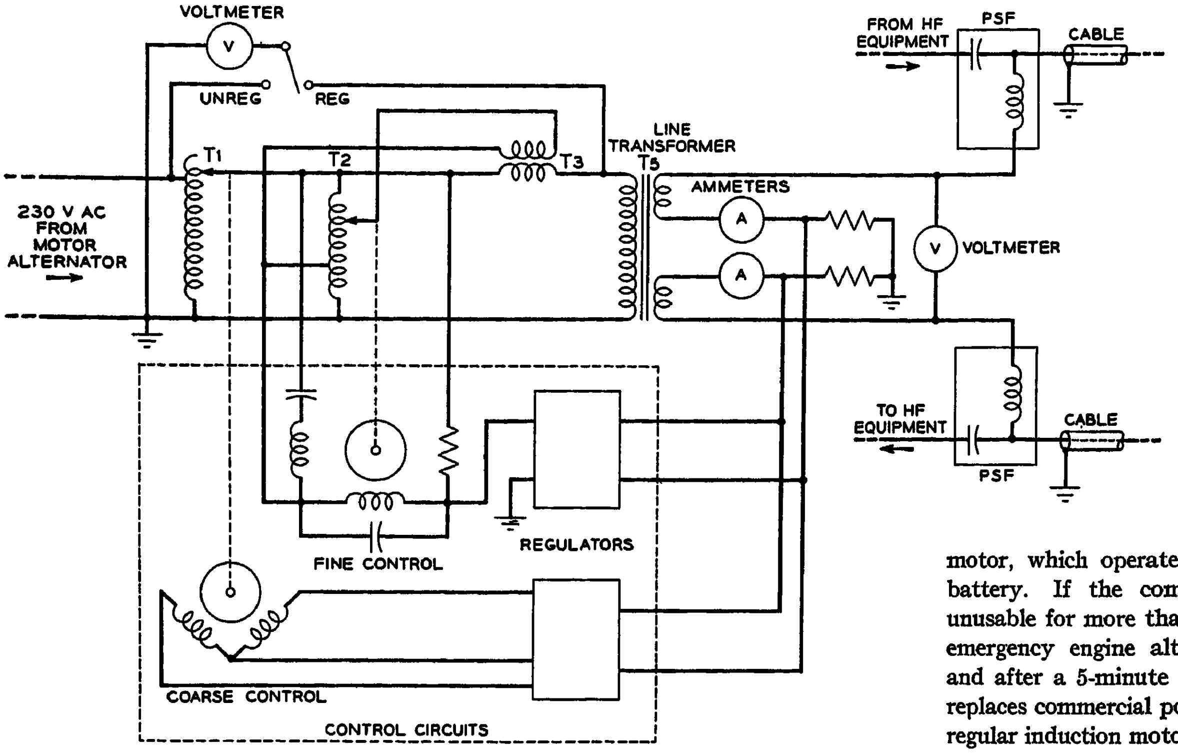

Fig. 22. Simplified schematic of the power control circuit through which regulated power is fed to the coaxial circuits

corporated in the submastergroup and mastergroup units to indicate trouble conditions and initiate maintenance procedures.

The carriers required for the channel, group, and supergroup units are supplied by equipment developed for the *L1* system. The arrangements for supplying the new carrier and pilot frequencies are shown in Fig. 21.

A problem of primary importance in carrier supply design is the accuracy of the frequencies. There is both an absolute accuracy and a relative accuracy requirement. For transmission of some types of signals there is a requirement that the difference in frequency between a carrier at two terminals be less than 2 cycles per second. This extreme accuracy is achieved by using the oscillator at one terminal to control the frequency of oscillators at other points. A line pilot generated at the terminal in which the master oscillator is located is used as a reference frequency at points along the line where other terminals are located, and by this means carriers are held to a relative accuracy of ±1 part per 30,000,000.

In order that requirements for high-quality television transmission may be realized on a 4,000-mile circuit, the output of the pilot supply must be extremely constant with both time and temperature changes. Deviations in the magnitudes of line pilots are maintained to less than 0.05 decibel.

Since a failure in the *L3* carrier and pilot supply could cause interruption to service on an extremely large number of circuits, many precautions have been taken to make the equipment reliable. In addition, stand-by units, which are automatically switched in place of the regular units in the event of failure, are provided to improve the over-all reliability of the system.

The terminal equipment is normally mounted on standard 11-foot 6-inch duct-type bays. The submastergroup and mastergroup equipment required to handle 1,860 channels occupies two complete bays and portions of two others. One carrier and pilot supply is mounted in three bays.

Power Generation and Transmission

Power is transmitted to the auxiliary repeater over the inner conductors of each pair of coaxials as noted earlier. A maximum of 21 auxiliary repeaters can be fed from a main repeater. This limit is determined by the maximum potential the cable can safely withstand. Shorter spacings are dictated by geographical and plant layout considerations.

The power supplied to the coaxials at the main stations is generated by a motor-alternator set which consists of the alternator, an induction motor, and a d-c motor and its exciter, all coupled together on the same shaft. Normally, commercial power is used to drive the induction motor. When this source fails or the voltage goes out of prescribed limits, the drive is transferred to the d-c motor, which operates from a 130-volt battery. If the commercial power is unusable for more than 2½ minutes, an emergency engine alternator is started and after a 5-minute warm-up period it replaces commercial power in driving the regular induction motor.

The constant current to the coaxials is supplied through a power control circuit which accurately regulates it to within ±1 per cent of the desired value. A simplified schematic of the power control unit is shown in Fig. 22. The unit consists of two motor-driven continuously variable transformers which supply power to the line transformer. The course control variable transformer is relay controlled and maintains the line current within ±3 per cent of the prescribed value. The range of this transformer is sufficient to permit reducing the voltage to zero in order to turn down power on the system for maintenance purposes. The fine control variable transformer is regulated by an electronic regulator to maintain the line current within ±1 per cent of the desired value.

The change in the line current in response to commercial power transients and transients introduced by changes in the motors driving the alternator requires careful consideration. By increasing the inertia of the motor alternator set with a fly wheel and carefully designing the frequency response of the power control regulator just described, a satisfactory transient response has been obtained.

For the maximum length power section the potential applied to the cable at the main stations is about 2,000 volts rms from center conductor to ground. This potential diminishes about 100 volts per repeater section in going out from the power feed point or as the power section is shortened. (The maximum potential applied to the cable in *L1* systems is about 800 volts rms between center conductor and ground). Extensive tests on the installed cable showed that corona develops in the cable at potentials varying in a random fashion between 1,200 and 1,600 volts rms. This would allow power feed points to be placed at a maximum spacing of about 100 miles. By replacing the nitrogen, with which the cables are normally filled, with a large molecule gas, sulfurhexafluoride (SF_6), the corona potential of the cable is increased well above the maximum operating potential. Only the cable sections exposed to potentials greater than 1,200 volts will be filled with the new gas. Elaborate and thorough tests have demonstrated that no deterioration of the cables will result from the use of this gas. Some additional precautions are required in entering manholes and using high-temperature torches for soldering when the SF_6 gas might be present.

Alarm Equipment

Since the auxiliary repeaters and certain of the main repeaters are unattended, it is necessary that arrangements be provided to indicate at the attended stations when some piece of equipment fails to perform satisfactorily.

Auxiliary repeaters using pilot regulators are equipped with microammeter relays which monitor the operation of the regulator continuously. These relays provide an indication of the operation of the regulator and the power of the 7,266-kc pilot at the output of the repeater. When conditions change from the nominal by a specified amount, the relay contacts close and are locked magnetically. This bridges an alarm pair in the cable and operates an alarm at the nearest attended repeater. By means of Wheatstone bridge measurements from this repeater over the same alarm pair, the repeater in trouble can be located and a maintenance crew dispatched to make the necessary equipment replacements. The relays can also be reset over the same alarm pair to aid in the location process or to clear alarms which were initiated at unaffected repeaters by deviations in the pilot due to troubles at preceding repeaters.

At main repeaters, microammeter relays are provided on all six pilots used to control the equalization of the system. Deviations in these pilots operate the automatic switching equipment and initiate the usual office alarms. Alarms are also provided to indicate fuse operation, transfers from regular to stand-by equipment, and the condition of electron tubes in the terminal equipment amplifiers.

Provisions for connection to special alarm systems are made at main repeaters which are not fully attended. These systems extend the alarms to the nearest attended repeater and enable the attendant to determine in considerable detail the condition at the remote repeater. The attendant may also perform certain operations such as switching a working line to a spare line at the remote repeater.

Maintenance

Maintenance of the *L3* system requires equipment and methods for routine checking of the system and trouble location. Normally the auxiliary repeaters will be visited at intervals of about 3 months, when checks will be made of the power voltages and currents, the electron tube bias and change in bias with a fixed change in heater voltage (activity), and the pilot magnitudes. At these times amplifiers and regulators which fail to meet prescribed limits will be replaced, the 7,266-kc pilot will be brought to its normal value by adjusting the regulator gain, and the amplifier gain control in the output beta circuit will be adjusted by observing the 3,096-kc pilot.

For these routine tests and adjustments two portable test sets are provided. The power test set plugs into the repeater, amplifier, or regulator and provides for measuring power supply voltage and currents and electron tube cathode-grid voltages to an accuracy of ±1 per cent. The pilot indicator makes it possible to measure the 7,266- and 3,096-kc pilots to an accuracy of ±0.1 decibel.

For trouble locations at auxiliary repeaters a portable transmission measuring set has been designed. It is capable of measuring the power in a 500-cycle band at any place in the frequency spectrum from 50- to 11,000-kc to an accuracy of ±0.5 to ±0.02 decibel, depending on its specific use and the care used in calibration.

At main repeaters, line sections will be checked for noise and modulation performance and equalizers will be adjusted at intervals of 1 week to several months. In addition, loss and gain measurements will be made on sections of the office suspected of being in trouble. For all general tests except equalization line-up, point-by-point measuring equipment is provided, consisting of a 50- to 10,000-kc oscillator, the tuned transmission measuring set referred to above, a milliwatt power meter accurate to ±0.035 decibel and a complement of attenuators, pads, and comparison switches.

The adjustment in a rapid and direct way of the manual gain equalizers to an accuracy of ±0.02 decibel is accomplished by special equipment described in the companion equalization paper.[10] A visual gain and delay transmission measuring test set, capable of measuring gain to ±0.05 decibel and delay to ±0.02 microsecond, has been developed for observing the line performance and adjusting delay equalizers when the system is used for television.

A maintenance center is provided at about 200-mile intervals along the line to service the equipment removed from repeaters. At these points facilities are provided for the following:

1. electron tube testing;
2. regulator repair and adjustment;
3. transmission measurements on passive components; and
4. amplifier testing of sufficient scope to permit changing tubes and to determine whether an amplifier is suitable for further service in the line.

L3 Coaxial System—Equalization and Regulation

R. W. KETCHLEDGE
NONMEMBER AIEE

T. R. FINCH
NONMEMBER AIEE

Synopsis: The equalization and regulation problems of the *L3* system are described and a theory of equalization of complex systems is outlined. The location and function of the various equalizers are explained, including the roles and design of the various fixed, dynamic, and manual equalizer networks. The analogue computer used in the regulation system is described, together with the cosine-equalizer adjusting technique used with manual equalizers. Finally the circuits and operation of the regulation system and its components are presented.

EQUALIZATION is the process of correcting system gain and delay deviations sufficiently to permit the satisfactory transmission of signals. Regulation refers to that part of equalization which, by automatic means, corrects for relatively rapid changes in transmission. In the *L3* coaxial system the transmission of television signals through more than 1,000 amplifiers introduces relatively severe equalization and regulation problems. Compared to the *L1* system, the *L3* system has nearly three times the bandwidth and over three times more stringent transmission objectives. Thus it has been necessary to devote considerable effort toward finding equalization methods that yield practical and economical solutions.

In previous systems it has often been the practice to design the bulk of the equalization system after the completion of an initial installation and the determination of the deviation characteristics of the system. To expedite the introduction of the *L3* system into the field, equalization study and planning were initiated at the very beginning of the development of the system. One of the design methods was to make highly detailed studies using relatively inadequate data to find the major problems. As the data improved, the studies were likewise improved. While on the surface it might appear more practical to have deferred this work until the data are more adequate, it has been found that these speculative studies are the only sure guide to getting the right data. Faced with such a complicated problem, it is difficult to select from the vast amounts of factors that might be important those relatively few items on which success or failure depends. In the *L3* system there have been a number of critical problems which required intensive effort to find acceptable solutions, for example, the design of stable regulators to permit operation of 700 regulators in tandem, the choice of shapes for manual and dynamic equalizers, and the selection of equalizer adjustment methods.

The design of equalization for the *L3* system is not yet complete since the dynamic equalizer shapes are still subject to considerable uncertainty and the details of some of the final television mop-up equalization are yet to be settled. However, no major difficulties are anticipated in equalizing the telephone system to be installed from Philadelphia to Chicago during 1953. Although amplifiers having the final gain characteristic were operated in the trial line between New York and Philadelphia for the first time in November 1952, it was immediately possible to transmit quite satisfactory television pictures over the 200-mile loop using existing equalizers. It therefore appears that equalization will not limit the rate of field installation of the *L3* system.

The Problem

The 4,000-mile coaxial cable has a gain distortion of nearly 40,000 decibels between 0.3 and 8.5 megacycles. Although the amplifiers reduce the distortion to perhaps 200 decibels, and 100 microseconds, they leave a residue characteristic that is considerably more difficult to equalize. Further, it is necessary to deliver service to intermediate offices spaced on the average about 120 miles apart. This requires equalization of high precision at numerous intermediate points. A further problem is the variability of the transmission characteristic due to manufacturing deviations plus time and temperature changes. Also, gain distortion cannot be permitted to exceed about 5 decibels at any point in the line or the signal misalignment will result in degraded signal-to-noise ratios.[1]

The over-all transmission objectives[1] are of the order of 0.25 decibel and 0.1 microsecond which, if allocated among the more than 1,000 amplifiers, lead to rather unrealistic amplifier requirements. In fact, individual amplifiers do not always meet the 4,000-mile over-all requirements. Thus it is the problem of the equalization designer to provide a mop-up system that will permit attainment of the transmission objectives at all service points and at all times.

Equalization Theory

One of the steps in the solution of the general problem has been to develop a theory of equalization. This theory merely applies information concepts to the equalization problem to determine what information is required, when it is needed, and how it may best be used. This theory has stimulated the development of novel equalizer adjustment techniques and has been of assistance as a guide to the attack on the general problem.

To equalize a system, the man (or machine) who is to perform the action must know what corrective steps are required, and for this he must have some kind of information as to the present state of the system and as to the desired state. Second, he must have the necessary tools to convert the system from its present state to the desired state. Consider the first problem, the determination of the corrective steps required. The problem is to determine what we need to know, when we need to know it, and especially in what form the information may be utilized most efficiently.

It can be assumed that the desired state of the system is known, which is usually a constant loss with constant delay over the frequency range of interest. As to the present state of the system, it may be noted that sufficient information can never be obtained to equalize a system perfectly because of the finite bandwidth of the system and because the system changes with time. This is not a new

Space does not permit listing all who contributed to the success of this work. However, the authors wish to mention S. A. Levin for his work on cause shapes, R. H. Klie for his leadership in system studies, E. T. Harkless for his study of cosine equalizers, and E. Ley for mechanical design of equalizers. Also, mention should be made of C. J. Custer and E. G. Morton for their work on regulator circuits, A. R. Rienstra for studies of gain enhancement, C. H. Bidwell for chain action analysis, and F. R. Dickinson for mechanical design of regulators.

fact, nor apparently a very important one, because the system need not be perfectly equalized for satisfactory transmission of signals. It leads, however, to the converse idea, which is important, namely that out of this infinite amount of information regarding the state of the system one should collect only the minimum amount needed. This implies making no more measurements of the state of the system than are absolutely necessary to perform the correction to a degree permitting satisfactory transmittal of the signals. The main purpose of this is, of course, to economize on the time and effort required to obtain information, but it should be noted that excess information may be a source of confusion to the equalization operator.

To put this in the form of a rule, we have:

Rule 1. "Collect only that minimum of information as to the state of the system as will permit equalization to the required degree for satisfactory transmission of the signals."

Having established that a minimum of information should be collected, we return to the time variation of the system, which in theory can make the information obsolete before it can be used. However, without yet bringing in the practical fact that its most rapid rate is relatively slow, we should introduce the fact that the ways in which the system can vary at its most rapid rate are quite restricted as compared with the manner in which it can vary at slower rates, and we note that even these are relatively limited. (This probably applies to most transmission systems, not just to the *L3* coaxial.)

Thus, while the information regarding the more rapid but simple changes must be collected more frequently, it consists of a small amount of information per sample; whereas the information regarding the slow, but more complex, changes need not be collected very often, but it represents a relatively large amount of information per sample. Since the total rate of information collection is proportional to the information per sample times the rate of sampling, the minimum information collection principle would say that the rate of sampling should also be held to a minimum.

This demonstrates the value of association of particular types of system change with the rate and amount of their variation, because one may thus eliminate from the more rapid sampling the collection of information about changes that occur at slow rates. Furthermore, one may establish the sampling rates for the various system effects at the lowest possible value. (There is also a very practical value in knowing the rates and amounts of the various deviations, because system misalignment requirements force the equalization to be suitably distributed along the line.)

In the form of a rule, this is:

Rule 2. "To the greatest practicable extent the over-all system behavior should be separated into individual effects, each having its own time rate of occurrence, and corrections should be made for each effect at the minimum tolerable rate for each."

It is of interest to note that, if we couple the logic of rule 2 with the fact that the fastest changes, caused by changes in the temperature of the repeater huts, take hours to become appreciable, we see that the continuous collection of information from continuous pilots (and the continuous correction by pilot-controlled regulators) is in principle unnecessary and inefficient, except of course for its other function of giving alarms under trouble conditions.

The technical problem of determining the equalization states of the system is normally solved by sending some kind of signals over the system and observing the effect of the system on those signals. The raw data are usually in the form of loss and delay as a function of frequency. On the basis of these data, the equalization operator desires to correct the system by means of some equalizers which have adjustable transmissions and delays as a function of frequency. Thus the operator has a group of controls to be operated plus some data which has encoded in it the information as to the proper adjustment of each control. From these data, and a knowledge of the effect of each control, the operator must suitably compute the proper adjustments. As this may be too complicated a process to attempt on on a trial and error basis, or by numerical methods, it is quite an obvious advantage to the operator to receive the data as to the state of the system, not in its original form, but in the form of the necessary adjustments to his equalizer controls. This new form on the data simply represents a decoding process based on the available controls. An operator with the same data, but different and perhaps more complicated equalizers, would need the data in a form suited to his different equalizers.

Consequently:

Rule 3A. "The information as to the state of the system may best be presented to the equalization operator in the form of the necessary adjustments of the available equalization controls."

This rule has a closely related corollary which is based on the fact that the available equalization controls determine the amount of information needed. For example, if the independent gain equalization controls are n in number, measurement of the gain of the system at n suitably chosen frequencies is sufficient to determine the settings. (If the controls are not independent, fewer than n frequencies need be measured.) This is, of course, a restatement of the fact that n unknowns may be determined by solu-

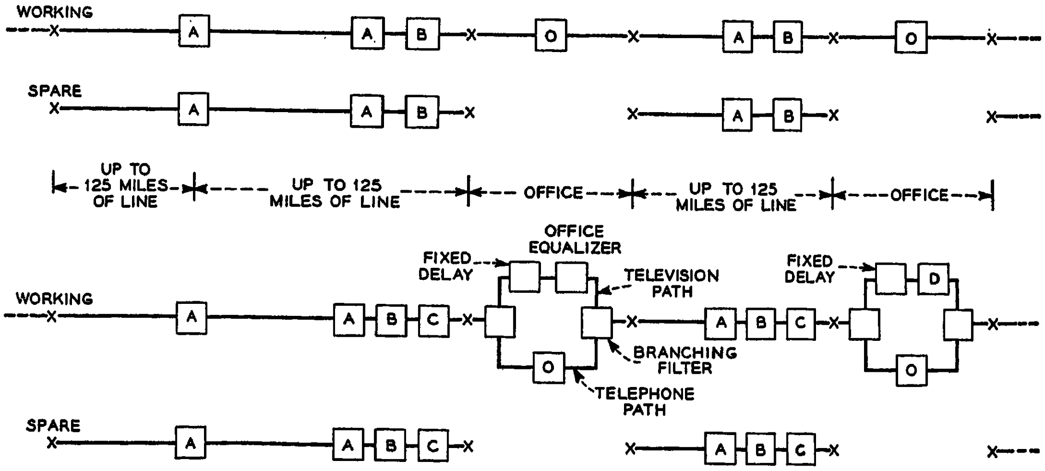

Fig. 1. Typical equalizer locations in telephone systems and in combined systems

tion of n independent simultaneous equations. The unknowns are the equalizer settings and the simultaneous equations are the relationships of the shapes controlled by each equalizer to the total system error.

Thus:

Rule 3B. "In general, the necessary and sufficient condition for the determination of n independent equalization control settings is the knowledge of the system's equalization error at n independent frequencies plus the knowledge of the effect of each of the n controls at each of the n frequencies."

It should be noted that this statement of the rule assumes analysis by frequency rather than by transient behavior. This approach is used because, at present, equalizers are usually designed on a frequency characteristic basis. The validity of the rule is, however, more general.

From these two rules we can derive another regarding the minimum information principle, which is similar to rule 1 but is actually quite independent of it.

Rule 4. "No more information should be gathered from the system than is necessary to provide sufficiently accurate control setting information for the equalization operator."

In this case the superfluous information may actually cause confusion or harm. It will, at the very least, confuse a manual operator to know of an error he is powerless to correct, whereas a mechanized system would probably go wild if it obtained too much information.

It is evident that the minimum amount of information that would be obtained in accordance with rule 4 would be the same as that obtained in accordance with rule 1 only if the design of the equalization were optimum, because then the equalizer shapes, and the number of shapes, would just suffice to permit satisfactory transmission of the signals.

Use of the Data

Up to this point it has been determined in general what information is needed, when it is needed, and the optimum form of its presentation. The next step is to examine what to do with the data, which involves considering the nature of the equalization operator as well as his equalization tools.

If we followed rule 2 vigorously, we should have several different types of controls, one for each of the effects having different time rates of occurrence. For purposes of illustration, however, we need assume only two rates, one quite rapid and the other very slow. It will be postulated here that very rapid equalization operations are most economically performed by machine such as, for example, the automatic regulation for cable temperature variations. Likewise, relatively infrequent adjustments will be assumed to be best performed by a suitably informed human operator.

The first principle to note is that the only real distinction here is the rate at which data should be refreshed and acted upon. In either case the data should be in the same form, a set of numbers (or their equivalent) representing equalizer changes.

Probably the most useful result of this theory of equalization has been the conclusion that mechanization of the equalization process, particularly with regard to computational techniques, permits substitution of simple logical methods for inefficient trial-and-error adjustment processes. This led to the use of an analogue computer in the regulation system and, for manual equalizers, the development of measuring circuits that read directly in terms of equalizer adjustment error.

Equalization

Location and Function of Equalizers

Fig. 1(A) shows the location of equalizers in the *L3* system when only telephone is transmitted. Combined telephone-television equalization is shown in Fig. 1(B). When telephone and combined systems use the same spare line, that line is equipped for television. The general features of the main-repeater layout have been described.[1] The detailed layout of equalization is designed to meet the requirements of both telephone and television service and the need for flexibility in television network arrangements. In addition, switching of telephone or television service to a spare line must not appreciably degrade service.

Switching sections longer than 120 miles must be provided with an intermediate step of equalization to prevent excessive signal misalignment. This intermediate point is referred to as an equalizing auxiliary repeater. It is provided with the so-called *A* equalizer consisting in turn of fixed, manual, and automatic gain equalizers. It reduces the gain error to less than 0.5 decibel using the fixed and manual sections, and prevents appreciable degradation of this residue during an ensuing 3-month period by the action of three office regulators using pilots at 308, 2,064, and 7,266 kc controlling three regulating networks. One of these networks is the $\sqrt{f}$ shape of the receiving amplifier.[2] The other two are first order corrections for vacuum-tube aging and repeater temperature changes.

At offices (switching main repeaters) on telephone systems further equalization is required to permit line switching of telephone channels and special service signals, such as telegraph. Also, it is not practical to provide telephone equalization on a cumulative basis over longer links than a switching link because of frogging and dropping.[1] No telephone channel rides for more than 800 miles in the same frequency location, and dropping breaks up the pattern still further. Thus, for telephone, the switching links, which may number between 30 and 40 in a long system, are independently equalized.

The *B* equalizer contains manual and automatic sections, the latter being three regulating networks omitted in the *A* equalizer. Thus an *A* plus a *B* forms the final telephone equalization. The residue of five independently adjusted *AB* links must meet telephone requirements without frogging, and 30 to 40 links must meet these requirements with 800-mile frogging. This performance must continue to be met in the presence of a normal amount of spare-line switching. Also it is very important that the character of the residues be such as not to throw an undue burden on the television equalization.

In combined systems the more stringent requirements require the addition of further manual equalization to the switching section. The residue at the output of a *C* equalized switching section must be sufficiently small that a 4,000-mile circuit will continue to meet television transmission requirements in spite of a normal amount of spare line switching. Also the *C* equalizer in conjunction with the *AB* must permit several switching links to be connected in tandem without further line equalization. The *C* equalization also contains an adjustable delay section which in conjunction with a fixed delay equalizer in the office path provides delay equalization for the television part of the band, 3.6 to 8.5 megacycles. This adjustable section builds out the line to match the fixed unit.

The *A*-*B*-*C* pattern is for equalization of individual switching lines and these equalizers are adjusted on a single switching link basis. On the office side of the switches are system components that also require equalization. In the telephone system these include such equipment as office cabling and hybrid coils. Also there is an office flat loss of nearly 30 decibels. Thus the lines are, in effect, operated to give a 30-decibel gain while the offices give a 30-decibel loss. Aside from the flat losses there are distortion shapes but fortunately these are all well approximated by a $\sqrt{f}$ shape and a single manually adjustable $\sqrt{f}$ equalizer plus suitable choice of flat loss provides adequate telephone office equalization. This is referred to as the 0 equalizer. It is adjusted to cause the particular office to have a flat characteristic.

In the office circuits of combined systems are branching filters to separate the telephone and television bands. The 0 equalizer is reused in the telephone path. The television path includes the fixed delay equalizer and a manual gain equalizer to correct for office cables, hybrids, etc. After the tandem combination of several independently equalized lines and offices further equalization will be required. This will be accomplished by a multicontrol manual *D* equalizer having both gain and delay sections, inserted in the television-only path at approximately 400-mile intervals. These *D* equalizers will be used to form 800-mile pilot links which are independently equalized to a degree permitting putting any five such links in tandem to form a 4,000-mile circuit without further equalization.

Fixed Equalizers

The line amplifier can properly be considered as the first step of fixed equalization.[2] Also acting at this same level are artificial cable networks used to build out the repeater spacing to 4 miles±0.2 mile, as well as the basic equalizer of the amplifier to take up differences between cable types.[1] The final step of fixed equalization is the so-called design deviation equalizer associated with all *A* equalizers. This equalizer comes in two forms, one for use with sections containing 23 to 32 repeaters and one for use in sections of 10 to 22 repeaters. In those few cases of less than 10 repeaters the fixed equalizer is omitted.

The function of the design deviation equalizer is, first, to correct for the design error of the average repeater and, second, to recenter the manual (cosine) equalizers. Although the average repeater matches its 4 miles of cable to within ±0.12-decibels, this design error accumulates to over 3 decibels in 30 repeaters and, further, the shape is a difficult one to equalize. To keep the number of designs to a minimum, only two sizes are used, 19- and 28-repeaters, and the residue is corrected by the manual equalizers. This residue may be positive or negative depending on whether the fixed equalizer over- or under-compensates. Thus there is only a small tendency for these residues to accumulate in long systems. However, the inaccuracies of match between the fixed equalizer and the gain of the average repeater section tend to accumulate systematically and must therefore be kept small. This brings out the importance of statistical quality control of amplifier manufacture,[2] since any systematic shift in the amplifier gain characteristic will accumulate and may consume excessive manual equalizer range or may lead to excessive equalization errors. For example, a shift of only 0.05 decibel in the gain of the average amplifier would represent 1.5 decibels in 30 repeaters and 50.0 decibels in 1,000 amplifiers, and thereby becomes an extremely serious matter. Thus quality control of the amplifier is a vital part of the solving of the equalization problem.

The various effects that consume the range of the manual equalizers produce for some shapes an unsymmetrical consumption of range. If uncorrected this would produce larger range requirements in the manual equalizers as well as introducing new shapes to be equalized. The manual equalizer shapes are symmetrical and their errors cancel if equal amounts of positive and negative range occur in the system. Any systematic offset of a particular shape tends to introduce new shapes because of the manual equalizer networks themselves. By appropriate modification of the shape of the fixed equalizer it is possible to recenter the manual equalizers so that on the average the manual shapes are in the center of their range.

Dynamic Equalizers

General

Any long transmission system suffers from relatively rapid gain changes and in the *L3* coaxial system, as in many previous systems, the necessary corrections are performed automatically by pilot controlled regulators. Pilot tones are transmitted over the line at a reference level and, at appropriate points, regulators pick the pilots off the line, observe the deviation in pilot levels from the reference values, and restore the pilots to or very nearly to the reference values by the use of regulating networks.

There are fundamentally two causes of fast gain changes, time and temperature. Time produces vacuum tube aging and in spite of their feedback the line amplifiers change gain. In one week a 4,000-mile system is expected to change by as much as 5 decibels because of the aging of the 6,000 tubes or so in the transmission path. Because of different thermal characteristics, temperature affects cable and repeaters semiindependently. In a 4,000-mile system 1 week is expected to engender as much as an 8-decibel gain change by change in repeater temperature. Cable changes can exceed 100 decibels per week. Thus these effects must be corrected to a very high order of precision to maintain good television or telephone service.

These gain changes are not the entire story; when the gain changes in the band it also changes outside the band and usually by an even larger amount. Thus equalization of the in-band gain leaves out-band (above 8.5 megacycles) gain changes which produce in-band delay changes of several microseconds. Because of the difficulty of providing automatic delay equalization, a complicated process, it is necessary to equalize these delay changes on a gain basis, by at least partial correction for out-band gain changes. Further, since satisfactory pilot transmission is possible only within the band, these out-band changes must be predicted from the in-band gain changes. This effect in itself indicates the use of equalizers whose individual shapes are those produced by specific system causes producing a correlated change in many elements. Thus building the regulating networks to match the effects of the individual system causes, and matching to 10 or 12 megacycles rather than merely to 8.5 megacycles, permits simultaneous gain and delay equalization. Such a set of shapes is also more accurate because it is matched to the special ways in which the specific system can change rapidly.

In theory, the regulating networks could be built to match linear combinations of the cause shapes but there are two difficulties. First, not all of the cause shapes are known accurately or often even roughly at the introduction of a new system into the field. The mixtures of shapes cannot be determined without the missing ingredients. Second, a system is not a static design. Experience suggests improvements and thus occasions will arise where one will want to change the correction for a particular cause. If the networks represent mixtures of the causes, it necessitates changing all the networks. If specific networks match specific causes only, the appropriate network needs replacement.

The Computer

The use of cause shapes leads to a problem to which the computer provides the solution. These cause shapes are broad effects covering the entire band and more. Thus no one pilot is a measure of a specific cause. However, by a process equivalent to the solution of simultaneous equations, the pilots determine the amounts of an equal number of cause shapes that will restore the pilots to normal. Thus the computer translates pilot errors into shape errors and drives the appropriate regulating networks to obtain the corrections.

Let the equalizer shapes be given by functions of the form

$$S_n(f)=k_nF_n(f) \qquad (1)$$

where

n = the subscript number identifying the particular equalizer. The capital N is reserved for the total number of equalizers.

$F_n(f)$ = the equalizer shape (on a unit basis) as a function of the frequency f

k_n = the amount of shape introduced by adjustment, and may be positive or negative

$S_n(f)$ = the resultant shape put in the system by adjusting $F_n(f)$ by an amount k_n

The total shape introduced by all N equalizers is obviously

$$S_{\text{total}}(f)=\sum_{n=1}^{n=N}S_n(f)=\sum_{n=1}^{n=N}k_nF_n(f) \qquad (2)$$

To obtain a match of S_{total} to the given equalization error, S_{given}, at M frequencies from $m=1$ to $m=M$, requires that

$$S_{\text{total}}(f_m)=S_{\text{given}}(f_m) \qquad (3)$$

at each frequency from f_1 to f_M. Or, in terms of equation 2

$$S_{\text{given}}(f_m)=\sum_{n=1}^{n=N}k_nF_n(f_m) \qquad (4)$$

again, at each frequency from f_1 to f_M.

All of the important conclusions regarding the action of an equalization computer are implicit in the M equations indicated by equation 4.

Consider a case where there are three shapes. Let the information as to the difference between the system state and its desired state be determined by the deviation of three pilot levels which are observed to be δ_1, δ_2 and δ_3 at the pilot frequencies f_1, f_2 and f_3. The problem is to find the values of k_1, k_2 and k_3 that will give a match at these frequencies. This means that the following equations must be satisfied

$$S_1(f_1)+S_2(f_1)+S_3(f_1)=\delta_1 \qquad (5)$$

$$S_1(f_2)+S_2(f_2)+S_3(f_2)=\delta_2 \qquad (6)$$

$$S_1(f_3)+S_2(f_3)+S_3(f_3)=\delta_3 \qquad (7)$$

Thus

$$k_1F_1(f_1)+k_2F_2(f_1)+k_3F_3(f_1)=\delta_1 \qquad (8)$$

$$k_1F_1(f_2)+k_2F_2(f_2)+k_3F_3(f_2)=\delta_2 \qquad (9)$$

$$k_1F_1(f_3)+k_2F_2(f_3)+k_3F_3(f_3)=\delta_3 \qquad (10)$$

The solutions for k_1, k_2 and k_3 take the form

$$k_m=a\delta_1+b\delta_2+c\delta_3 \qquad (11)$$

where a, b, and c depend solely on the shapes $F_m(f)$.

Thus the values of the δ's may be decoded into the values of the equivalent k's by the simple process of multiplying each δ by some fraction that is a function of the equalizer shapes or, more precisely, by a fraction that is a function of the values of the various shapes at the frequencies f_1, f_2, etc.

The circuit of the computer is quite simple, consisting of about N^2 resistors for the control of N networks by the deviations that are measured at $M=N$ pilot frequencies. This simplicity is valuable for its own sake but, as previously noted, there is considerable value in the fact that substitution of new equalizer shapes requires only that changes be made in the values of some of the resistors.

Fig. 2 illustrates the principle by showing the computer circuit required for the previous example of three shapes for which information is given at three frequencies, f_1, f_2 and f_3. The 3 direct voltages representing the deviations δ_1, δ_2 and δ_3 are decoded by simply cross-connecting them to the three pairs of output terminals through fixed resistors chosen to satisfy the relationships of equations 8, 9, and 10. The output voltages will be proportional to the desired equalizer correction quantities k_1, k_2 and k_3.

In general, the calculation of some of these resistors will give negative values. Thus it will generally be necessary to require that the direct voltages representing the errors δ_1, δ_2, etc., be available in both polarities. Alternately, the errors can be provided in only one polarity, and the circuits to which the computer outputs connect can provide the push-pull circuit. This latter course has been used in the *L3* regulators as indicated in Fig. 2.

The effect of using the computer is as follows. If one pilot changes, all regulating networks correct, but in such proportions and polarities as to produce no gain change at any pilot frequency except at the one originally disturbed. If all pilots deviate in proportions corresponding to one of the shapes, no network corrects except the one corresponding to the original pattern of pilot deviation.

If conventional regulator circuits were used with particular pilots assigned to

(b) SHUNT TYPE

Fig. 5 (right). Block diagram of Bode regulating network

particular shapes, the interactions would be intolerable. Thus the computer removes the restrictions on the choice of shapes imposed by regulator interactions. In turn, this permits freedom in changing shapes as system data improve. It is important to provide the initial equalizers before adequate data on the system are available. As the system grows in length, the equalization must be improved but the data improve also. Thus there is an economic benefit in providing a flexible equalization plan which allows the earliest possible commercial use of the system.

Dynamic Equalizer Requirements

Because temperature and aging variations can result in both gain and loss variation with respect to the average transmission, the equalizers must be capable of inserting both loss and gain compensation. Also, it is extremely desirable that equal gain and loss settings for the equalizer result in symmetrical transmission characteristics with respect to the average. In a long transmission system, some of the sections will insert excess gain and others, excess loss. If the equalizer gain and loss characteristics are symmetrical, the residue will be related to the system deviation and some constant part of the equalizer characteristics. If this is not the case, the residues can produce new variable deviation shapes and thereby lead to increased complexity in following the stages of equalization.

As previously described, equalization of both gain and loss is required and this implies active equalizers. Although a number of methods were studied, noise and modulation requirements led the *L3* system to the so-called block-of-gain–block-of-loss design. The equalizers are passive networks and, to realize both gain and loss adjustability, the normal setting loss must at least equal the total amount of gain adjustment. The various equalizers are combined into two to four groups whose loss is compensated by corresponding numbers of flat gain amplifiers.[2]

The required number of such blocks of loss and gain depends upon the amount of system gain variation to be equalized. The determination of the shapes and magnitudes of system variations is an important system problem. Extensive study is necessary to evaluate the system sensitivity to various changes; the determination of the magnitude of these causes, such as temperature variation, aging rates, etc., and the determination of maintenance intervals that provide an economic balance between maintenance expense and system cost. These must be studied in detail to provide the equalizer designer with shape and range data for his dynamic equalizer designs. The equalization characteristics and maximum ranges for the two most important dynamic equalizers aside from cable temperature, namely, repeater temperature T and vacuum tube aging $\mu\beta$ are shown in Fig. 3. To maintain satisfactory transmission during a maintenance interval, the dynamic equalizers must be able to match any characteristic within the maximum ranges and throughout the transmission band to within 1 to 2 per cent. As noted previously, the necessity for simultaneous delay equalization requires the dynamic networks also to make at least an approximate correction in the out-band region. This is shown in Fig. 4.

The control element in the equalizers is a thermistor whose available resistance range is 30 to 1,050 ohms. ($\sqrt{f}$ of line amplifier,[2] 125 to 2,000 ohms). Thus the regulation ranges shown in Fig. 3 are realized, using this one variable resistance element in each equalizer.

The following is a summary of the dynamic equalizer requirements:

1. To provide symmetry in regulation characteristic.
2. To minimize flat loss.
3. To match prescribed gain variation to a high degree of accuracy within transmission band.
4. To provide satisfactory equalization of in-band delay distortion caused by out-band gain change.
5. Each equalizer to be controlled by a single variable resistance element.
6. The desired performance to be realized in 75-ohm circuits.

Dynamic Equalizer Design

The design used is the structure commonly known as the Bode Regulator,[3,4] and shown in block schematic form in Fig. 5. An ideal regulating network would insert a deviation characteristic

$$\theta = f(R_T) f(\omega) \text{ decibels} \qquad (12)$$

Such a network would yield a given shape independent of setting and thus would have linearity as well as symmetry. Actually the Bode network has symmetry but only approximates linearity. As shown, it may be designed to insert a variable impedance either in series or in shunt with the line. When using only one control element it is not a constant resistance structure and must be operated between terminations of the design value. The choice of series or shunt configuration

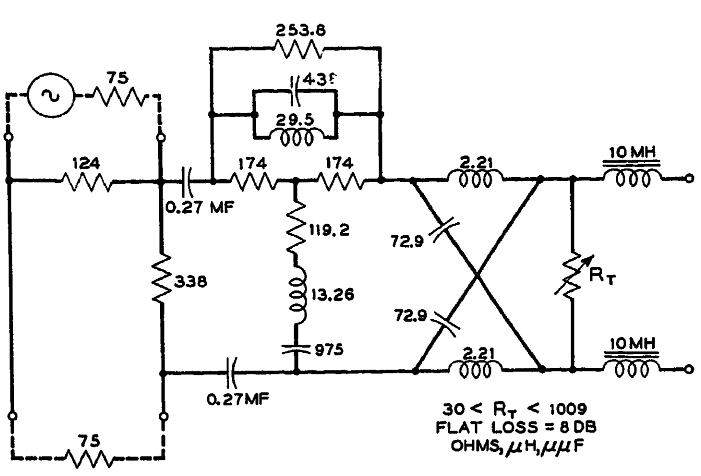

Fig. 6 (left). Circuit of the regulating network for repeater temperature

was governed for *L3* by the fact that very low thermistor resistance would require excessive d-c currents from the regulators. For a 75-ohm circuit and this thermistor limitation the series regulator provides lower normal-setting loss.

The insertion gain for the series regulator may be written as

$$\theta=\theta_N+2\,\text{arc tanh}\left[\frac{R_1-R}{R_1+R}\rho\epsilon^{-2\Gamma}\right] \qquad (13)$$

where

θ_N = the normal setting flat loss as given by

$$\alpha_N=20\log\frac{R_1}{R}\text{ decibels} \qquad (14)$$

R_1 is the symmetry-determining resistor and is in parallel with the input terminals of the shaping network for the purpose of limiting the maximum value of the series impedance. The equation of symmetry may be expressed as

$$R_1^2=\left(1+\frac{R_1}{2R_0}\right)R^2 \qquad (15)$$

where

R = the image impedance of the shaping network. The thermistor has this value at its normal setting.

R_0 = the impedance of the circuit in which the regulator is inserted, in this case, 75 ohms.

ρ = the reflection factor between the network impedance R and the thermistor impedance, R_T, and is given by

$$\rho=\frac{R_T-R}{R_T+R} \qquad (16)$$

Γ is the image transfer constant of the shaping network and may be expressed as

$$\Gamma=\sigma+i\psi \qquad (17)$$

Returning to equation 13 for the insertion gain, if the series expansion of the arc tangent is used and the higher order terms discarded, the insertion transfer constant becomes

$$\theta=\alpha_N+K\epsilon^{-2\sigma}\cos 2\psi+iK\epsilon^{-2\sigma}\sin 2\psi \qquad (18)$$

or the insertion loss may be expressed

$$\alpha=\alpha_N+Ke^{-2\sigma}\cos 2\psi\text{ nepers} \qquad (19)$$

$$K=2\frac{R_1-R}{R_1+R}\,\rho \qquad (20)$$

This approximation is valid for design purposes if the regulation range is not too large or the accuracy required too great. For example, omission of the cubed term in the repeater temperature design produced a maximum error of 0.014 decibel and in the tube aging design, 0.007 decibel.

From this expression it is seen that both real and imaginary parts of the image transfer constant for the shaping network enter into the insertion loss expression, and thus the relationship between the desired insertion loss and the shaping network makes the design process difficult. At this stage in the design considerable art and ingenuity are required to continue the design efficiently. The approach taken depends upon the regulation characteristic desired and the experience of the designer. Since both loss and phase are involved, familiarity with loss-phase relations is important. After a design has been blocked out, repeated modifications of the network parameters usually indicate the adequacy of the configuration chosen. Usually several sections in tandem are required in the shaping network to obtain precision of match, and some of these will very likely be all pass sections to control the phase ψ independently of the real part σ. It may be noted that at cross-over points in the regulation characteristic, that is, zero regulation, either the phase ψ must be 45 degrees, or odd multiples thereof, or the loss σ must be infinite. Usually the phase is made the controlling term in both zero and peak regulation points.

The designs presently used on the *L3* system for the repeater temperature- and tube-aging equalizer are shown in schematic form in Figs. 6 and 7. The 0.27-microfarad capacitors and the 10-millihenry inductors are employed to supply the d-c heating current to the thermistor. The shunt resistors placed across the 75-ohm line, in one case 124 ohms, and in the other, 133.4 ohms, are used to make the left side driving point impedance equal 75 ohms at normal setting of the thermistor. These networks are used in cascade with the manually adjusted, constant-resistance networks, and it seemed desirable that the impedance characteristic of the dynamic equalizers be relatively good at one pair of terminals.

MANUAL GAIN EQUALIZERS

One of the more difficult equalization design choices is the selection of shapes

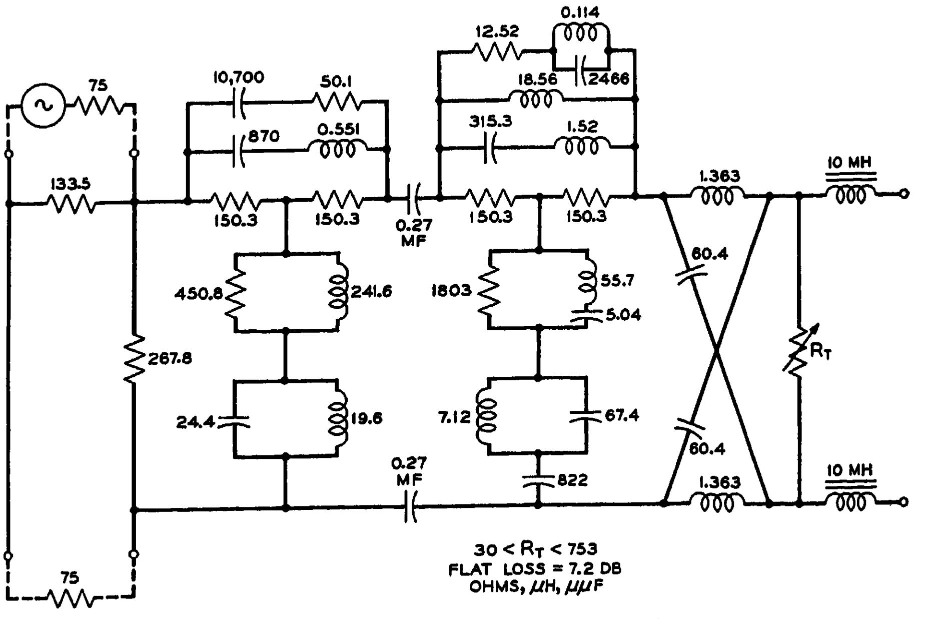

Fig. 7. Circuit of the regulating network for tube aging

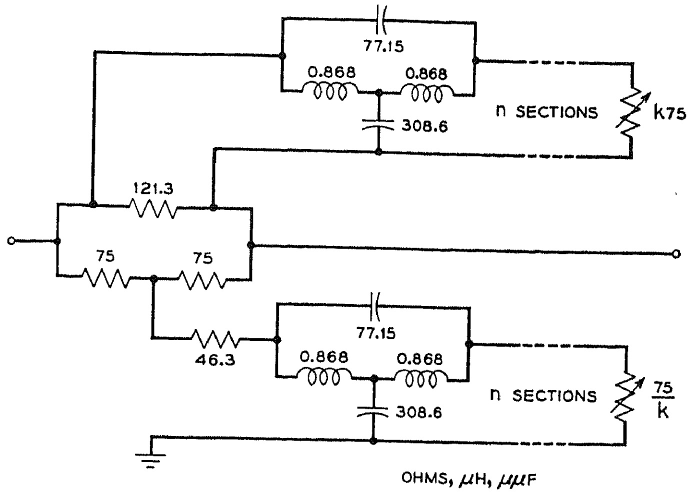

Fig. 8. Circuit of a cosine equalizer without dissipation correction

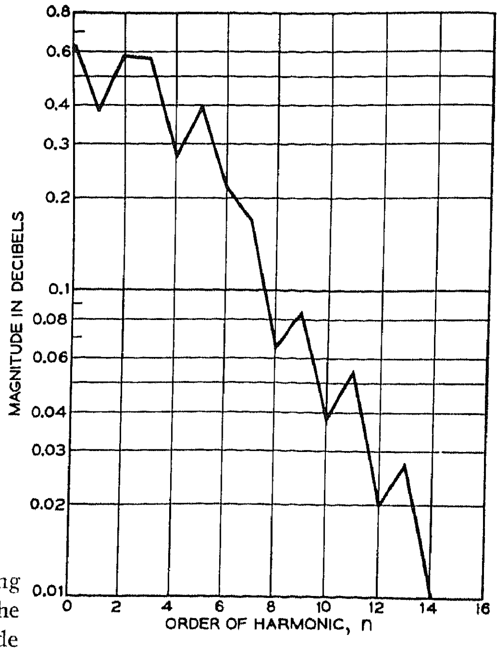

Fig. 9 (right). Range required for various cosine terms because of expected manufacturing variations of eight critical elements. The magnitudes are based on RSS addition in 25 repeaters

for the manual equalizers. In the *L1* system some of the shapes used were so-called bump shapes. This type of shape reduces the amount of shape overlap and thereby tends to reduce the adjustment problem when conventional adjustment methods are used. For the *L3* system many types of shapes and circuits were carefully studied. The computational concepts of equalizer adjustment resulted in the consideration of shapes that would otherwise be impractical.

The shapes finally chosen for *L3* are cosine shapes. Any continuous function may be matched over a 180-degree interval by a Fourier series of cosines only. By making the 180-degree interval the frequency range from 0 to 8.5 megacycles, the cosines are those of frequency and can match any gain characteristic if enough terms are used. These cosine equalizers have the following advantages:

1. The range required for any term is less than the total shape to be matched, usually less than half.
2. The residues are always higher harmonics and therefore easily matched if necessary.
3. The controls are easily adjusted, using methods to be described.
4. If better equalization is required at any point, the existing equalizer is retained and additional harmonic terms are added.
5 The major portions of the equalizers require only one value of inductance and two values of capacitance to form the delay lines used in the networks. This also assists in the application of distribution requirements.
6. The manual equalization can be designed with a minimum of information about the system characteristics.
7. The equalization is on a least-square error basis rather than minimum peak error.

The networks used to realize these cosine shapes are constant resistance Bode regulating networks[3] employing second-degree all-pass sections.[5] If the phase of the all-pass sections were made proportional to frequency, the transmission performance within the frequency band of interest would be that provided by a Fourier series composed of cosine terms in the variable ω. By appropriate choice of the all-pass sections, the frequency-phase relationship can be warped to give greater weighting to a specified portion of the frequency range. The phase of the all-pass section is given by

$$\psi = 2\cot^{-1}\left[\frac{b}{2}\left(\frac{fc}{f} - \frac{f}{fc}\right)\right] \tag{21}$$

Small b and high f_c weights the low frequencies, the linear-phase case $b=1.2$, f_c-$=10.2$ megacycles gives uniform weighting and large b weights the high frequencies. A$b=2, f_c=13.75$ megacycles, was selected for the *L3* equalizers because it weights somewhat the higher frequencies where the television signal is transmitted and, also, each unbalanced bridge *T* network section can be constructed with only four elements, two like inductors and two capacitors. For b's smaller than 2, coupling between the two like coils is required, and for b's larger than 2, an additional element is required.

The all-pass networks are designed on a 75-ohm impedance level and thus the flat, normal setting of each regulating network is 4.18 decibels maximum. The 75-ohm level makes the series and shunt networks identical and also facilitates manufacturing testing. A special dual variable resistor is used as the control element. It has a resistance range of 15 to 375 ohms and provides a regulation range of ±2.78 decibels maximum.

A schematic of this network is shown in Fig. 8. In the case of the O harmonic, flat gain, the phase sections are omitted. For the nth harmonic term, n sections are used in both the series and shunt arms. The constant resistance structure permits the complete equalizer to be formed by a cascade of such networks without interaction effects. This provides a loss characteristic given by

$$\text{Loss} = k_0 + k_1 \cos 2\psi + k_2 \cos 4\psi + k_3 \cos 6\psi + \dots \tag{22}$$

where ψ is the phase of the individual all-pass section which goes from 0 to 90 degrees between 0 and 8.5 megacycles. The k's are adjusted by means of the dual adjustable resistors. Note that each term of the series is represented by a corresponding equalizer.

Application of this mop-up polynomial to a larger number of *L3* deviation characteristics indicates that considerably less range than the maximum ±2.78 decibels will be required for most of the cosine terms. Fig. 9 illustrates this convergence of the series for the eight largest amplifier manufacturing variations. This and other studies show that after the first three harmonics the range may be reduced. It can be shown,[6] for example, that if the system gain deviations are finite within the range of interest, or interval of convergence, the coefficients of the approximating polynomial will decrease in magnitude linearly proportional to the number of the terms, that is, the nth coefficient will be smaller than some constant divided by n. If the deviation characteristics are continuous and hence have finite first derivatives, then the coefficients of the approximating polynomial will decrease as the square of the number of the term. If all derivatives are finite the coefficients will decrease exponentially. This last case is

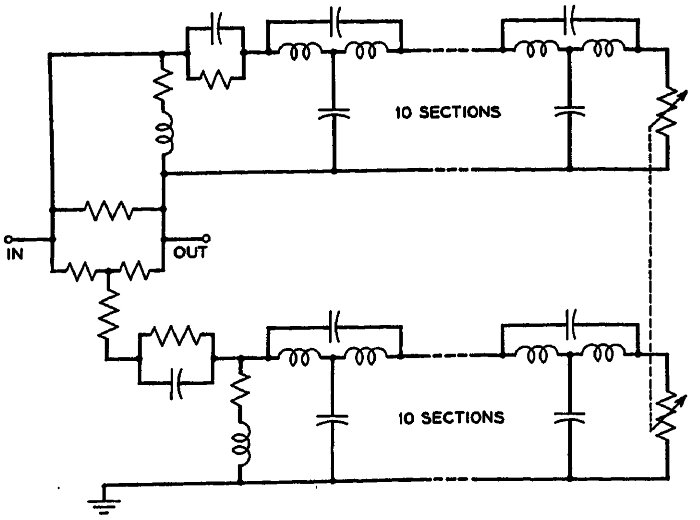

Fig. 10. Cosine equalizer circuit (tenth harmonic) showing dissipation and range corrections

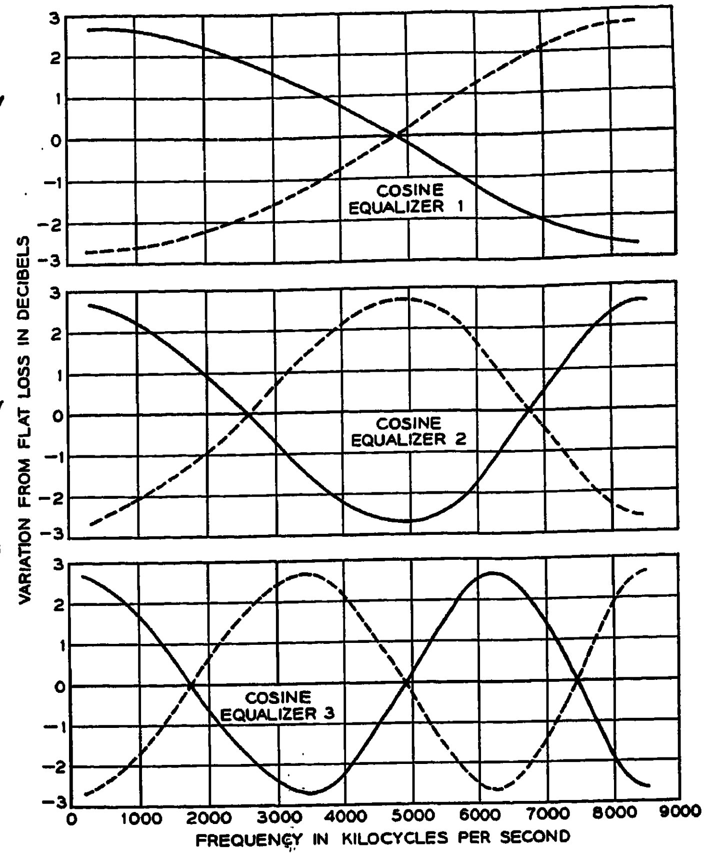

Fig. 11 (right). Shapes introduced by the first three cosine harmonics

believed to describe the convergence for at least most of the *L3* system shapes. Thus for the high order terms that require little range it is possible to reduce the flat loss of the networks.

To reduce the flat loss without changes in the 75-ohm impedance level of the phase sections or in the dual adjustable resistors, pads are inserted between the resistance T and the all-pass sections. In this manner the loss could be reduced to 2.2 decibels for ±0.5-decibel range if it were not for the dissipation in the all-pass sections. This dissipation occurs because of the coils, and it increases with frequency. It tends to produce a reduced cosine amplitude in the high-frequency part of the band. To correct this effect, the pad is actually made an equalizer section whose loss change with frequency corrects for the dissipation in the coils, thereby yielding cosine amplitudes independent of frequency. The price of this is an increase in the flat loss to 3.4 decibels for a ±0.5-decibel range. The circuit of the term 10 network is shown in Fig. 10. The range of this term is ±0.5 decibel as is that of all higher terms (to 24). Terms 1, 2, 3 have full range, 4, 5, 6 have 1.5 decibels and 7, 8, 9 have 1 decibel. The 0 term, flat gain, is also 1 decibel because additional flat shape is obtainable from the flat amplifiers used to make up for the equalizer loss.

The shapes provided by the first three terms are shown in Fig. 11. Note that the shapes are cosines of a warped frequency variable and that on this warped scale the shapes are orthogonal. In all, 24 such harmonics plus flat gain are used in the high-frequency line for combined systems. For all-telephone use only 14 harmonics plus flat gain are required. Fig. 12 shows the construction of one of the cosine networks. These are mounted in groups of five as indicated in Fig. 13. The fixed equalizer and regulating networks are mounted to the rear of the cosine assembly.

HARMONIC ADJUSTING SET

To make a mental harmonic analysis of a complicated gain characteristic is difficult, if not impossible. Therefore a special cosine-equalizer adjusting set has been developed which eliminates trial and error from the adjustment process and which leads to a unique optimum adjustment. Broadly, the method consists of using sweep-frequency methods to convert the gain-frequency characteristic into a repetitive voltage-time function. Gain cosines on the warped frequency scale are converted to voltage cosines of time and the audio harmonic-spectrum components are individual measures of equalizer control-setting errors. By the adjustment process these audio harmonics are removed, thus yielding a gain characteristic describable in terms of only the higher cosine components not available to the equalization operator.

The operation can be explained using the block diagram shown in Fig. 14. The sweep oscillator sends a constant-level, variable frequency, over the line and through the cosine equalizer to the detector. The output of the detector on terminals X—X at any instant is a measure of the transmission of the line and equalizer at the frequency being sent by the sweep oscillator at that instant. The sweep frequency starts at zero and sweeps to 8.5 megacycles in a period t_1. As shown in Fig. 15 the frequency-time relationship is warped to correct for the warping of the equalizer phase-frequency relationship. The sweep oscillator therefore scans at a linear rate in cosine degrees versus time. Upon reaching 8.5 megacycles the sweep reverses and returns to zero. If the cosine shapes were linear cosines of frequency the sweep would be a triangular wave.

Assume that the line is perfectly equalized except that the first harmonic term is misadjusted. As the sweep goes from 0 to 8.5 megacycles, the voltage at X—X follows the first harmonic curve of Fig. 16 from 0 to t_1. When the oscillator scans back to 0, the voltage at X—X follows the first harmonic curve from t_1 to $2t_1$. Then the cycle repeats. The voltage at X—X thus becomes a pure cosine of time oscillation of frequency, $1/2t_1$. Although the equalizer shapes are actually cosine on a decibel basis rather than an amplitude basis, this has little practical effect because for small deviations the two are nearly identical.

If, instead of a first harmonic error, the second or third cosine harmonic is misadjusted, the voltage at X—X will

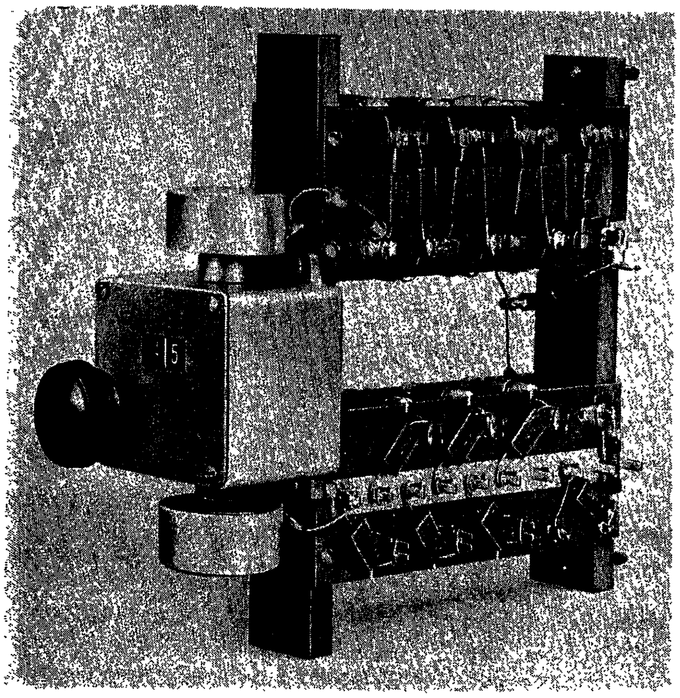

Fig. 12. View of a single cosine term network

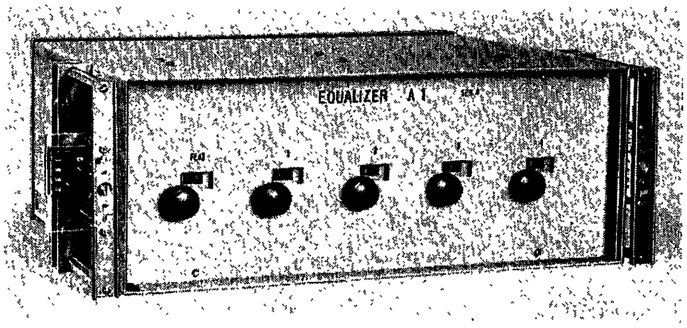

Fig. 13. Assembly of five cosine terms. Five of these assemblies are required by a C equalizer, a B equalizer requires three, and an A, two

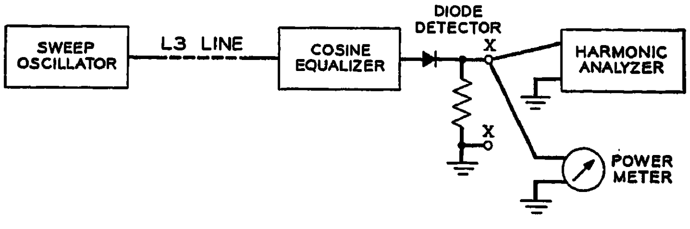

Fig. 14. Block diagram showing the method used to adjust cosine of other orthogonal equalizers

follow the appropriate curve of Fig. 16. The d-c component measures the zero harmonic but in practice only the a-c components are measured and the flat gain is set as a final step to make the pilot levels correct at the line output. If it takes 0.01 second for the oscillator to scan up and back, the first harmonic produces 100 cycles per second (cps) output from the detector. The second harmonic equalizer produces 200 cps, the third 300 cps, etc. Therefore at the output of the detector there exists a set of audio-frequency harmonics whose amplitudes are a measure of the equalization error of the setting of the cosine controls of corresponding periodicity.

These harmonics can be separated by convention filtering techniques, for example, by an audio-tuned detector or harmonic analyzer as noted on Fig. 14. The analyzer can be tuned to 100 cps and the first harmonic control rotated to remove the 100-cps component. Then, tuning to 200 cps, the second control is operated, etc. This null method is similar to bridge balancing and may be instrumented to similar high precision. After all of the harmonics corresponding to equalizer controls have been removed, the process is complete and the equalization residue must be composed solely of those terms not provided by the equalizer.

The harmonic analyzer method requires tuning or switching and thus, to simplify the method still further, the actual field equipment uses a power indicator in place of the analyzer as noted on Fig. 14. Given a spectrum of signals of differing frequencies, removing any one of these reduces the total power. Therefore the entire spectrum may be applied to a power indicator and the reading reduced by adjusting the various equalizer controls. In practice this process is assisted by filtering out the high harmonics which cannot be equalized. This reduces the total power and increases the ease of reading the meter. While the method has been demonstrated, with the use of an ordinary 60-cps wattmeter, an electronic wattmeter is used in the field equipment.

While the receiver unit can be quite simple, the sweep oscillator is complicated by such things as circuits to control the warping and to hold the sweep limits accurately In practice the sweep is between 0.3 and 8.5 megacycles and is at a 37-cps rate. Further there are six pilots on the system and, although the dynamic regulators at the adjusting point are paralyzed during the cosine adjustment, the pilots to intermediate regulators must not be disturbed. Thus the sweep frequency is shifted very rapidly through the pilots. When the sweep frequency gets within about 25 kc of a pilot, it is shifted suddenly to the other side of the pilot frequency. This materially reduces the interference to the pilot without producing transients in the receiver.

While other methods of cosine equalizer adjustment were tested and found to work satisfactorily, the method described was found to be superior. In addition, removal of the filtering permits the power meter to read the rms equalization error and thus the equalization operator can determine the quality of the job and observe whether the state of the line is satisfactory. Also, the power method is usable with saw-tooth as well as triangular scanning and, further, works on any set of orthogonal gain or delay shapes. Thus the basic equipment is readily adaptable to the adjustment of *D* equalizers if their gain and delay shapes are orthogonal.

Field Performance

In the *L3* system the function of the dynamic equalizers is solely to prevent

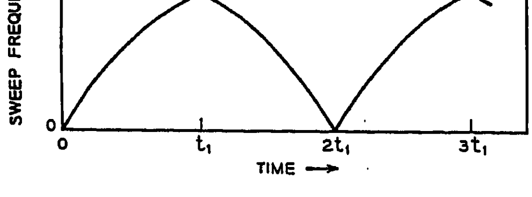

Fig. 15. Method of scanning the system gain characteristic to convert cosines of frequency into cosines of time

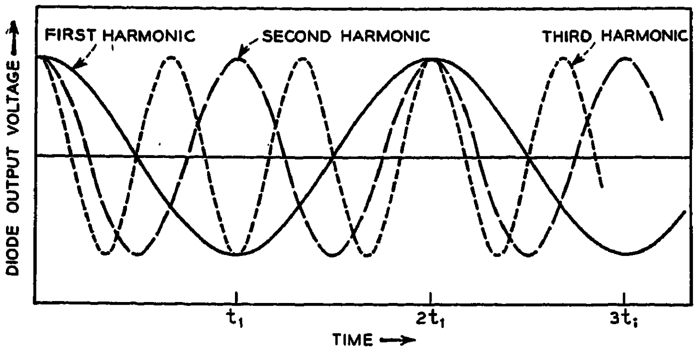

Fig. 16. Detector output produced by scanning the first three cosine shapes

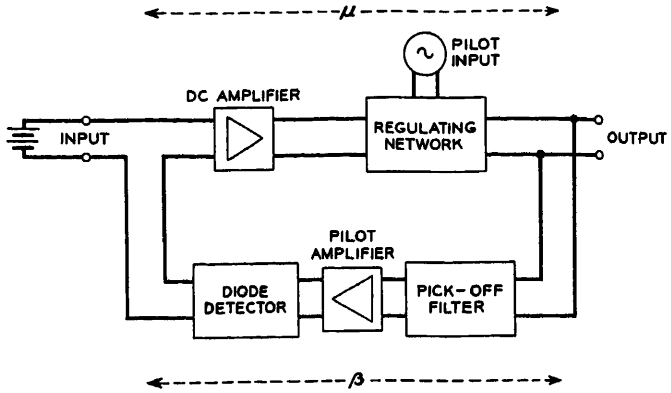

Fig. 18. Block diagram of regulator showing the feedback structure

excessive deterioration of the transmission characteristic from one manual line-up to the next. During the manual adjustment, the dynamic networks are held at that point in their range, which minimizes the probability of running out of range in either direction before the next manual line-up. This is done to hold the dynamic ranges to a minimum. Thus the transmission errors remaining at the completion of a manual line-up occur chiefly because of the fixed and manual equalizers. It should be noted however that, when the dynamic regulators are restored to operation after the manual adjustment, any residues will be seized by the dynamics and regulated.

As yet, the field experience with the regulation system and the dynamic shape performance is quite limited. However, the stability of the regulation system and the action of the computer have been well established. It would appear that the major remaining regulation system problem will be the determination of the cause shapes to the accuracy required for long television systems.

Somewhat more experience has been gained with the cosine equalizers. Using a fixed equalizer design based on ten line amplifiers from initial production, a 100-mile circuit, equalized and using 15-cosine terms, yields the residues plotted in Fig. 17. The ripple at the extreme high end of the band is largely caused by the failure of the fixed equalizer to match the very sharp cut-off of the line between 8.35 and 8.50 megacycles. Since telephone channels are not transmitted in this region, and since television requirements are less severe at such high video frequencies 4.2 megacycles, this effect does not limit the transmission quality. Also note that long television circuits, over 400 miles, will have a further level of equalization *D*. There is no visible impairment of ordinary television pictures as a result of insertion of the 200-mile *L3* line in their path. With critical types of test patterns there is a slight effect. While there are problems yet to be solved before 4,000-mile transmission can be obtained, the 200-mile performance is most encouraging.

In the past the adjustment of manual equalizers has often been a difficult and time-consuming task. The cosine adjusting set described previously appears to have made sizable inroads on the solution of this problem. The adjustment of the 25 controls used for television is a 3-minute job. The fact that the equalization operator is working toward a unique solution and therefore knows when he is done appears to be of material value.

Regulation

General

The *L3* regulation system is in many respects similar to the *L1* system. However, the design of a stable regulation system for over 500 regulators in tandem introduces unusual problems. Also the accuracy and stability requirements have led to the use of novel regulator circuits including, for example, an analogue computer as an element of the system.

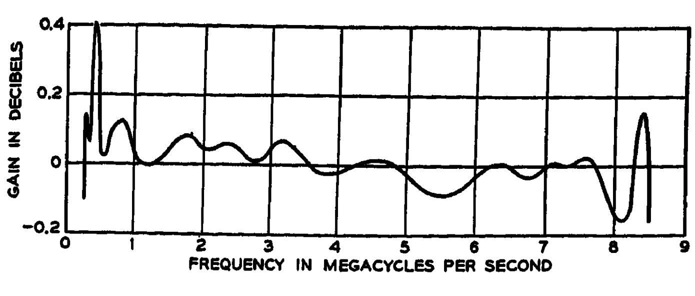

Fig. 17. Final gain characteristic of a 100-mile L3 line after equalization with 15 cosine shapes

Six pilots are used, of 308, 556, 2,064, 3,096, 7,266, and 8,320 kc. These frequencies were selected as the best for measuring the anticipated system changes as restricted by where signal allocations would permit their insertion. For example, the wide gap from 3,096 to 7,266 is largely caused by the difficulty of inserting and removing pilots in the lower video frequencies of television signals. The problem of finding a satisfactory set of pilot levels and frequencies which will at the same time be compatible with the desired signals is an important part of the system design problem.[1]

The change of 4-mile cable loss with temperature is so large (±1.2 decibels) that regulation is required at each repeater. It takes 3 months or more for the cable loss to change 2 decibels but the normal line maintenance interval is of this order. A gain error of this magnitude could not be allowed to accumulate over very many repeaters before the signal-to-noise performance of the system would collapse. Other effects such as vacuum-tube aging and repeater-temperature changes can be allowed to accumulate over as many as 30 repeaters before regulation. These facts dictate the location of regulators in the system. At each repeater there is a line regulator controlling a square-root-of-frequency-shape regulating network. Then at equalizing points and dropping points office regulators correct for the remaining effects.

Chain Action

Pilot-controlled dynamic regulators derive much of their advantage from the fact that they prevent gain changes from accumulating from repeater to repeater. This advantage is one manifestation of what might be called the chain action of a series of regulators. There is however the corresponding disadvantage of disturbances of the pilot causing the accumulation of unwanted gain fluctua-

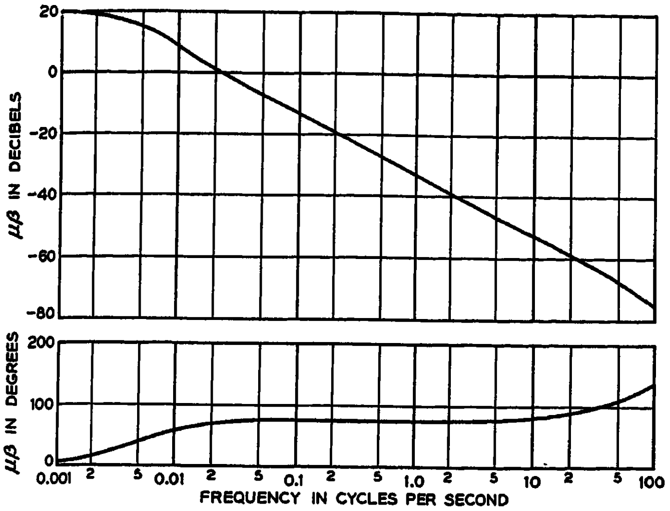

Fig. 19. Loop gain characteristic for the line regulator

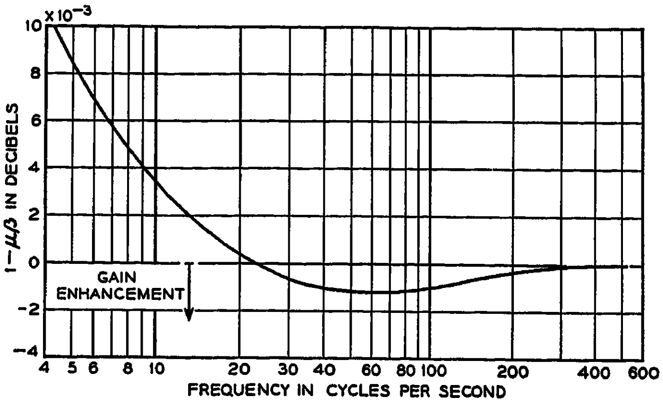

Fig. 20. Feedback characteristic for the line regulator showing the gain enhancement effect

tions. In previous systems this disadvantage has been aggravated by positive envelope feedback (1-$\mu\beta$ less than one) at some frequencies, an effect known as gain enhancement. In the *L3* system the gain enhancement is nearly negligible but the television requirements still require careful control of certain types of gain fluctuations.

The advantage noted can easily be demonstrated by a simple example. Consider a chain of regulators each having 20-decibel envelope feedback so that pilot level changes are reduced by 10 to 1. Now consider what happens if each cable section changes loss by 1 decibel. Table I illustrates the action.

The first regulator inserts a gain change of 0.9 decibel in response to the 1.-decibel input change. The 0.1 decibel-error increases the input change to the second regulator to 1.1 decibel and it therefore inserts a 0.99-decibel correction. The total resultant error of 0.11 decibel adds to the change at the third regulator input, etc. Simply stated, the error of the first regulator rides through the system forcing the other regulators to make an accurate correction. Actually, of course, this statement is oversimplified, but it should be clear that the effective feedback of the regulation system is the (voltage) sum of the feedbacks of the individual regulators. Thus 100 regulators each having 20 decibels of feedback tend to act as a single regulator having 60 decibels of feedback. The rigorous treatment of these effects will be developed later.

Table I. Example of Chain Action

Regulator Number	Input Pilot Change	Inserted Correction	Output Pilot Change
1	1 decibel	0.9 decibel	0.1 decibel
2	1.1	0.99	0.11
3	1.11	0.999	0.111
4	1.111	0.9999	0.1111

Fig. 18 shows a block diagram of a regulator in a form intended to indicate the feedback structure. The feedback loop includes a pilot pickoff filter, amplifier, and rectifier. This converts the output pilot level into a direct voltage. The battery, or actual input signal for the circuit, represents the equivalent of the desired pilot output level. The signal applied to the d-c amplifier is a d-c signal representing the error in pilot level. This d-c signal is, in effect, converted back to a pilot level by the action of the regulating network and its modulation of the input pilot level. Thus changes in input pilot level are equivalent to gain changes in the μ circuit of the feedback structure and are resisted by feedback action just as in any other feedback amplifier. It is also valuable to note the respective μ and β roles played by the various components since the stability requirements, etc., then become clear. For example, the pilot amplifier is in the Beta circuit and therefore must be a highly stable device. On the other hand, the d-c amplifier is in the μ circuit and its drifts are reduced by the loop feedback.

Having developed the feedback nature of the structure and the roles of the components, the conventional feedback art can be used for the analysis of the individual regulator. It can be shown that

$$\frac{\text{Change in output pilot level}}{\text{Change in input pilot level}}=\frac{1}{1-\mu\beta} \qquad (23)$$

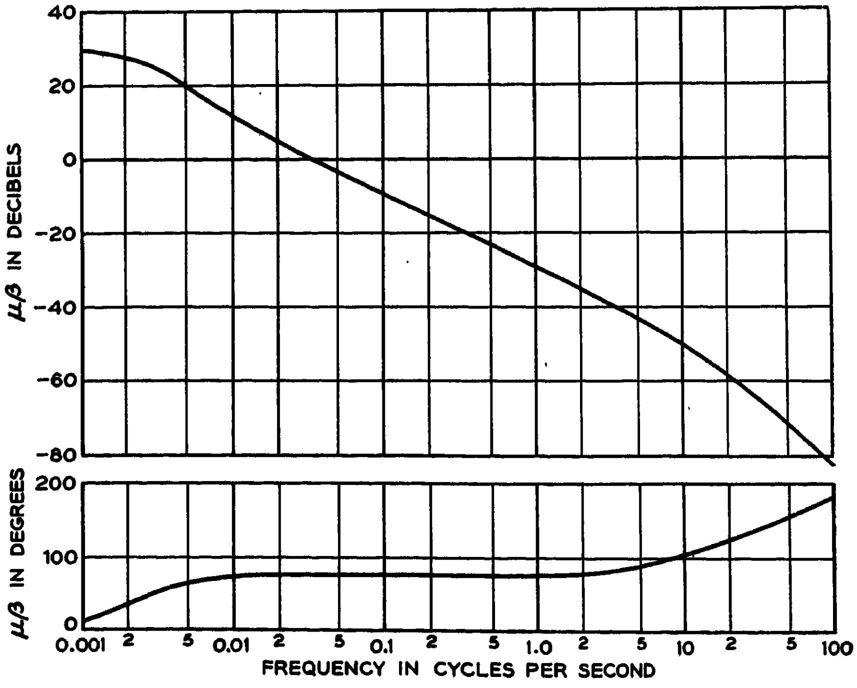

Fig. 21. Loop gain characteristic for office regulators

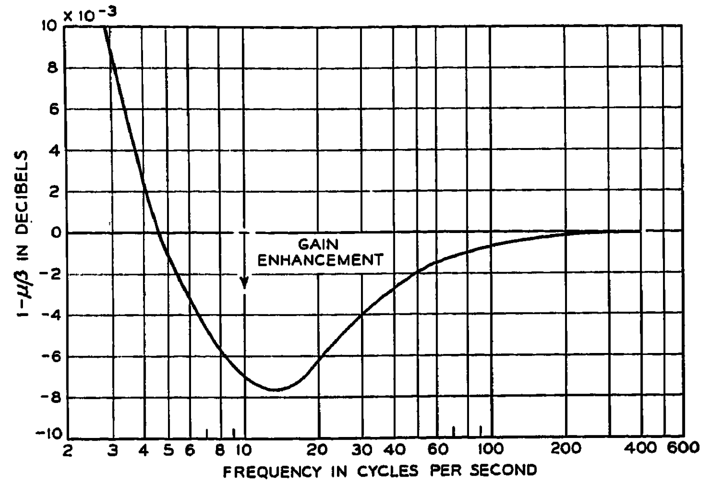

Fig. 22. Feedback characteristic for office regulators showing the gain enhancement effect

$$\frac{\text{System gain change to pilot frequency}}{\text{Change in input pilot level}}=\frac{\mu\beta}{1-\mu\beta} \qquad (24)$$

This result is not very surprising but it can be used to determine the performance of the following regulators in a chain. Many different cases must be considered. Sometimes the pilot levels change because of an effect distributed all along the system. In other cases the change occurs only at the input to the line. Sometimes the pilot level changes are the important effect. In other cases the importance resides in the gain change to the signals. In all cases the results may be complicated by the fact that $\mu\beta$ is, in general, a complex number and thus phase as well as amplitude is important.

Adopting the notation

ΔP_{in} = fractional change in input pilot at nth regulator
ΔP_{on} = fractional change in output pilot at nth regulator
ΔG_n = gain change to signals (near pilot frequency) of nth regulator
ΔG_t = total system gain change $=\Sigma G_n$

one can readily show the following:

Case I. Disturbance of pilot only at input to system:

$$\frac{\Delta P_{on}}{\Delta P_{i1}}=\left[\frac{1}{1-\mu\beta}\right]^n \qquad (25)$$

$$\frac{\Delta G_n}{\Delta P_{i1}}=\mu\beta\left[\frac{1}{1-\mu\beta}\right]^n \qquad (26)$$

$$\frac{\Delta G_T}{\Delta P i_1}=\left[\frac{1}{1-\mu\beta}\right]^n-1 \qquad (27)$$

Case 2. Equal gain change in each regulating section:

ΔP_c = fractional gain change of section

$$\frac{\Delta P_{on}}{\Delta P_c}=\frac{1}{\mu\beta}\left[\left(\frac{1}{1-\mu\beta}\right)^n-1\right] \qquad (28)$$

$$\frac{\Delta G_n}{\Delta P_c}=\left[\left(\frac{1}{1-\mu\beta}\right)^n-1\right] \qquad (29)$$

$$\frac{\Delta G_T}{\Delta P_c}=\left\{\frac{1}{\mu\beta}\left[\left(\frac{1}{1-\mu\beta}\right)^n-1\right]-n\right\} \qquad (30)$$

As an example of the application of these equations, consider the effect of television-induced compression. The presence of the television signal reduces the gain of the line amplifier. The effect is small but cumulative. In the absence of regulator action it merely compresses the television signal slightly and makes a negligible change in the contrast rendering of the picture. However the regulators observe a gain change to the pilots and attempt a correction. The very rapid changes are ignored but 60 cps, for example, is partially corrected. This introduces a 60-cps gain change which will lag the picture and therefore must meet 60-cps bar pattern requirements. This problem is solved by keeping the regulator response low at 60 cps.

For $\mu\beta$ of −70 decibels, 90 degrees, at 60 cps a chain of 700 regulators will insert a total gain change approximately one-tenth that of the total compression. If the $\mu\beta$ were allowed to approach −50 decibels, the total gain change would equal the compression, and certain types of pictures would be degraded.

This example brings out one of the important facts: When designing regulators for long systems the $\mu\beta$ characteristic must be carefully controlled to losses much higher than is customary in amplifier design. In a conventional feed-back-amplifier loop-cutoff the magnitude and phase of $\mu\beta$ are no longer of much interest after the magnitude drops below −10 decibels. In *L3* regulators the loop is of vital interest to losses of the order of 70 decibels. This is of course largely due to the fact that the chain action increases the effective system feedback by nearly 60 decibels. Thus the over-all system is similar to conventional amplifier practice. Loop gain $\mu\beta$ and feedback 1-$\mu\beta$ characteristics for the line and office regulators are shown in Figs. 19, 20, 21, and 22. Note that 1,000 line regulators in tandem

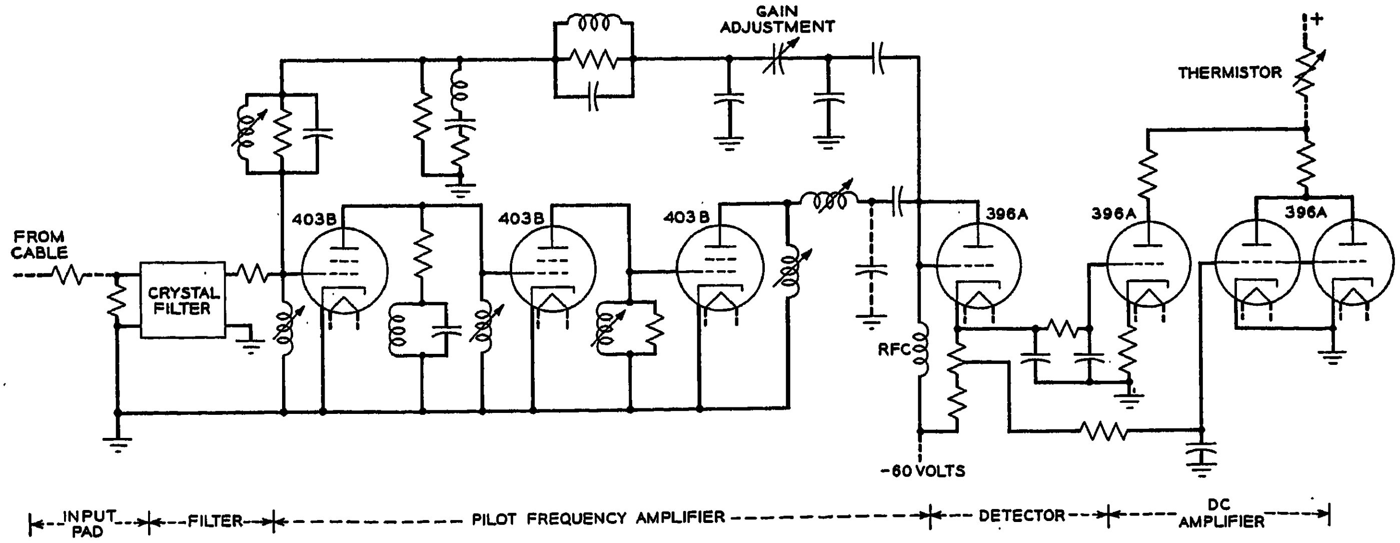

Fig. 23. Simplified schematic of the line dynamic regulator showing the signal circuits

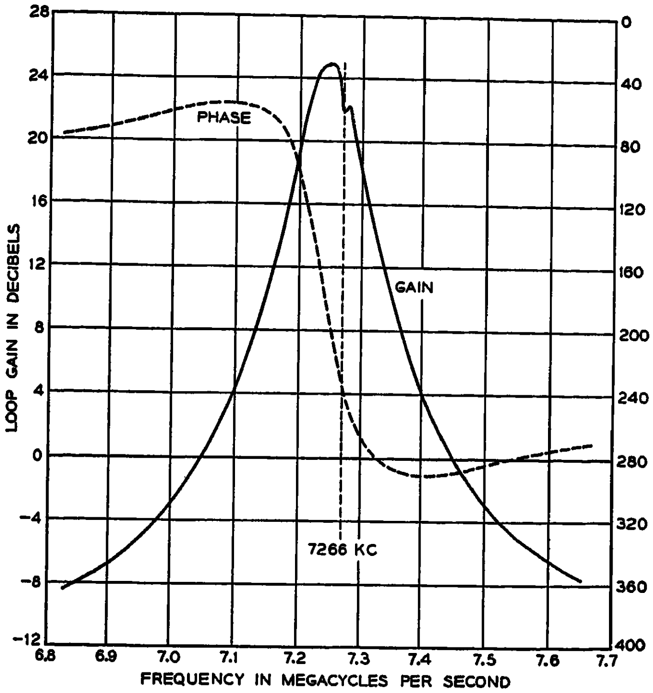

Fig. 24. Loop gain and phase of the 7,266-kc pilot amplifier

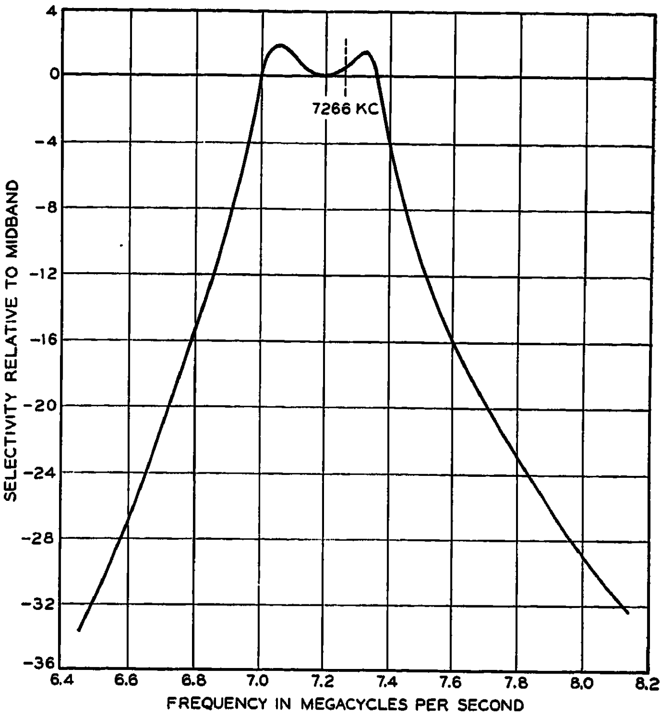

Fig. 25. Regulator selectivity without the crystal filter

give an over-all gain enhancement of only 1.2 decibels. This would be even less it it were not for a 100-cps roll-off in the d-c amplifier to reduce noise. One hundred office regulators give an 0.8-decibel gain enhancement even with their 20-cycles per second roll-off.

The Dynamic Line Regulator

As indicated in Fig. 23, a crystal filter is used to pick the pilot off the line in the presence of the other signals. The filter impedance goes through resonances caused by the crystals, and introduces a gain characteristic on the line that cannot, in practice, be equalized. Thus it is necessary to hide the filter from the line with loss. To hold the transmission distortion of signals to 0.15 decibel with 500 regulators, or 0.0003 decibel per regulator, requires a voltage loss of 23 decibels with the filter impedance changing by large factors from its nominal 25,000-ohm level. The power loss bridging on the 37.5-ohm (75 into 75) circuit is, of course, much greater.

The 7,266-kc pilot level at the line amplifier output is 16 decibels below 1 milliwatt into 75 ohms. The filter and pad loss totals 24 decibels (voltage ratio) leaving an available pilot signal of about 0.002 volt in 25,000 ohms. To solve drift and stability problems in the d-c circuits, the pilot is converted to a d-c voltage of 60 volts. This requires an amplifier-rectifier of a 90-decibel voltage gain, stable with time and temperature.

As indicated in Fig. 23, the amplifier consists of three stages using *403B* (long-life *6AK5*) tubes. Feedback is taken shunt-shunt, output plate to input grid, to stabilize the input and output tuned circuits against Q changes with temperature. The regulators are designed to operate from −20 to +160 degrees Fahrenheit and the amplifier gain does not change by more than 0.3 decibel over this range.

The β circuit contains an adjustable condenser divider for field gain adjustment. The tuned sections are heavily damped to get temperature stability, but nevertheless compensate for the cutoffs of the μ circuit. The resultant loop gain and phase are shown in Fig. 24. It will be noted that the phase margin against singing is rather large, being about 60 degrees. This permits tube replacement without retuning as well as protection against tuning changes caused by time and temperature.

Grid-plate capacity places a limit on the permissible interstage impedance for stability. Thus the output circuit between the third stage and the rectifier is operated as a reactive transformer giving a voltage step-up of 2. This increases the output voltage obtainable without raising the impedance facing the third tube above 12,500 ohms.

About 16 decibels of local d-c feedback is used on each stage to stabilize the cathode current. Insofar as transconductance depends upon cathode current, transconductance changes are reduced. This is of material value in further reducing the effects of vacuum tube aging.

Fig. 25 shows the external gain of the 7,266 kc amplifier without the crystal filter. The filter response is shown in Fig. 26. The relatively wide 3-decibel bandwidth of ±1.5 kc is to reduce the contribution of the filter to the gain enhancement problem. The large rejections to frequencies further removed from the pilot prevents operation of the regulator by signals other than the pilot. Also note that for very strong signals such as the television carrier at 4,139 kc the filter is aided by the amplifier selectivity.

The diode detector is also designed to reduce the effects of interference. The time constant of the detector is made short so that the output will follow envelope fluctuations up to about 40 kc. Thus the output of the detector in the presence of an interfering signal within 40 kc of the pilot becomes the power sum rather than the voltage sum of the two signals. This is readily understood from Fig. 27. Here E_p is the normal rectified pilot. In the presence of the interfering signal E_i a diode detector with a long time constant will deliver a d-c output of E_p+E_i, and thus give voltage addition between the pilot and the interference. With a fast time constant the detector output can follow the nearly sinusoidal envelope variations and the d-c level is changed only slightly. The a-c component may be suppressed by the cutoff of the d-c amplifier but, even if this is not the case, the thermistor being a thermal device responds to the total power rather than to

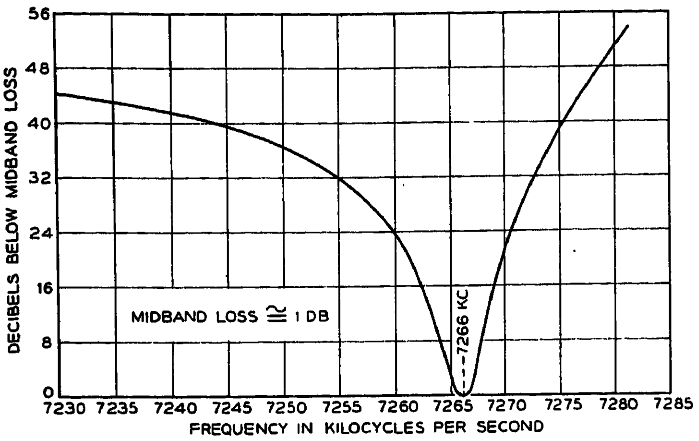

Fig. 26. Loss characteristic of the 7,266-kc crystal filter

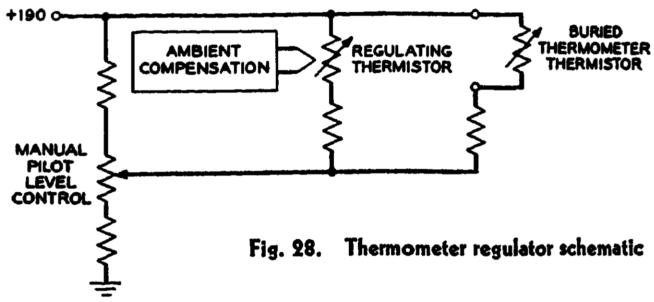

Fig. 28. Thermometer regulator schematic

the peak amplitude. Thus the diode time constant is made long enough to hold over a few cycles of the pilot frequency but short enough to follow the important interference difference-frequencies.

The d-c amplifier consists of three triode sections essentially in parallel but with the biases and feedbacks differing for the purpose of providing a voltage-current characteristic that corrects for sensitivity changes of the thermistor with operating current. This maintains the over-all loop feedback relatively constant over the 1-to-20-milliampere current range. The thermistor is directly heated by the plate current of the d-c amplifier to obtain single time-constant performance of the thermistor. The thermistor transmission, plate current changes as an input and pilot level as an output, is the main frequency characteristic of the regulator loop.

Line Thermometer Regulators

It is possible to dilute the regulation system with less costly, less accurate regulators without undue loss of over-all performance. This is accomplished by the use of thermometer regulators at alternate regulating points. These consist of a thermometer thermistor buried in the ground, electrically in parallel with the regulating thermistor. The circuit is quite simple as indicated by Fig. 28. Ground temperature changes vary the resistance of the thermometer thermistor, thereby changing the current and resistance of the regulating thermistor. The manual control is used to effect initial alignment of the system. The regulating sensitivity is designed to overcompensate slightly for cable loss changes to ease the burden somewhat on the following dynamic regulator.

Ambient Temperature Compensation

Both types of line regulators require the assistance of ambient temperature compensation of the regulating thermistor. Conventional compensation circuits would hold the thermistor resistance within about 20 per cent but this would produce an error of 1 decibel at a thermometer regulator, and about 0.2 decibel at a dynamic unit. Thus an improved compensation scheme was required which would connect only to an indirect heater, the bead itself being already controlled by d-c heating from the regulators.

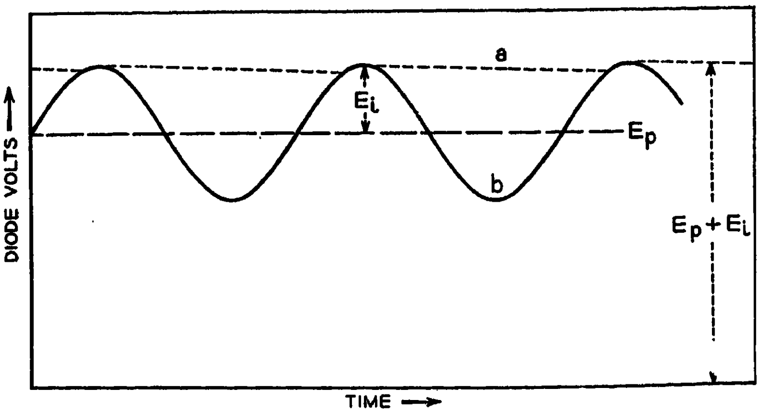

Fig. 27. Diode detector output in presence of interference E_L. Ep is normal pilot signal. Curve a obtains with long time-constant, b with short time-constant

The compensation circuit adopted is shown in Fig. 29. A second thermistor called the compensating thermistor is mounted in the same glass envelope as the regulating thermistor. The fixed resistor R_1 and the compensating thermistor together with transformer T form a bridge which is made a feedback path for tuned amplifier A. The feedback is positive when the compensating unit is cold so oscillation begins at the tuning frequency 4 kc. These oscillations heat the thermistor and tend to bring the bridge into balance. The bridge stabilizes at a small unbalance just sufficiently to yield a loop gain of unity. The level of oscillation is forced to that value which will maintain this small unbalance. Any changes in balance thereafter produce deviations of loop gain from unity and the oscillation level increases or decreases until the equilibrium is re-established. Thus the level of oscillation changes with temperature but the resistance of the compensating thermistor is held constant.

Because the circuit supplies nearly perfect temperature compensation to the unit in the bridge, a suitable fraction of the oscillator power may be fed to the heater of the regulating thermistor to achieve very close compensation of it. Resistors R_2 and R_3 are adjusted in manufacture to correct for slight differences between the two thermistors. Note that the compensating thermistor is provided with an unused heater to match the thermal properties of the two units.

The amplifier consists of a single *403B* tube with 20-decibel d-c feedback for current (and transconductance) stabilization. This feedback is vital because it also introduces a slight compressive action in the amplification of the tube and thereby prevents rapid wild changes in oscillation level. Bypassed d-c feedback on an amplifier causes d-c second-order distortion to increase the bias and thereby reduce the transconductance. This effect overcomes the tendency of the third-order distortion to create expansion in this particular tube. If the thermistor response were fast compared to the reciprocal of the bandwidth of the amplifier,

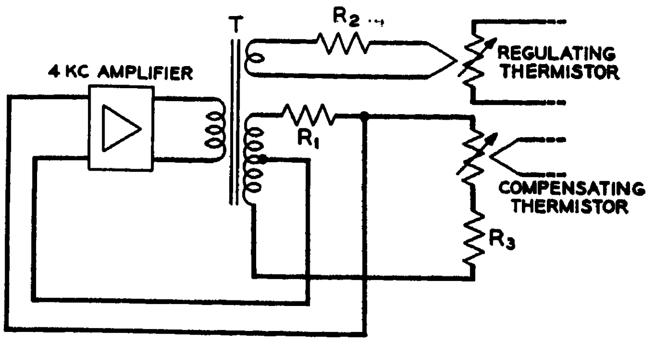

Fig. 29. Ambient temperature compensation oscillator

the compression action would be unnecessary. However, with an audio-frequency amplifier and a 100-second thermistor, the compression is essential in preventing motorboating.

The field limits on the compensation of the regulating thermistor over the range −20 to +160 degrees Fahrenheit are ±3 per cent in resistance from all causes including manufacture and aging. Specific units can be adjusted to yield compensation to a fraction of 1 per cent.

OFFICE REGULATORS

The *L3* office regulators are similar in design to the line regulator. However the office regulators operate their regulating networks via an analogue computer, and of course a variety of pilot frequencies are employed. Because signals are dropped at offices, higher loop feedbacks are used to insure accurate equalization. However, temperature variations are smaller and conventional thermistor ambient temperature compensation is adequate. Also the smaller number of office regulators permits less isolating loss for nick effect (except for the 7,266-kc office regulator).

The lower levels of the pilots (except 7,266) are compensated by reduced isolation loss, 12 instead of 23 db, and reduced detector level, 40 instead of 60 volts. Thus the gain required is not substantially increased. The pilot amplifier design is therefore different primarily in the tuning frequency and in the simplifications in the lower frequency units permitted by the higher permissible interstage impedances.

The diode detector feeds a cathode follower to obtain the d-c voltage representing the deviation of the pilot from its assigned value as a low-impedance source to feed the computer. The appropriate signals from the computer are fed to the d-c amplifier. This amplifier differs from that used in the line regulators in that:

1. A push-pull input is provided.
2. Higher gain is required to produce greater feedback, 30 decibels, and overcome computer losses, 5 decibels.
3. The output stage supplies somewhat higher currents, 1 to 30 milliamperes, except 7,266, because the regulating networks use a lower impedance thermistor.

OTHER REGULAR FUNCTIONS

The regulators are also used for alarm and pilot indicator functions. At line dynamic regulators the current flowing through the diode detector load resistance is also passed through a relay to obtain an alarm indication whenever the pilot level deviates from normal by more than 3 decibels. At offices, similar arrangements operating on a 2-decibel error are provided both for alarm and switch initiation purposes. If any pilot deviates by 2 decibels the service switches to the spare line. In addition, fast switch initiation is obtained from the 7,266-kc regulator by direct connection to the detector output. This arrangement avoids the time delay of the relay operation. For pilot level indication the diode load current is read on appropriate meters. This avoids the necessity of providing separate pilot level indicators and is possible because of the reliability and stability of the regulator amplifiers.

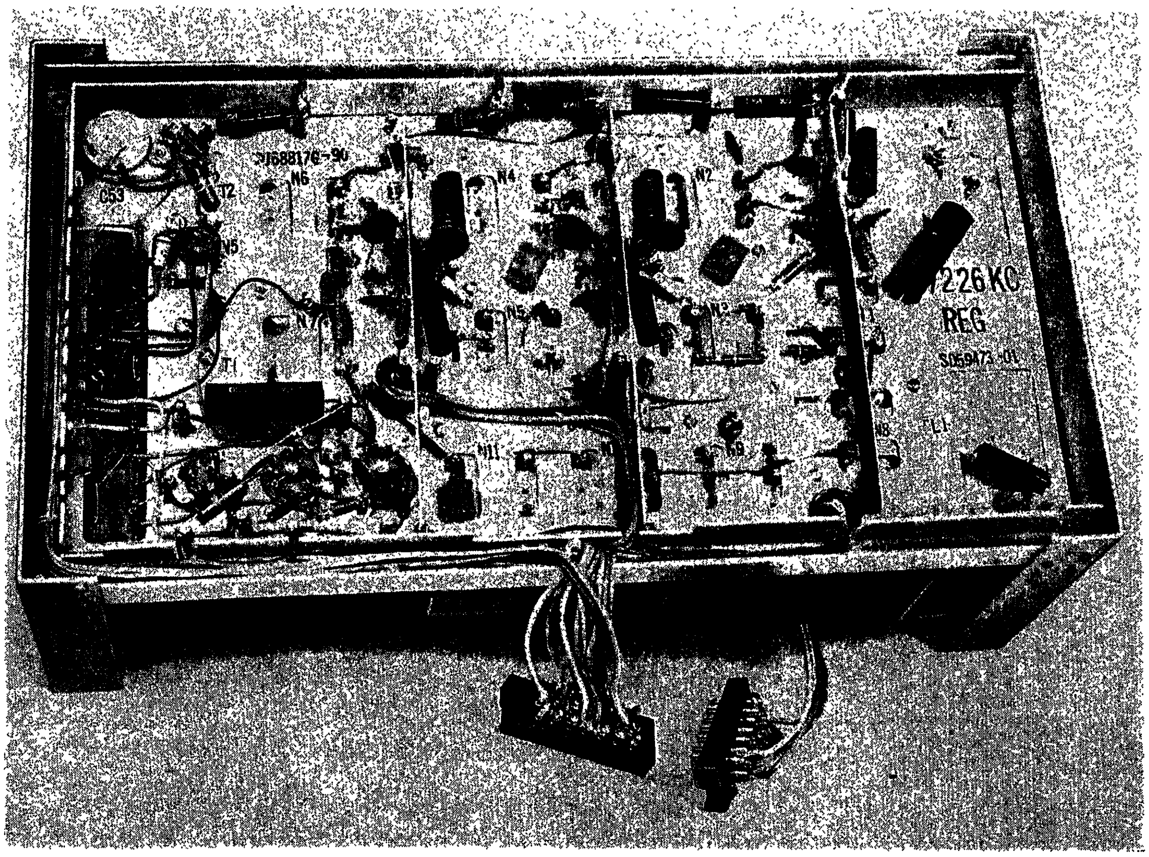

Fig. 30. Line dynamic regulator as seen from wiring side

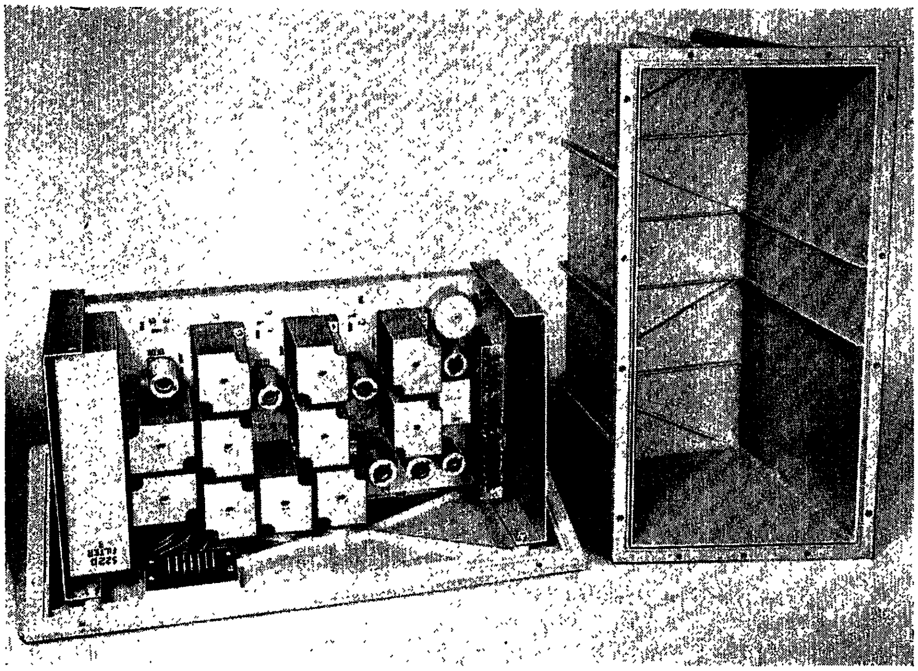

Fig. 31. Top view of line dynamic regulator showing case

MECHANICAL FEATURES

Figs. 30 and 31 are views of a regulator seen from the wiring side and from the top respectively. The chassis consists of two steel end plates riveted to steel angles, with a punched copper plate screwed to this structure. The salient feature of this type of construction is that one universal punched plate can be used for all the regulators, including the thermometer regulator, any individual regulator being fabricated by mounting the necessary component cans and vacuum tube sockets on it. Power wiring and all leads that are not critical as to length or placement can be run in the wiring trough around the edge of the chassis shown in Fig. 30. This eliminates the necessity of lacing the wires into a cable, a significant saving in production effort.

The component cases are shown in Fig. 31. They are zinc die castings and contain network elements assembled on stypol forms which fit inside the cans. One universal case accommodates 64 different combinations of elements required by the various regulators. The necessary wiring of the individual cases may be completed before assembly on the regulator chassis. This feature also saves production effort.

The whole chassis is mounted inside a die-cast zinc housing, and all power and test leads are brought into the regulator through airtight connections. The two parts of the housing when assembled together are made airtight by a rubber gasket which fits into the slot around their inner edges. The general construction features and size of the regulator assembly can best be understood by inspection of the photographs.

Electron-Ion Recombination at Low Pressures

SIDNEY BOROWITZ
NONMEMBER AIEE

AS THE name implies, the recombination process describes the situation in which a neutral gas is ionized and the electrons and ions which are thus formed recombine to form neutral atoms and molecules again. Its importance in the field of gas discharge derives from the fact that this process constitutes one of the important agencies whereby charges disappear from a discharge. From the point of view of physics in general, it is one of the fundamental processes which all the artillery of classical and modern physics must be capable of explaining.

The pioneering work in this field has been done by Kenty[1] and Mohler,[2,3] and has been summarized by Loeb.[4] Since these experiments were performed, and especially in recent years, a considerable amount of literature has appeared relating to the recombination process. It is not the purpose of this paper to summarize all of this work, but rather to discuss those experiments which seem to shed most light on the nature of the fundamental process involved.

The recombination process is described mathematically by noting that the rate of disappearance of electrons per unit volume must be proportional to the product of the density of electrons and the density of positive ions. If, as is almost always the case, the density of electrons and positive ions are equal, we have

$$\frac{dn}{dt} = -\alpha n^2 \qquad (1)$$

Paper 53-263, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 3, 1952; made available for printing April 20, 1953.

where

n = the number of electrons per cubic centimeter
α = the recombination coefficient, which measures the rate at which the process proceeds

If α is not a function of n, equation 1 can be integrated to give

$$\left(\frac{1}{n}-\frac{1}{n_0}\right)=\alpha t \qquad (2)$$

where n_0 is the electron density at time $t=0$. It is seen, therefore, that the problem of the measurement of the recombination coefficient resolves itself to a problem of the measurement of n as a function of t. Basically, all of these experiments are performed in identical ways. Some gas in a discharge tube is ionized and the electron density is measured in the tube as a function of the time after the power has been turned off. Of course, in the interpretation of the experiment, one must be certain that the electrons are really lost by recombination. This means that some account must be taken of the electron loss due to processes which compete with recombination. For example, n may change, due to diffusion to the walls or attachment to neutral atoms, molecules, or impurities. The experiments which are most easily interpreted are those done with gases which do not attach electrons very readily and are of high purity; also, the experiments should be either at pressures high enough so that wall diffusion does not contribute significantly to electron loss, or an evaluation of the contribution of wall diffusion should be possible.

If one considers a collision of a positive ion and an electron, it is clear that recombination cannot take place if there are no other forces acting on this system. For if one examines the collision in the coordinate system in which the center of gravity is at rest before recombination, one sees that the center of gravity must remain at rest after the collision; that is, in order to conserve momentum, the neutral atom or molecule must be at rest in this system. However, if this were true, since the forces between these particles are attractive, and the potential energy of the combined system is less than that of the particles when they are separated, we could not satisfy both the conservation of energy and momentum laws. Therefore, in order for recombination to take place, a third body must be present to absorb some additional energy, if the two basic conservation laws are to be satisfied simultaneously. This third body can be only some complex of the neutral gas, the container walls, another charged particle, or a light quantum. A knowledge of the properties of the recombination coefficient allows us to discriminate between these possibilities.

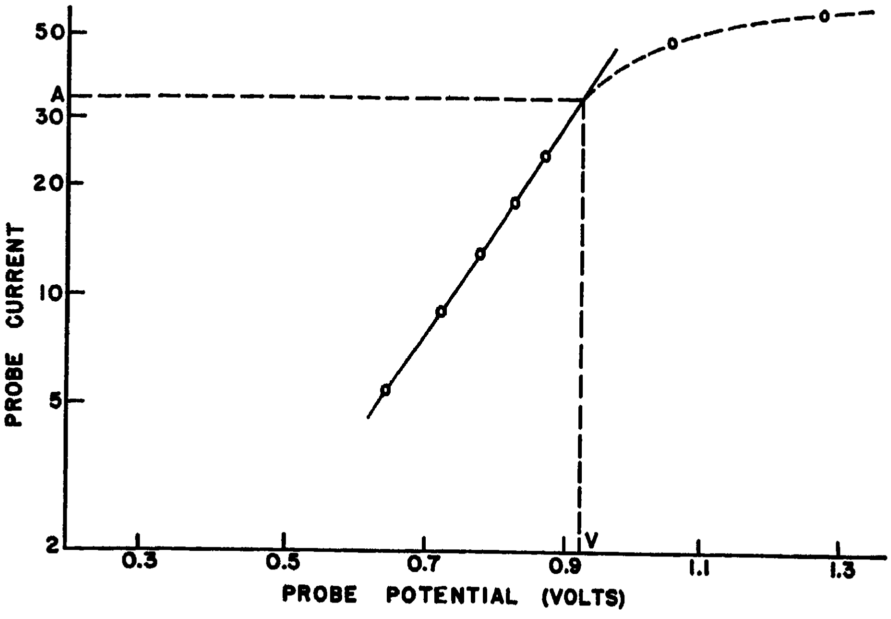

Fig. 1. Probe characteristics

For example, if α is pressure independent, the third body cannot be a neutral constituent of the discharge. If one finds experimentally that equation 2 is satisfied, we can be reasonably certain of two things:

1. That diffusion to the walls is an insignificant process;
2. That the third body is not another charged particle.

For if the former were the case, dn/dt would be proportional to n, and if the latter were true, it would be proportional to n^4; in neither case would the reciprocal of the electron density be proportional to t. If one could decide that a photon must be the third body, either by the elimination of any other possibility, or by demonstrating in some other way that every recombination leads to the emission of light, one has still another way of measuring the recombination coefficient, namely by measuring the light intensity as a function of the time after the discharge has been turned off.

With this introduction, we turn now to a discussion of the various measurements of α as a function of temperature and pressure for various gases.

Basic Experimental Techniques

As indicated in the preceding section, the measurement of the recombination coefficient involves basically a measurement of the electron density in a decaying plasma as a function of the time, or possibly it involves a light-intensity measurement. In this section, we shall discuss briefly the various possibilities for these measurements.

One of the oldest methods of electron charge-density measurement still in use today is an outgrowth of an idea of Langmuir.[5,6] If one inserts a small probe into the discharge, the current to the probe i_p is given by the formula

$$i_p=A\epsilon^{\frac{v-V}{kT}} \qquad (3)$$

where

$$A=Nea\frac{ekT}{2\pi m}$$

where

N = electron density
a = area of the probe
v = potential of probe
V = potential of plasma
e,m = charge and mass of electron
T = gas temperature
k = Boltzman's constant

Equation 3 is valid when $0<v-V<<1$ and the velocity distribution of the charged particles is Maxwellian. If one plots the logarithm of the probe current, as a function of the probe potential, the resulting curve is a straight line as long as our hypothesis holds. When $v=V$, the curve will cease to be linear, and the plot of log i_p versus V will show a change in curvature, as shown in Fig. 1. The slope of the straight-line portion will be a measure of the gas temperature, and the value of i_p at which the curve becomes nonlinear, gives the value for A. Thus a determination of the characteristics of the

Fig. 2. Block diagram of the apparatus. The oscilloscope sweep is synchronized to start as the magnetron is turned off

Langmuir probe enables one, in principle, to obtain a simultaneous measurement of the temperature and the density.

Another method of measuring the electron density is based on the fact that the conductivity and, consequently, the resonant frequency of a cavity depends on the electron density of the material in it. In fact, Slater[7] has shown that under certain conditions, which are always met in the experiments

$$\Delta\lambda = C\lambda^2 n_a \tag{4}$$

where

λ = wave length corresponding to the resonant frequency of the cavity when it is empty
$\Delta\lambda$ = the change in wave length due to the presence of electrons
n_a = average electron density in the cavity

The coefficient C can be calculated and depends on the geometrical configuration of the system and on the distribution of charges and electric field within the cavity. A typical experimental arrangement using this method is illustrated in Fig. 2.[8]

A tunable continuous-wave signal generator produces a small signal (less than 1 millowatt) which is fed through a slotted line into the cavity containing the bottle which has the decaying plasma. The frequency of the generator differs from the natural frequency of the cavity by a few megacycles. A point on the line can be determined[8] such that a probe placed there will have a minimum amount of power flowing into it when the resonant frequency of the cavity is equal to the frequency of the signal generator. The oscilloscope is triggered to go on when the discharge goes off. By noting at what time one gets a minimum in the oscilloscope trace one can determine at what time the resonant frequency of the cavity was the same as the generator frequency. Thus, since the change of frequency (or wave length) is proportional to the electron density with a known proportionality constant, one point on the electron density versus time curve can be obtained. Other points can be found by varying the frequency of the signal generator.

Kenty[1] was the first to demonstrate that light intensity measurements can be used to measure the recombination coefficient. He noted that for several milliseconds after the power was turned off, light was emitted from the discharge tube. In his experiment with argon he made a spectroscopic analysis of this afterglow, and found lines of the atomic argon spectrum originating from a level 0.084 volt below the ionization level. This is 15.6 volts above the ground state and 3.9 volts above the metastable level. Yet, when a small amount of sodium was added, the D-lines of sodium were not excited. He concluded therefore, that since but 2 volts are required to excite the sodium D-lines, the spectrum of argon could not be due to the acceleration of the electrons by space charge, but is associated with the recombination process.

The methods that have been used to measure the light intensity of the afterglow are standard. Mohler[2,3] used a photometer and a standard source, Holt[10] and Biondi and Holstein[11] a photomultiplier tube with an amplifier.

Results for the Recombination Coefficient

The three most important measurements of α involving the use of the Langmuir probe have been made by Kenty,[1] Mohler,[2,3] and Sayers.[12] Kenty's measurements were made in argon at a pressure of 0.8 millimeters of mercury and at a temperature of 3100 degrees Kelvin. Those of Mohler were made in mercury at a pressure of 0.27 millimeters of mercury and at temperatures ranging from 1560 to 2300 degrees Kelvin, and in caesium at a pressure of 0.11 millimeters of mercury and at temperatures of 1200 to 1360 degrees Kelvin. The values obtained by them varied from 2×10^{-10} to 4×10^{-10} cubic centimeters per second. In both these sets of measurements, the correction for diffusion was determined by measurements of the density of the current to the walls and by then computing the recombination coefficient from the equation

$$\frac{4}{3}\pi r^3 \frac{\Delta n}{\Delta t} = \frac{4\pi r^2}{e} i_w + \frac{4}{3}\pi r^3 \alpha n^2 \tag{5}$$

where

n = particle density
i_w = current to the wall
r = radius of the spherical container used
e = electronic charge.

In addition, Mohler[2,3] attempted to measure the light intensity from the afterglow.

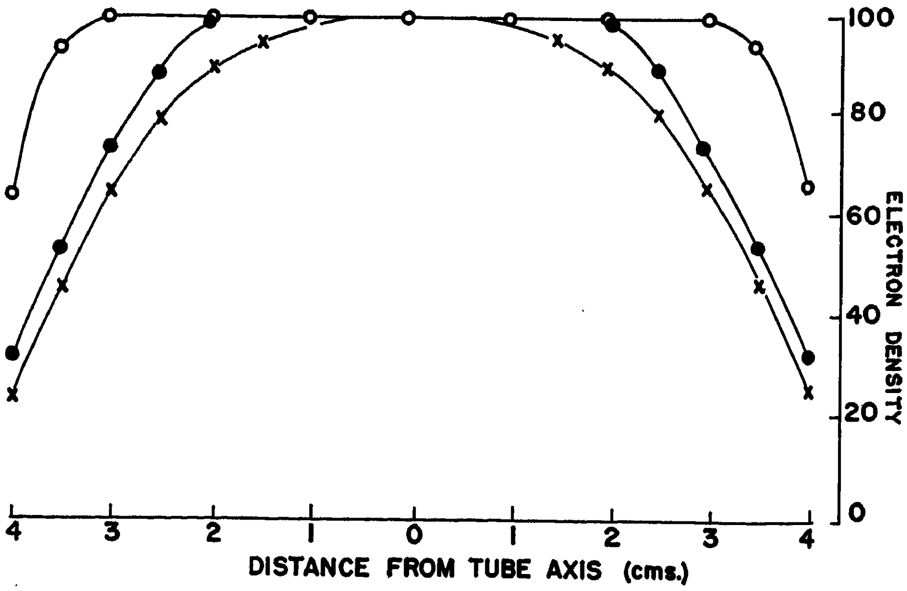

Fig. 3. Distribution of electron concentration across the tube diameter at various intervals of time in the recombination period

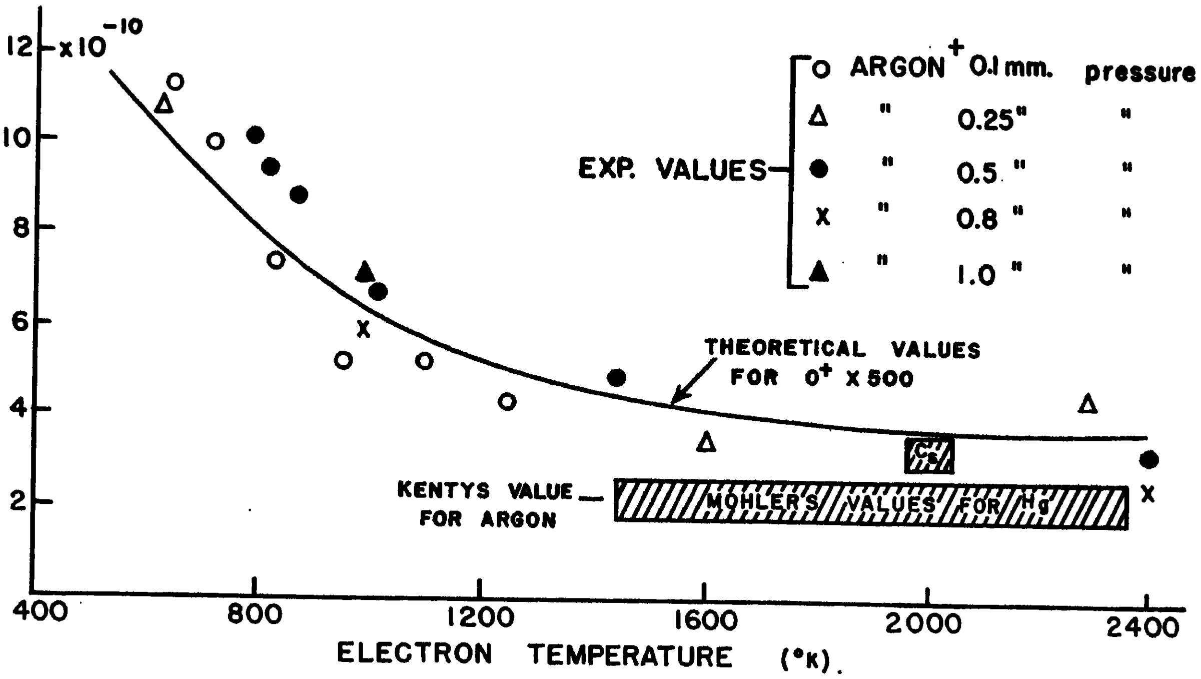

Fig. 4. Combined results of recombination coefficient for various electrons temperatures and gas pressures, and comparison with curve for radiative recombination

If one assumes that the light is due solely to recombination, then the light intensity j would be proportional to dn/dt and consequently to n^2. Thus $n=Kj^{1/2}$. Substituting in equation 2, we have

$$\left(\frac{1}{j_1^{1/2}}-\frac{1}{j_0^{1/2}}\right)=K\alpha t \qquad (6)$$

Mohler found that a plot of $1/j^{1/2}$ versus time was indeed a straight line for several milliseconds, and the slope of this line determines $K\alpha$, according to equation 6. K is then independently determined by comparing the electron density as measured by a Langmuir probe and a light intensity measurement at some particular time. The values of α thus obtained agree with the probe measurements.

Sayers[12] has made measurements in argon at pressures ranging from 0.1 to 1 millimeter of mercury, and at temperatures ranging from 600 to 2400 degrees Kelvin. He has employed a novel way of correcting for wall diffusion. Instead of using a single probe, he uses approximately twelve of them spaced along a diameter. A record for a typical run is summarized in Fig. 3.[12] He attributes the more rapid decrease of electron density near the walls as compared to its decrease at the center, to wall diffusion. If one restricts oneself to times such that the "plateau" has not "eroded" to the center of the discharge tube, no correction for wall diffusion is necessary. Only the decrease in electron density at the center of the discharge tube is used to determine the recombination coefficient. Sayers found no pressure dependence over the range of pressures examined. His results, as well as those of Kenty[1] and Mohler,[2,3] are summarized in Fig. 4.[12]

The experiments measuring the recombination coefficient by using the resonant-frequency measurement as described in "Basic Experimental Techniques" have been carried out by Biondi and Brown[9] and Holt[10] and his coworkers. Since there is no possibility of an independent temperature measurement using this method, it is necessary to wait until the electrons have cooled down to the temperature of the gas. This does not allow as wide a variation of temperature measurements as does the probe technique. Some experiments have been done, however, with the gas cooled to as little as 77 degrees Kelvin and as high as 410 degrees Kelvin. The results of these investigations are consistent with each other. Although a wide variety of gases have been used, we shall mention only the results for the noble gases.

Biondi and Brown[9] have measured the electron density as a function of the time, using the resonant-cavity technique, after ionizing the gas by an electrodeless microwave discharge. By plotting the reciprocal density as a function of the time, one can deduce from the slope of the curve, if it is a straight line, the value for α according to equation 2. To insure a straight line for the plot, it is necessary to work at relatively high pressures. Their results at 300 degrees Kelvin over the pressure range 15 to 30 millimeters of mercury are summarized in Table I.

Holt[10] has used the same technique, but has added a light measurement by means of a photomultiplier tube. He calibrates the photomultiplier by a density measurement at some particular time, and finds that the recombination coefficient for neon is substantially the same as those reported above.

The measurements using the Langmuir probe and those using the resonant cavity differ from each other by several orders of magnitude, even though each group is consistent within itself. It is true, of course, that the same temperature range has not been covered by each and that the measurement of the recombination coefficient by the Langmuir probe method at 300 degrees Kelvin might remove the discrepancy. It is not inconceivable that the recombination coefficient is an extremely sensitive function of temperature between 300 to 600 degrees Kelvin. However, in evaluating which of the results is more nearly correct it might be well to keep in mind the fact that the resonant cavity method is simpler, from a theoretical point of view, than the Langmuir-probe method, and the latter method involves additional difficulties in measurements of this sort, as pointed out by Johnson and Malter.[13]

Comparison with Theory

The indication in the experiments that α is independent of pressure suggests very strongly that the mechanism is essentially

Table I. Reciprocal Densities[9]

Gas	Cubic Centimeters per Ion Second
He	1.7×10^{-8}
Ne	2.03×10^{-7}
A	3×10^{-7}

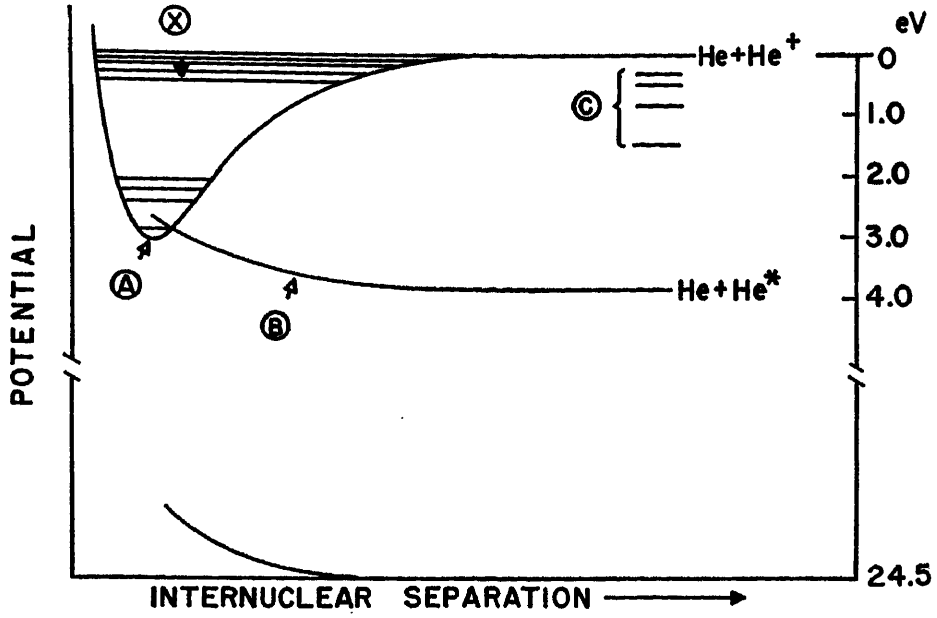

Fig. 5. Dissociative recombination for He_2^+. Some of the vibration levels are omitted

a two body process accompanied by the emission of a photon. Theoretical estimates of this type of recombination process have been made by Bates[14] for oxygen atoms, by Stueckelberg and Morse[15] and Oppenheimer[16] for hydrogen atoms, and by Goldberg[17] and Huang[18] for helium. If one uses the probe measurements, the results differ from the theoretical estimates by a factor of 500. For the others, the discrepancy lies between 10^3 and 10^6. While the theory for the most part deals with gases not used in the experiments, and some of the theoretical estimates are necessarily rough, the magnitude of the discrepancies suggest strongly that the mechanism of the recombination is not simply radiative in the experiments that have been done. The care that the experimenters have exercised in using pure gases, and the fact that the recombination coefficient is independent of the pressure, poses a real dilemma in understanding by what process as fundamental a phenomenon as electron-ion recombination takes place.

Recently, Bates[21] has suggested that the molecular ion X_2^+ plays a fundamental role in the recombination process, and that the mechanism is $X_2^+ + e \rightarrow X + X'$, which he called dissociative recombination. Even though the molecular ion must be formed by a three-body collision, the recombination coefficient would be pressure independent, provided that the atoms recombine much more slowly than the molecular ions are formed. The problem of calculating α for this process quantum mechanically represents enormous difficulties, and the best hope of discussing the reasonableness of the hypothesis is further experimentation.

Further Experiments and Conclusions

In an effort to learn more about the recombination process the microwave-breakdown technique was combined with an analysis of the recombination spectrum.[19] In the case of helium at pressures of 10 to 27 millimeters of mercury, it was found the most prominent spectral lines consisted of He_2 bands. This phenomenon is consistent with dissociative recombination and subsequent formation of the excited helium molecule by a three-body collision. It may also be due to radiative recombination and subsequent formation of the excited helium molecules. The latter possibility, however, has difficulties discussed in the section entitled "Comparison with Theory."

One could test the dissociative recombination hypothesis further by reducing the number of processes that could possibly take place in a discharge. For example, if the pressure of helium were so low that no subsequent formation of He_2^+ were possible, one could learn more about the products of the dissociation, since analysis of atomic spectra is simpler than molecular spectra. By reducing the pressure still further, it might be possible to inhibit the formation of molecular ions altogether, and thus the role played by dissociative recombination could be analyzed.

Biondi and Holstein[11] and Biondi[20] have recently carried out two experiments with these objectives. The first of these was a repetition of the previously mentioned experiment by Holt with helium but at pressures of 1 to 5 millimeters of mercury. A simultaneous determination of electron density, absolute light intensity, and spectrum of the afterglow was made. At these pressures, atomic lines of helium were observed, presumably because the excited helium atoms did not have time to recombine. The measurement of the electron density poses some problems at these pressures since recombination is by no means the dominant process and the analysis given in "Results for the Recombination Coefficient" does not hold. At low pressures, where diffusion loss outweights recombination, the electron density is approximately given by

$$\frac{n}{1+\alpha Tn} = \frac{n_0}{1+\alpha Tn_0} e^{-\frac{t}{T}} \tag{7}$$

as a function of the time. n_0 here is the electron density at the time $t=0$. T is the mean decay time due to diffusion, and is related to the ambipolar diffusion coefficient D_a and the diffusion length Λ by

$$T = \frac{\Lambda^2}{D_a} \tag{8}$$

Since D_a, and hence T, is known from previous measurements, a measurement of n enables us to determine α. The results of the Biondi and Holstein[11] experiment can be summarized as follows: The absolute light intensity in the afterglow is proportional to n^2. Absolute-intensity measurements indicate that, for each electron lost by recombination, one light quantum is emitted. The radiation in the visible region are atomic lines arising from states, all of which are within 1.5 electron volts of the atomic ionization potential. By referring to Fig. 5[11] one can see what the implications of these conclusions are with respect to the hypothesis of dissociative recombination. The molecular ion cannot be in its ground state, since the repulsive branch of the He, He* potential curve lies below the discrete levels from which the radiation originates. The only possibility of salvaging the dissociative recombination hypothesis is to assume that the molecular ion has energy greater than the discrete levels (C in Fig. 5) and therefore must be in some excited state (such as X in Fig. 5). While this is an extreme hypothesis, it has been estimated by Massey[22] that these high vibration states are metastable, and may persist long enough to participate in the recombination process.

The more recent work of Biondi[20] had as its objective the examination of the recombination process when the pressure was so low as to affect the formation of molecular ions. To this end, Biondi measured the electron loss in the afterglow of a microwave discharge in a mixture of helium and 0.1 per cent argon. The metastable state of helium has sufficient energy to ionize the argon atoms, so that if one waits long enough, the only ions that are present are those of the argon. The measurement of the electron loss enables one to measure the characteristic time constant, T of equation 7, and hence the ambipolar diffusion coefficient; see equation 8. A knowledge of this quantity allows one to compute the mobility μ_+. This value agrees with previously[23] estimated values of the mobility of argon ions in helium, confirming that the ion under consideration is really A^+. The experimental data on the electron loss can be fitted by a pure exponential, so that one concludes from equation 7 that α is very small. A detailed estimate of the experimental errors shows that $\alpha < 10^{-3}$ times the recombination coefficient of pure argon. This may mean that in this experiment we have radiative recombination to the atomic ion and its value is 0.001 of the value ordinarily measured, or that we still have recombination to the molecular ion whose concentration is smaller than in ordinary discharge.

We have confined ourselves in this report to those experiments which shed some light on the fundamental mechanism of recombination of ions and electrons. We have omitted many interesting details about peculiar temperature and pressure dependence, since we have felt that the mechanism of the process should be clear before the complications are considered. Even for the fundamental process, the final chapter has not been written. At this moment, I believe we can conclude, however, that the molecular ion plays a decisive role in the process; and we may say that the experimental results are not in contradiction with the hypothesis of dissociative recombination.

Equivalent Machine Constants for Rectifiers

I. K. DORTORT
MEMBER AIEE

IN CALCULATING the short-circuit currents on a d-c system and the contribution by a particular machine, the task would be greatly simplified if each connected machine could be replaced by an equivalent machine having a constant electromotive force (emf) and linear internal resistance and inductance. Even the highly ramified 250-volt d-c system of a present-day steel mill would then lend itself to rather accurate analysis.

The characteristics of practical machines are not linear over the entire range from no-load to short circuit, and cannot be accurately matched with equivalent constants, except by sections. This is particularly true of rectifiers, which pass through various modes of operation between no-load and short circuit. Matching equivalent constants to sections of the characteristic is not too great a hardship when solving for steady-state fault currents, but does not lend itself to transient condition studies.

The Report on Protection of Electronic Power Converters[1] treats the calculation of fault currents in rectifiers at short circuit only. The subject of equivalent machine constants was purposely avoided because of the lack of groundwork and

supporting literature. The voltage regulation curve of rectifiers having only primary reactance had not been worked out except over the normal operating range.

Scope

The first requirement is, then, the complete voltage-current characteristics of rectifiers having little or no secondary reactance, the usual condition met in practice. The necessary equations have been derived and are shown graphically in Fig. 1. These equations and the constants based on them apply only to the 6-phase double-way and double-wye rectifier connections, circuits 23, 45 (and variations) of the American Standards Association standard *C34.1–1949*.[2] The double-way circuit is commonly used in mechanical rectifiers; most low-voltage mercury-arc rectifiers use the double-wye.

No attempt has been made to arrive at a complete system of equivalent constants. It became apparent early in the study that any simplified method having general applicability would lead only to first approximations. Accurate solutions for transient conditions will require laborious step-by-step processes. The treatment is confined to external faults.

Nomenclature

As far as possible the symbols have been made consistent with the nomenclature of the AIEE Committee Report.[1]

E_a = arc drop
E_{ao} = arc drop at no load (projected)
E_d = d-c output voltage
E_{do} = induced direct voltage
E_r = direct voltage drop caused by losses
$\mathcal{E}_o$ = emf of equivalent machine for first mode
$\mathcal{E}_s$ = emf of equivalent machine at or near short circuit
I_d = d-c load current
I_{dn} = rated d-c load current
i_d' = instantaneous transient direct current
K = transient factor $=1+e^{-3.22R_c/X_c}$
$\mathcal{L}$ = inductance of equivalent machine
$m=2$ for double-way rectifier
$=1/2$ for double-wye rectifier
P_r = copper losses at rated load
R_a = equivalent resistance of arc drop
R_c = commutating resistance
$\mathcal{R}$ = resistance of equivalent machine
$\mathcal{R}'$ = equivalent transient resistance
$S=X_{cpu}I_d/I_{dn}$, load ratio $=\sqrt{2/3}F_x$ (F_x is the commutating reactance factor defined in the American Standards Association standard *C34.1–1949*.[2] The relation between S and F_x holds for both connections discussed in this paper)
u = angle of overlap
X_c = commutating reactance
Subscript pu denotes per-unit quantities
Subscripts f, h, i, j, and k refer to particular curves

Voltage Regulation Curves

Since both single-way and double-wye rectifiers are being considered here, the terms primary and secondary reactance should be clarified: The current through a primary reactance has no d-c component; the current through a secondary reactance is unidirectional. More definitively, this applies to the leakage fluxes. In most industrial rectifiers the secondary reactance is only a small part of the total and can be neglected.

The direct voltage drop produced in the output of a rectifier by the commutating current acting on the commutating reactances is linear with load current over the normal range when supplying a highly inductive load, and almost linear for a noninductive load. This holds true until the angle of overlap u becomes equal to 60 degrees. Then another mode of

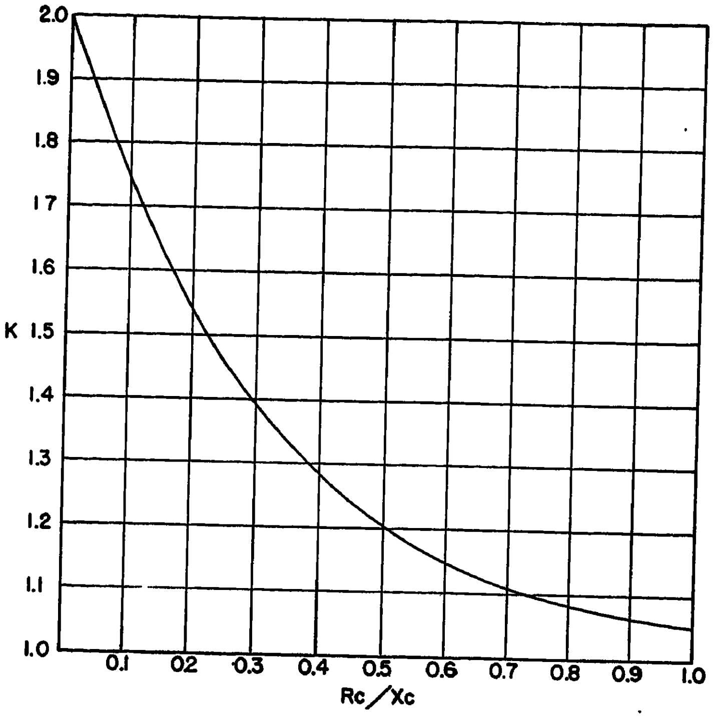

Fig. 2. Transient factor for determining crest value of short-circuit d-c transient current

operation occurs in which u remains constant. Additional voltage drop is produced by progressive delay in the pickup of the incoming phase in a manner resembling phase control. When supplying a highly inductive load, a third mode occurs in which u again increases to 120 degrees at short circuit.

There is a marked difference in the regulation and sustained short-circuit currents of rectifiers with no inductance in the d-c circuit and those with highly inductive d-c circuits. The d-c circuit can be considered highly inductive if $L_d > 20X_c/2\pi f$ for the double-way rectifier or $5X_c/2\pi f$ for the double-wye rectifier.

In a loss-free rectifier with inductive d-c circuit, from $X_{cpu}I_d/I_{dn}=0$ to 1/2 ($u=60$ degrees)

$$\frac{E_d}{E_{do}}=1-\frac{1}{2}\,\frac{I_d}{I_{dn}}\,X_{cpu}=1-\frac{1}{2}\,S \qquad \text{(curve } a\text{, Fig. 1)} \quad (1)$$

For $S=1/2$ to $\sqrt{3}/2$

$$\frac{E_d}{E_{do}}=\frac{1}{2}\sqrt{3}\sqrt{1-S^2} \qquad \text{(curve } b\text{)} \quad (2)$$

From $S-\sqrt{3}/2$ to $2/\sqrt{3}$ at short circuit

$$\frac{E_d}{E_{do}}=\sqrt{3}-\frac{3}{2}\,S \qquad \text{(curve } c\text{)} \quad (3)$$

For the case with a noninductive d-c circuit, from $S=0$ to $\sqrt{3}/\pi$ ($u=60$ degrees), E_d/E_{do} is given by curve d of Fig. 1. As a straight-line approximation we can use

$$\frac{E_d}{E_{do}}=1-\frac{\pi}{4\sqrt{3}}\,S \qquad \text{(curve } d\text{)} \quad (4)$$

From $S=\sqrt{3}/\pi$ to $2\sqrt{3}/\pi$ (at short circuit)

$$\frac{E_d}{E_{do}}=\frac{1}{2}\sqrt{3}\,\sqrt{1-\left(\frac{\pi}{2\sqrt{3}}\,S\right)^2} \qquad \text{(curve } e\text{)} \quad (5)$$

The arc drop can be expressed with fair accuracy as the sum of a fixed voltage, which is the arc drop projected to no-load, and a resistance drop which increases linearly with load.

$$E_a=E_{ao}+mR_aI_d \qquad (6)$$

where m is 2 for the double-way, and 1/2 for the double-wye rectifier. In most cases E_{ao} can be neglected at heavy overloads.

Copper losses also produce a voltage drop which varies linearly with load, and the total drop caused by losses is

$$E_r=mR_aI_d+\frac{P_r}{I_{dn}^2}\,I_d+E_{ao} \qquad \text{(curve } f\text{)} \quad (7)$$

Expressing the net voltage-current characteristic in per-unit quantities based on E_{do} and I_{dn}/X_{cpu}, we have

$$E_{dpu}=f(S)-\frac{E_r}{E_{do}} \qquad (8)$$

Equivalent Machine Constants

SUSTAINED CURRENTS

For steady-state conditions, any part of the characteristic can be matched with an approximate equivalent resistance

$$\mathcal{R}=\frac{\Delta E_d}{\Delta I_d}=\frac{\Delta E_{dpu}}{\Delta S}\,\frac{E_{do}}{I_{dn}}\,X_{cpu} \qquad (9)$$

The straight portions f and i of the net regulation curves for inductive and noninductive d-c circuits respectively can be represented in network equations by

$$\mathcal{R}_f=\frac{1}{2}\,\frac{E_{do}}{I_{dn}}X_{cpu}+mR_a+\frac{P_r}{I_{dn}^2} \qquad (10)$$

and

$$\mathcal{R}_i=\frac{\pi}{4\sqrt{3}}\,\frac{E_{do}}{I_{dn}}\,X_{cpu}+mR_a+\frac{P_r}{I_{dn}^2} \qquad (11)$$

The equivalent induced voltage in this region is

$$\mathcal{E}_0=E_{do}-E_{ao} \qquad (12)$$

In many cases sufficient accuracy over the entire range is obtained by assuming a straight-line characteristic between limiting conditions. An average line, such as the one drawn to S_k for curve fgh in Fig. 1 is a good first approximation and will indicate absolute short-circuit current on the high side.

For greater accuracy, the regulation curve is represented by two straight lines, the first corresponding to curves f or i, and the second line drawn through S_h or S_j to match the lower section of the curve as closely as possible.

The slope of this second line represents the equivalent resistance for faults near short circuit. The intersection of the projection of this line with the zero ordinate determines the equivalent emf, $\mathcal{E}_s$, to be used in solving for near short-circuit currents.

If the solution leads to a current outside the range of the straight-line section chosen, the work must be repeated with another set of constants suitable to that region.

TRANSIENT CURRENTS

If the d-c circuit is inductive, that is, $L_d > 20X_c/2\pi f$, for the double-way circuit, or $L_d > 5X_c/2\pi f$ for the double-wye, the equivalent internal inductance of the rectifier can be neglected for practical cases.

In any case if the external impedances involved in the fault are such that they will limit the short-circuit current during the first cycle to less than 0.55 I_{dn}/X_{cpu}, the equivalent internal inductance of the rectifier will be

$$\mathcal{L}=2X_c/2\pi f \qquad (13)$$

for the double-way circuit, and

$$\mathcal{L}=1/2\;X_c/2\pi f \qquad (14)$$

for the double-wye. For most purposes these inductances are negligible.

The report on protection[1] points out that a short-circuited rectifier reaches the transient crest current in less than 1

Table I. Test Results on Sustained and Transient Current, Rise Rate

	By Calculation, from Report[1]	Equivalent Constants	Test Results
Average sustained current	8,500	8,100	7,700
Crest transient current	12,500	11,900	11,000
Average rate of rise in first 1/3 cycle, amperes per second	2,000,000	1,870,000	

cycle, and the current quickly falls back to the sustained value. With an inductive d-c circuit, as defined previously, the current will never exceed the sustained value, except for the peak of the 6-phase ripple. The equivalent inductance of a rectifier therefore is of practical value only in analyses of short-circuit or near short-circuit conditions with little or no inductance in the fault path.

The expedient of substituting two or more straight lines for actual characteristic of the rectifier in the solution of the transient condition has not been investigated. A step-by-step process is possible, but appears cumbersome.

For a first trial we can get an approximate solution by assuming an equivalent resistance corresponding to E_{do} and S_j for the steady-state conditions.

$$\mathcal{R} \approx \frac{X_{cpu}}{S_j} \frac{E_{do}}{I_{dn}} \tag{15}$$

Up to the transient peak, if a peak occurs, the equivalent resistance is reduced by a factor $3/(\pi K)$, dependent on the resistance-reactance ratio of the commutating circuit. K is given in Fig. 2, which is the same as Fig. 11 of reference 1.

$$\mathcal{R}' \approx \frac{3}{\pi} \frac{\mathcal{R}}{K} \tag{16}$$

The current form up to the peak is fairly well matched by the empirical equation

$$i_d' = \frac{E_{do}}{\mathcal{R}'}(1 - \epsilon^{-\omega t}) \tag{17}$$

from which

$$\mathcal{L} = \frac{\mathcal{R}'}{\omega} \tag{18}$$

Equations 17 and 18 tend to give currents on the high side in the first third of the cycle immediately after the fault is applied, and slightly low at the peak. Since $\mathcal{L}$ is generally very small, any appreciable external inductance will make the error negligible.

Conclusion

The equivalent constants presented for use in solving steady-state problems introduce errors which are understood and can be evaluated. The constants derived for transient analyses are less satisfactory but will provide usable answers if judiciously applied.

No check of the method by actual test has been made. However, curves *r*, *fgh*, and *ij* in Fig. 1 are based on the test rectifier described in Fig. 15 of the report on protection[1] and used for the short-circuit test of Appendix II of the report. Since only one point is available for comparison the construction of the net regulation curve is confirmed only at short circuit. See Table I.

No Discussion

Flow of Energy in D-C Machines

EDWARD I. HAWTHORNE
MEMBER AIEE

Synopsis: The flow of electromagnetic energy is traced in a typical, somewhat idealized, d-c generator, using an adaptation of Poynting's vector, after a discussion justifying this procedure. Quantitative analysis of the flow within the conductors and in the gap is carried out following the specification of the electromagnetic fields. Qualitative analysis of the flow in intermediate regions and to machine output leads is presented. Extension to other types of machines and to less idealized situations is discussed.

THE STUDY of energy flow in d-c machines, carried out on the basis of the electromagnetic field analysis, is presented. In the customary analysis of the machine the much simpler electric and magnetic circuit approach is employed as an excellent and useful approximation. Because of the complexity of the field approach to the analysis of electric devices at low frequencies in general, relatively few authors have considered problems in electric machinery on this basis.[1–4] The study of electromagnetic fields and energy flow in rotating machines affords a better understanding of their operation from an educational and analytical standpoint, and may be of value in improving their design. With this objective in mind this paper is presented.

Energy and Energy Flow Postulates

Before proceeding with the analysis of the flow of energy in a particular device such as the d-c machine, it is essential to ascertain clearly the basis for and the validity of the concepts of electromagnetic energy and energy flow.[5–9] Unnecessary confusion and concern over apparent paradoxes[10–11] frequently result from the failure to state clearly the fundamental aspects and limitations of these concepts.

Neglecting such nonlinear effects as saturation and hysteresis phenomena, as well as any problems requiring microscopic and relativistic considerations, all physical situations of electromechanical nature may be described completely by supplementing the relations of mechanics with the field equations of Maxwell and the force equation of Lorentz

$$\text{curl}\,\mathbf{E} = -\partial\mathbf{B}/\partial t; \ \text{div}\,\mathbf{D} = \rho \tag{1}$$

$$\text{curl}\,\mathbf{H} = \mathbf{J}_C + \rho v + \frac{\partial D}{\partial t}; \ \text{div}\,\mathbf{B} = 0 \tag{2}$$

Paper 53-266, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 26, 1953; made available for printing May 8, 1953.

Edward I. Hawthorne is with the University of Pennsylvania, Philadelphia, Pa.

The author is deeply grateful to Dr. J. G. Brainerd of the University of Pennsylvania for his inspiring help and guidance in the study of the problem.

Nomenclature

Rationalized meter-kilogram-second units have been presumed.

a = number of paths in the armature
$\mathbf{B}$ = magnetic flux density
c = machine constant depending on load, equation 38
$\mathbf{D}$ = electric displacement density
$\mathbf{E}$ = electric field intensity
$\mathbf{F}$ = force
g = gap thickness
h = conductor height
$\mathbf{H}$ = magnetic field intensity
$\mathbf{I}$ = current
$\mathbf{J}$ $(\mathbf{J}_C)$ = (conduction) current density
k = machine parameter, equation 39
m = machine constant, equation 41
n = speed in revolutions per minute
p = number of poles
$\mathbf{P}$ = energy flow vector
q = electric charge
Q = number of slots, or commutator bars
r = radial co-ordinate
R = radius of the armature
s = thickness of conductors; distance
$\mathbf{S}$ = surface
t = time
$\mathbf{T}$ = normalized energy flow vector
u = pole arc
$\mathbf{v}$ = velocity
V = Maxwellian scalar potential
V_t = terminal voltage of the machine
w = pole pitch
x = circumferential co-ordinate
y = vertical co-ordinate in conductors (radial)
z = axial co-ordinate
Z = number of conductors
α = machine constant depending on load, equation 15
β = space angle of $\mathbf{P}$ in the gap
γ = number of slots per pole arc
δ = reciprocal of γ
ϵ_0 = permittivity of free space
ζ = normalized z co-ordinate
θ = angular co-ordinate around the armature
λ = axial length of the armature
μ_0 = permeability of free space
ξ = normalized x co-ordinate
ρ = electric charge density
σ = conductivity
τ = volume
ϕ = air gap flux per pole

$$d\mathbf{F}=dq(\mathbf{E}+\mathbf{v}\times\mathbf{B}) \qquad (3)$$

together with the empirical relations between the field vectors **D** and **E**, **B**, and **H**, and **J** and **E**, determined by the parameters of the medium. Maxwell's equations define these useful field vector concepts in consistence with experimental evidence, and the force equation provides for the essential tie with mechanics, in accordance with experimental fact. The only new postulated concept, which permits the description of electrical phenomena, not possible with the science of mechanics alone, is that of an electric charge, or current, or any other single quantity. The electromagnetic field formalism, defined by the field vectors of Maxwell, obviates the necessity of thinking in terms of action at a distance in favor of first determining the field of sources of electromagnetism, and then, employing this field concept with the aid of the Lorentzian force law, to study the effects as a local interaction between the field and charged matter. This procedure generally simplifies analysis both mathematically and conceptually.[12]

The role that the concept of electromagnetic energy plays in this formulation is not always made clear. The well-known fact[7,9,11] should be emphasized that there is nothing inherently present in Maxwell's equations which uniquely specifies such concepts as electromagnetic energy, electromagnetic energy storage density in the field, or electromagnetic energy flow vectors. These concepts are definitions based on the process of integration of the field equations. Carrying out the integration over a region of space, there results, after some manipulation, the energy balance equation

$$\underbrace{\iiint \operatorname{div}(\mathbf{E}\times\mathbf{H})d\tau}_{(a)}+\underbrace{\iiint(\mathbf{E}\cdot\partial\mathbf{D}/\partial t+\mathbf{H}\cdot\partial\mathbf{B}/\partial t)d\tau}_{(b)}+\underbrace{\iiint \mathbf{J}_c\cdot\mathbf{E}d\tau}_{(c)}+\underbrace{\iiint \rho\mathbf{v}.\mathbf{E}d\tau}_{(d)}=0 \qquad (4)$$

By reference to the force equation 3 the terms c and d in equation 4 are identified as the time-rate at which work, mechanical in nature, is being done on charged matter within the region τ (since the **B**-field can do no work). It is almost universally accepted to regard the term b as representing the rate of increase of electromagnetic energy storage in the region. This concept has proved to be extremely useful, although other formulations are possible.[7,9] For isotropic media a further subdivision of b is made, which results in the common definitions of electric and magnetic energy storage densities per unit volume in the field, a concept of useful although arbitrary nature, capable of no experimental verification and requiring none.[7,9] With this definition of electromagnetic energy, the term a acquires the significance of representing the rate at which electromagnetic energy is leaving the region τ, in order that an over-all energy balance be preserved.

The procedure described is generally adapted to define the Poynting's energy flow vector at every point in space

$$\mathbf{P}=\mathbf{E}\times\mathbf{H} \qquad (5)$$

as representing the time-rate at which electromagnetic energy is transported through space per unit area. This definition, originally due to Poynting,[13] is again quite arbitrary, although extremely convenient, especially at higher frequencies. It must be realized that only a closed surface integral of **P**, to which the term a in equation 4 is reducible, has a true significance of over-all rate of flow of electromagnetic energy out of the enclosed region, with the conventional electromagnetic energy definition. Any other flow vector, differing from **P** by a curl of an arbitrary vector field, that is, having the same divergence as **P**, is equally satisfactory and significant.[9] Furthermore, if alternate postulates for electromagnetic energy are adopted, then other energy flow vectors, differing from **P** even in divergence, may be chosen for an equally valid formulation of the energy

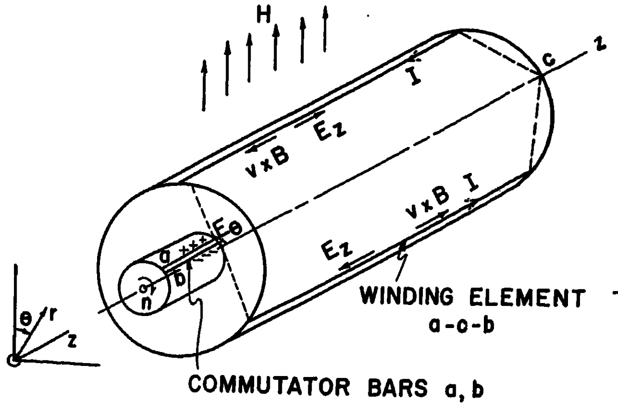

Fig. 1 (left). Typical winding element of a d-c generator

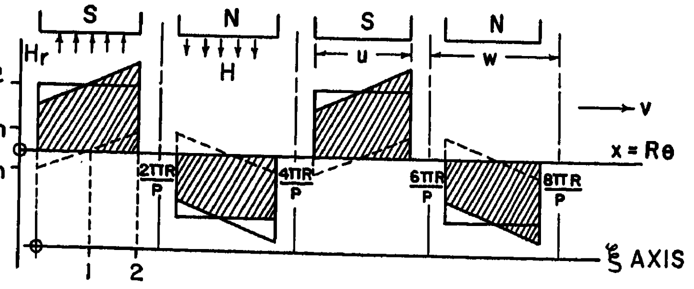
Fig. 2 (below). Radial magnetic field intensity versus distance around the gap



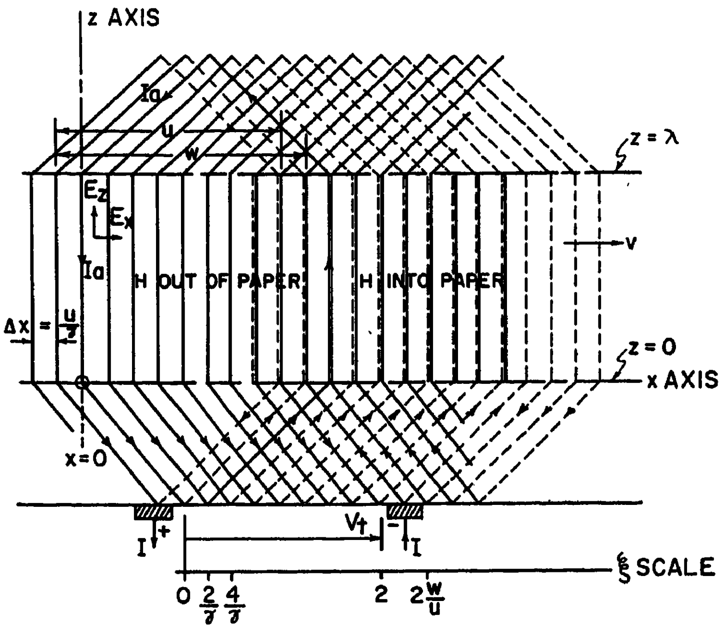


Fig. 3. Developed lap winding of the d-c generator

flow.[9] Thus it is not surprising that a literal application of the Poynting's vector leads to paradoxical occurrences of circulatory energy flow in cases where apparently no energy is being transmitted or transformed.[10–11] In all such cases, however, integration of the **P** vector over a closed surface invariably leads to an unambiguous resolution of the difficulty.

Space does not permit further discussion of the different aspects and various possibilities of flow vectors. The relative simplicity of Poynting's vector is ample justification for its selection in the analysis of the d-c machine to follow, with the following modifications. In the light of the foregoing, components of Poynting's vector having zero or negligibly small divergence may be omitted from it as representing an irrelevant circulatory flow of energy, in comparison with the components which represent a net transfer of power.

One such modification of the Poynting's vector leads, in its integrated form, to the commonly employed voltage-current postulate for power measurement. The connection between the voltage-current postulate and Poynting's vector has been investigated by Slepian[2,8] and others.[14] Thus the voltage-current approximation for the Poynting's vector is essentially valid in lumped parameter circuit studies, for the tracing of energy flow along a distributed parameter transmission line,[8] but not within transformers, wave guides, or rotating machinery.

D-C Generator at No Load

A somewhat idealized d-c generator will be considered, first under no-load conditions, in steady-state operation at constant speed. High-permeability iron with negligible saturation and hysteresis properties will be assumed, so shaped that the radial magnetic field in the gap is uniform under the pole shoes at no load and zero in the interpolar region of the gap. The effect of the presence of the large number of slots and of the ventilating ducts on the field in the gap will be neglected. Linear commutation will be assumed with the brushes located on the neutral axes. A 2-layer, simplex lap armature winding, with one turn per winding element, will be assumed, so that there are two conductors per slot, and the number of slots is equal to the number of commutator bars. To simplify the analysis, a permanent-magnet field excitation will be assumed. To study the flow of energy associated with the more common d-c field winding, an analysis of the flow of energy in a reactor is required. This has been worked out but will not be presented here, since the resulting modification of the analysis to follow would be of rather minor nature.

In order that the net force on the free charges within each winding element revolving in the steady magnetic field of the gap be zero in the steady state, an axial electric field must exist within and near the conductors on the surface of the armature, equal and opposite to the $\mathbf{v}\times\mathbf{B}$ term of equation 3. This field, an electrostatic one with respect to the fixed frame of reference, is associated with a charge distribution along the conductors and produces a potential difference between the commutator bars. Referring to Fig. 1, showing a typical winding element

$$E_z = -[\mathbf{v}\times\mu_0\mathbf{H}]_z \tag{6}$$

where

$$v = R\frac{d\theta}{dt} = \frac{\pi R n}{30} = \frac{wpn}{60} \tag{7}$$

Since the line integral of **E** around any closed path on the surface of the armature must be zero for the static **E**-field, there is also present an E_θ component everywhere, that is, between the charged armature conductors. A complete specification of this field is presented for the more general case of the loaded machine. One manifestation of this E_θ field is the voltage induced between commutator bars such as a and b in Fig. 1, given by

$$\begin{aligned} V_a - V_b = V_{ab} &= \int_a^b E_\theta dx = \oint_{acb} E_z ds \\ &= -\oint_{acb} \mathbf{v}\times\mathbf{B}\cdot d\mathbf{s} \end{aligned} \tag{8}$$

The interaction between the **E** field and the **H** field in the gap results in a Poynting's vector whose divergence, however, is zero everywhere, as proved in the Appendix. The resulting apparent circulatory flow of energy may be

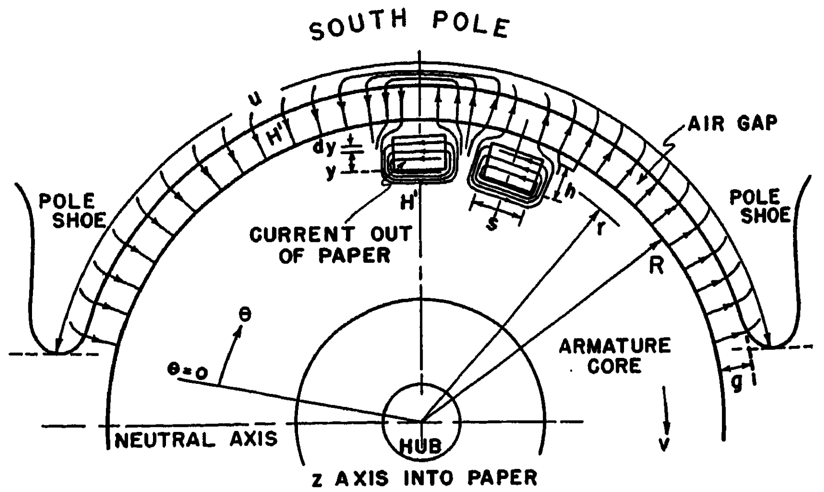

Fig. 4. Cross-sectional sketch of the magnetic field lines in a d-c generator

disregarded, and no net transfer of energy takes place.

Table I. Axially Directed Power Flow Through the Boundary of the Air-Gap (Surface Integrals of the P_x Component)

	Left Half-Plane $0 \leq \xi \leq 1$	Right Half-Plane $1 \leq \xi \leq 2$	Total

Electromagnetic Field in Gap of a Loaded Generator

The simplest procedure to follow is to determine first the complete radial magnetic field in the gap, to which armature currents now contribute. Using equation 6, the electric field component E_z may be specified. Then the E_θ component may be determined by means of equation 8, or by the requirement that curl **E** be zero everywhere.

The radial magnetic field in the gap is shown developed in Fig. 2 for an idealized machine. Consider the developed plane of the gap, with the co-ordinates normalized to an axial co-ordinate ζ and circumferential co-ordinate ξ, given in the following:

$$\xi = 2x/u;\ \zeta = (z/\lambda)(1/\gamma) \tag{9}$$

where

$$x = R\theta;\ \gamma = \left(\frac{u}{2\pi R}\right)Q \tag{10}$$

Let H_r'' be the constant radial field component caused by the field excitation and let H_r' be the component caused by armature currents. Its maximum value H_{rm}' can be calculated, considering the armature as a solenoid carrying a current I/a and having $(Z/p)(u/w)$ effective turns per pole, as follows

$$H_{rm}' = \frac{1}{2g}\frac{I}{a}\frac{Z}{p}\frac{u}{w} = \frac{I\gamma}{ga} \tag{11}$$

since $Z = 2Q$ and $wp = 2\pi R$. Taking as the origin for ξ the leading south pole tip, we have, for the region $0 \leqslant \xi \leqslant 2$ under the south pole

$$H_r(\xi) = H_r'' + H_{rm}'(\xi - 1) \tag{12}$$

The electric field component $E_z(\zeta)$ in the gap can be computed directly from equations 6 and 12 if the conductors are assumed lossless. In the region $0 \leqslant \xi \leqslant 2$, it is given by

$$E_z(\xi) = \mu_0 v H_r'' + \mu_0 v H_{rm}'(\xi - 1) \tag{13}$$

Noting that the total flux per pole ϕ is unaffected by armature reaction in this machine and is given by

$$\phi = \mu_0 u \lambda H_r'' \tag{14}$$

and letting

$$\alpha = H_{rm}'/H_r'' \tag{15}$$

we obtain

$$E_z(\xi) = \frac{aV_t}{2p\lambda\gamma}[1 + \alpha(\xi - 1)] \tag{16}$$

where

$$V_t = \frac{np\phi}{60a} \tag{17}$$

For the simplex lap winding $p = a$, and hence

$$E_z(\xi) = \frac{V_t}{2\lambda\gamma}(1 - \alpha + \alpha\xi) \tag{18}$$

The θ or x-directed component E_x can be determined with the aid of the developed lap winding shown in Fig. 3. The $E_z(\xi)$ component sets up a potential gradient in the (ξ,ζ) plane, which results in an E_x component that varies both with ξ and with ζ. Assuming the commutator bars to be closely spaced, E_x may first be determined at the $\zeta = 0$ boundary directly from equation 8

$$\frac{2\pi R}{Q}E_x(\xi,0) = 2\lambda E_z(\xi) \tag{19}$$

yielding

$$E_x(\xi,0) = \frac{V_t}{u}(1 - \alpha + \alpha\xi) \tag{20}$$

Integrating equation 20 under a pole shoe over $0 \leqslant \xi \leqslant 2$, that is, $0 \leqslant x \leqslant u$, we obtain V_t, which can therefore be identified as the terminal voltage between brushes. Since equation 17 agrees with the usual expression for the terminal voltage of a lossless d-c machine, a check on the procedure has been obtained. At the boundary $\zeta = 1/\gamma$ $(z = \lambda)$ the following condition must be satisfied

$$E_x(\xi, 1/\gamma) = E_x(\xi + \delta, 0) \tag{21}$$

where δ is half the distance between successive commutator bars and is given in units of ξ as

$$\delta = \frac{1}{2}\frac{2\pi R}{Q}\frac{2}{u} = \frac{1}{\gamma} \tag{22}$$

Consequently

$$E_x(\xi, 1/\gamma) = \frac{V_t}{u}(1 - \alpha + \alpha/\gamma + \alpha\xi) \tag{23}$$

Since E_z is constant along each constant ξ line, E_x varies linearly with ζ, and we have, therefore, on the basis of equations 20 and 21

$$E_x(\xi,\zeta) = \frac{V_t}{u}(1 - \alpha + \alpha\xi + \alpha\zeta) \tag{24}$$

Equation 24 could have been derived directly from equation 18 and from the condition curl $\mathbf{E} = 0$, which condition equations 18 and 24 may now readily be seen to satisfy.

Had the losses within armature conductors not been neglected, equation 6 would have to be modified to read

$$E_z = -[\mathbf{v} \times \mu\mathbf{H} + \mathbf{J}/\sigma]_z \tag{25}$$

The expressions for E_z and E_x would, by a simple revision of proceeding steps, then become respectively

$$E_z = \frac{V_t}{2\lambda\gamma}(1 - \alpha + \alpha\xi) - J_z/\sigma \tag{26}$$

and

$$E_x = \frac{V}{u}(1 - \alpha + \alpha\xi + \alpha\zeta) - \frac{\lambda\gamma^2}{u}\frac{J_z}{\sigma}\zeta \tag{27}$$

Note that V_t, still given by equation 17, no longer represents the terminal voltage of the generator.

Energy Flow within Armature Conductors

The lines of the H' field are sketched in Fig. 4. Within the conductors, assumed for simplicity to be rectangular, the field H is x-directed and is given very nearly by

$$H_x(y) = -\frac{I}{a}\frac{y}{hs} = -Jy \tag{28}$$

The energy flow vector within the conductors is therefore directed radially everywhere and is given, using equations 5, 26, and 28, as

$$P_y(\xi, y) + \frac{V+J}{2\lambda\gamma}(1 - \alpha + \alpha\xi)y - (J^2/\sigma)y \tag{29}$$

The divergence of this **P** vector, which represents the net generation of power per unit volume within the conductors, may be readily identified with the sum of two terms

$$\operatorname{div}\mathbf{P} = \frac{\partial Py}{\partial y} = \mathbf{v} \times \mathbf{B} \cdot \mathbf{J} - J^2/\sigma \tag{30}$$

The first of these represents electromagnetic power converted from mechanical power per unit volume of the conductor

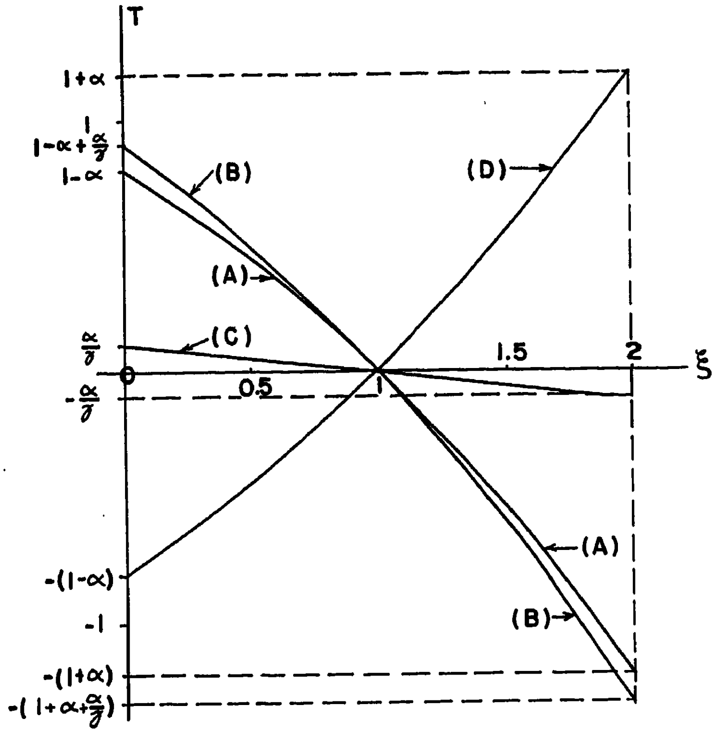

Fig. 5. Variation of the normalized energy flow vectors around the gap

Curve A: T_z(normalized P_z) at $z=0$
Curve B: T_z (normalized P_z) at $z=\lambda$
Curve C: Difference curve, (B)−(A)
Curve D: T_x(normalized P_x)

and the second constitutes the corresponding power loss. It may also be ascertained readily that the energy balance equation 4 is satisfied for every portion of the conductors. It is also satisfied for the armature as a whole, since the summation over all the conductors of the integral of P_y over the conductor surfaces at $y=h$ can be shown to yield

$$\sum_{\text{all conductors}}\left\{\int\int\int P_y(\xi,h)dS_y\right\}=\frac{Znp\phi I}{60a}-I^2\frac{1}{4}\frac{Z}{\sigma}\frac{\lambda}{sh} \qquad (31)$$

which represents the generated power less the armature resistance losses.

Having indicated how internal losses may be included, we shall neglect them for the sake of simplicity in the analysis to follow.

The consideration of energy flow in the immediate vicinity of armature conductors, as it enters the gap, is postponed temporarily to study the conditions within the gap on a somewhat idealized basis.

Energy Flow in the Gap

As a result of the interaction of the H_r field with the E_x and E_z field, two components of P exist, namely

$$P_x=E_zH_r \text{ and } P_z=-E_xH_r \qquad (32)$$

It will suffice to investigate the flow of energy under a south pole of Fig. 3, since both E and H reverse under the north pole, leaving the P vector unchanged. Furthermore, it will suffice to consider the armature reaction part of H_r. Previous reasoning based on the Appendix indicates that the H_r'' field produces components of **P** whose divergence is zero, and which, therefore, represent a circulatory flow of energy of no physical value. Using the H_{rm}' $(\xi-1)$ part of equation 12 for H_r together with equations 18 and 24, equation 32 yields

$$P_x(\xi)=\frac{IVt}{p}\frac{1}{2\lambda g}(\xi-1)(1-\alpha+\alpha\xi) \qquad (33)$$

$$P_z(\xi,\zeta)=\frac{IV_t}{p}\frac{Q}{2\pi Rg}(1-\xi)(1-\alpha+\alpha\xi+\alpha\zeta) \qquad (34)$$

These expressions are consistent with the energy balance equation 4. Integration of the P_x and P_z components over the side walls and over the front and rear walls respectively of a portion of the volume of the gap of height g, length λ, and width of one slot-tooth space, may be shown readily to yield, at any ξ, a power of $(2\lambda I/p)E_z(\xi)$ watts. This is exactly equal to the power emerging from the two conductors in the slot below, calculated from equation 29 for $\sigma=\infty$.

Investigation of the P_z and P_x components gives an insight on the flow of energy in the gap and reveals certain fundamental differences between them. The P_z component is $+z$-directed in the right half-plane ($\xi>1$) and $-z$-directed in the left half-plane ($\xi<1$). Although its divergence is not zero, the P_z component, when integrated over the front and rear walls of the gap at $\zeta=0$ and $\zeta=1/\gamma$ respectively produces zero net outflowing power from the region under a pole. (The same conclusion may be reached by noting that the volume integral of $\partial P_z/\partial z$ under a pole is zero.) The results of carrying out the surface integrals are summarized in Table I, which shows the outflowing, z-directed power at the boundaries of the gap under a pole.

The z-directed flow of energy may be best pictured by plotting the variable part of P_z, given by the normalized flow vector

$$T_z(\xi,\zeta)=(1-\xi)(1-\alpha+\alpha\xi+\alpha\zeta) \qquad (35)$$

as a family of ζ curves versus ξ. Typical curves at the two extreme values of ζ are shown in Fig. 5, where T_z $(\xi,0)$ is drawn to scale for $\alpha=0.2$ as curve A, and where the displacement of the $T_z(\xi,1/\gamma)$ curve B from it for an assumed $\gamma=20$ is exaggerated ten times for the sake of clarity. It is evident that most of the z-directed energy which enters the gap at $z=0$, leaves it at $z=\lambda$. The net amount retained within the gap at any ξ is measured by the difference between the B and

A curves and plotted as curve C in Fig. 5, also exaggerated ten times. This difference curve C is a linear function of ξ. The net power, measured by the area under this difference curve, is zero.

While the P_z component contributes markedly to the direction of the flow of energy at each point in the gap, it is the relatively smaller P_x component that accounts for the net transfer of power out of the gap. The normalized form of it

$$T_x(\xi)=(\xi-1)(1-\alpha+\alpha\xi) \qquad (36)$$

which is independent of ζ, is also drawn in Fig. 5 for $\alpha=0.2$ as curve D. While the curves for T_x and T_z are of similar appearance, their meaning is quite different, since they are both plotted as functions of ξ. The plot of $T_x(\xi)$ indicates that energy flows in the $+x$ direction in the right half-plane and is $-x$ directed in the left half-plane. The amount of this outflowing energy is continuously increasing, as a result of the contributions from the upcoming P_y power from the armature conductors below, as the $\xi=0$ and $\xi=2$ boundaries are approached. The total outgoing power is given by the arithmetic sum of he lengths of the ordinates at $\xi=0$ and $\xi=2$ as

$$[(1-\alpha)+(1+\alpha)]\frac{V_tI}{2p\lambda g}(\lambda g)=\frac{V_tI}{p} \text{ watts per pole}$$

It is of interest to investigate the angle β which the lines of **P** make with the x-axis in the plane of the gap. It is given by

$$\tan\beta=P_z/P_x=-\frac{2\gamma\lambda}{u}\left(1+\frac{\zeta}{c+\xi}\right) \qquad (37)$$

where

$$c=(1-\alpha)/\alpha \qquad (38)$$

The angle β is constant along the family of straight lines given by

$$\zeta=k(c+\xi) \qquad (39)$$

These constant $-\beta$ lines are sketched in Fig. 6 in the x-z plane for α-0.02, showing that the maximum value of $k=(\gamma c)^{-1} \ll 1$. In terms of k the angle β =

$$\beta=\pm\pi/2+\tan^{-1}\frac{m}{1+k} \qquad (40)$$

where, for practical machines

$$m=\frac{u}{2\lambda\gamma}\ll 1 \qquad (41)$$

Very nearly, then

$$\begin{aligned}\beta&\cong\pi/2+m-km,\ 0\leqslant\xi\leqslant 1\\ \beta&\cong-\pi/2+m-km,\ 1\leqslant\xi\leqslant 2\end{aligned} \qquad (42)$$

The direction of the flow vector **P** in the gap is therefore very nearly constant in practical machines, except for a revers 1 of 180 degrees at each half-pole, and is almost parallel to the axis of the shaft. The largest difference in direction between the $0,\gamma$ and $u,0$ points in the x,z plane, is

$$|\Delta\beta|_{\max}=mk_{\max}=\frac{u}{2c\lambda\gamma^2} \qquad (43)$$

which for $\alpha=0.2$ and $\gamma=20$ is only 0.0179 (u/λ) degrees. The largest deviation of β from the z-direction in this case is only 0.143 (u/λ) degrees. At light loads the lines of **P** make everywhere an angle of m radians with the z axis. As the load increases the **P** vector tends to curve towards the z-direction, while $|\Delta\beta|_{\max}$ increases.

The magnitude of **P** is given by

$$P=P_x\sqrt{1+\left(\frac{1+k}{m}\right)^2}\cong P_x\left(\frac{1+k}{m}\right) \qquad (44)$$

It is very nearly independent of ζ and varies with ξ in the manner shown in Fig. 5(D) for T_x. The phase reversal occurs at $\xi=1$ where P diminishes to zero. Its variation with ζ along any constant ξ-line is caused by the variation of the k parameter, as illustrated in Fig. 6.

The lines P in the (x,z) plane are sketched in Fig. 7 for an exaggerated case of $k_{\max}=0.5$, $m=0.1$, corresponding to $\alpha=1/3, u/\lambda=1/5$, $\gamma=1$. Even for this much exaggerated case the angles are all very nearly equal to $\pi/2$. The lines of energy flow under light load are dotted for comparison, while the dashed lines represent the constant = β (or constant = k) lines of Fig. 6. Here the maximum angle with the vertical is 5.72 degrees and the maximum variation of this angle is 2.86 degrees.

Energy Flow from Armature Conductors to Gap

directed flow of the P_x and P_z vectors of equations 33 and 34, can be studied if the magnetic field is specified, a very difficult task from the analytical standpoint. Qualitatively, the situation may be described with reference to Fig. 8, where lines of the H-field are sketched. It is seen how the lines of P_y gradually curve to become the lines of the P_x flow, as a result of the interaction with the E_z-field. Within the iron core, where H is small, there is very little flow of energy, except for the amount necessary to supply the stored energy and internal losses. The lines of E_x are not shown. The E_x field between the conductors in the iron teeth also contributes to the small energy flow there. In the gap the E_x field interacts with the H_r'-field to give the lines of energy flow their z-component, not shown. This interaction does not take place until the region well into the gap is reached where H_r' is appreciable. This curvature is out of the paper under the trailing half of each pole and into the paper under the leading half, as demonstrated in the preceding section. South pole is shown in Fig. 8 but, as discussed previously, the situation is unchanged under the north pole.

Flow of Energy from Gap to Output Leads

We restrict our attention to the P_x lines representing a net energy output. The mechanism whereby this energy is directed from the gap to the output leads between brushes is closely dependent on the process of commutation. Fig. 9 shows a coil side at three successive points in time as it undergoes commutation, starting with the $x=u$ position. The E_c and H_c fields associated with the coils undergoing commutation bear a close similarity to the fields between and near the wires of a transmission line, discussed by Slepian.[8] Space does not permit further elaboration here. Suffice it to say that the interaction of the E_{c1} field, produced by the charges along the conductors with the magnetic field H_c of the time-varying commutation currents, results in the flow vector P_c, whose lines are sketched on Fig. 10. The energy associated with the P_x vector enters the region of the neutral axis of the machine and is redirected by this P_c vector towards the output terminals, as shown on the sketch. Similarly the fields E_0 and H_0, associated with the output loop, result in the P_0 flow vector, which guides the energy out along the output transmission line of the generator. In an analogous manner the P_z-directed energy in the gap may be shown to be redirected to the adjacent regions of the gap by the leakage fields of the end turns, in accordance with the energy balance requirements of Table I.

Concluding Remarks

A suitable mechanical energy flow vector may be similarly postulated and employed to describe the flow of mechanical energy from the prime mover to the generator, and the conversion of this energy within the machine to electrical energy. Space does not permit its inclusion here.

The extension of this development to the d-c motors and to self-excited machines presents no special problem. For instance, the situation in a d-c shunt motor is identical with the separately excited generator except for a reversal of polarities. The refinement of the analysis to take into account such practical effects as the presence of teeth, slots, and ventilating ducts, nonuniform gap, or appreciably low permeability iron entails serious computational difficulties, and requires the exact specification of the fields, which must be obtained by a point-to-point field plot or by measurement. Eliminations of the assumption of linearity to include saturation and hysteresis effects presents a most serious computational as well as conceptual obstacle. This problem has not been attempted.

In spite of these limitations, it is hoped that the study of energy flow presented will serve the useful purpose of better basic understanding of the operation of d-c machines, and that it may be of value for designers of practical machines, which the somewhat idealized machine of this paper approaches.

Appendix

Let $\mathbf{E}_1$ be the electric field associated with a static charge distribution on the surface of a conductor 1 and let $\mathbf{H}_2$ be the magnetic field associated with a steady current distribution in a conductor 2. If $\mathbf{P}=\mathbf{E}_1\times\mathbf{H}_2$, then by equations 1 and 2

$$\text{div}\,\mathbf{P}=\mathbf{H}_2\cdot\text{curl}\,\mathbf{E}_1-\mathbf{E}_1\cdot\text{curl}\,\mathbf{H}_2=-\mathbf{E}_1\cdot\mathbf{J}_2$$

since curl $\mathbf{E}_1=0$. However $\mathbf{J}_2=$zero everywhere except within conductor 2, where $\mathbf{E}_1$ is zero. Hence div $\mathbf{P}=0$ everywhere.

Applications of Integral Equations to the Solution of Nonlinear Electric Circuit Problems

L. A. PIPES
MEMBER AIEE

Synopsis: This paper presents a mathematical technique useful in the solution of certain nonlinear electrical and mechanical problems of practical importance. The mathematical procedure involves the formulation of the problem in terms of nonlinear integral equations, and, by its use, practical results may be obtained in many cases where the approximate solution of the integral equation may be effected by the assistance of the Laplace transform theory. No attempt is made to present a general theory, but instead the general method is illustrated by applying it to the solution of typical problems of technical importance such as the analysis of electric circuits with nonlinear resistance, nonlinear inductance, nonlinear capacitance, and to the steady-state solution of van der Pol's equation.

THE MATHEMATICAL analysis of most of the phenomena that occur in nature usually leads to the formulation of the problems in terms of nonlinear differential equations. The fact that several of the classical theories of different branches of science have been formulated in terms of linear differential equations is evidence that in many important cases it is possible to linearize the equation under consideration without a loss of the essential features of the problem. For example, the theory of propagation of sound in air is based on the assumption that it involves adiabatic processes and that the pressure variation is infinitesimal, despite the fact that all audible sounds are associated with a finite pressure variation. The linear theory of sound explains the observed phenomena very well unless the sound intensity is great.

There are, however, certain phenomena that cannot be explained by a linearization of the equations that describe them, and it is then necessary to obtain a solution of the pertinent nonlinear differential equations in order to explain and predict the observed behaviour. At the present time, there is a growing importance in the study of nonlinear differential equations in connection with the following subjects:

1. Electrical circuits with saturable reactances and capacitances;
2. Large deflection elastic theory;
3. Mechanical vibrations;
4. Electrical machinery;
5. Aerodynamics;
6. Plasticity;
7. Wave motion of finite amplitude; etc.

Interest in developing analytical methods for solving nonlinear differential equations has been shown in Russia and is now growing greatly in the United States and Britain. Several books that summarize the various methods that have been devised to solve nonlinear differential equations have been published in recent years.[1–6] A survey of the existing literature on the solution of nonlinear differential equations indicates that the number of methods that have been devised for the solutions of nonlinear problems that arise in practice is small. It is the purpose of this discussion to present a method for solving nonlinear differential equations that is based on the theory of nonlinear integral equations,[7] and to apply it to some problems of importance in electrical engineering.

A Series Circuit with a Nonlinear Element

The general features of the method to be presented are clearly demonstrated by applying it to a series circuit containing a general nonlinear element. Such a circuit is represented by Fig. 1. This circuit consists of a linear component whose operational impedance, $Z(D)$ (where $D=d/dt$, the time derivative operator) is the argument of the impedance operator Z, in series with a nonlinear component. It will be assumed that the potential drop across the nonlinear component is a function $F(i)$ of the current that flows through it.

The differential equation that expresses the potential balance of the circuit may be written in operational form

$$Z(D)i(t)+F[i(t)]=e(t) \tag{1}$$

where $i(t)$ is the current that flows in the circuit and $e(t)$ is the applied potential. In order to formulate equation 1 as an integral equation, let the p-multiplied Laplace transforms be introduced.[8]

$$\mathfrak{L}i(t)=p\int_0^\infty \epsilon^{-pt}i(t)dt=I(p) \tag{2}$$

$$\mathfrak{L}e(t)=E(p) \tag{3}$$

$$\mathfrak{L}F[i(t)]=G(p) \tag{4}$$

Paper 53-265, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted November 10, 1952; made available for printing May 6, 1953.

L. A. Pipes is with the University of California, Los Angeles, Calif., and the United States Naval Ordnance Test Station, Inyokern, China Lake, Calif.

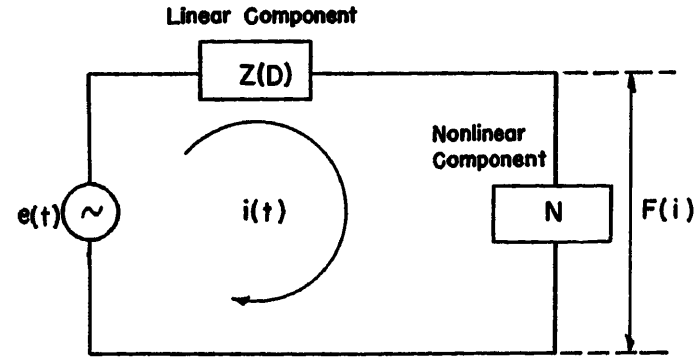

Fig. 1. General nonlinear circuit

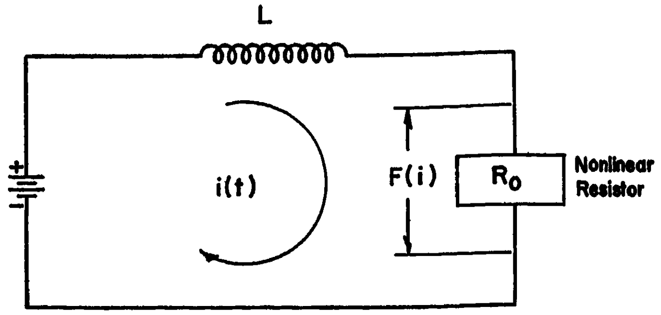

Fig. 2. Circuit with nonlinear resistor

Let it be assumed that initially the circuit is at rest so that at $t=0$, $i(0)=0$ and $q(0)=0$. That is, the initial current i and the charge separation, $q(t)$ of the circuit are both zero at $t=0$, therefore $i=\dot{q}$.

With these initial conditions, the Laplace transform of equation 1 is given by

$$Z(p)I(p)+G(p)=E(p) \tag{5}$$

or

$$I(p)=\frac{E(p)}{Z(p)}-\frac{G(p)}{Z(p)} \tag{6}$$

For simplicity, introduce the notation

$$H(p)=\frac{p}{Z(p)} \tag{7}$$

Hence equation 6 may be written in the form

$$I(p)=\frac{E(p)H(p)}{p}-\frac{G(p)H(p)}{p} \tag{8}$$

Let the inverse Laplace transform of $H(p)$ be $h(t)$, that is

$$\mathcal{L}^{-1}H(p)=\mathcal{L}^{-1}\frac{p}{Z(p)}=h(t) \tag{9}$$

The current of the circuit $i(t)$ may be obtained by taking the inverse Laplace transform of equation 8 in the form

$$i(t)=\mathcal{L}^{-1}\frac{E(p)H(p)}{p}-\mathcal{L}^{-1}\frac{G(p)H(p)}{p} \tag{10}$$

If the Faltung or superposition theorem of the theory of the Laplace transform[8] is applied to the right-hand member of equation 10, the result is obtained

$$i(t)=\int_0^t h(t-u)e(u)du-\int_0^t h(t-u)F[i(u)]du \tag{11}$$

If $F(i)=0$, so that the nonlinear component of the circuit is not present, then equation 11 reduces to

$$i_0(t)=\int_0^t h(t-u)e(u)du \tag{12}$$

This is the current that would flow in the circuit of Fig. 1 in the absence of the nonlinear component. Thus it is seen that equation 11 may be written

$$i(t)=i_0(t)-\int_0^t h(t-u)F[i(u)]du \tag{13}$$

This equation is known in the mathematical literature as Lalesco's nonlinear integral equation.[4] It can be shown[9] that the limit of the infinite sequence of functions

$$\begin{aligned}
i_0(t)&=\int_0^t h(t-u)e(u)du\\
i_1(t)&=i_0(t)-\int_0^t h(t-u)F[i_0(u)]du\\
i_2(t)&=i_0(t)-\int_0^t h(t-u)F[i_1(u)]du \qquad (14)\\
&\cdot\\
&\cdot\\
&\cdot\\
i_{n+1}(t)&=i_0(t)-\int_0^t h(t-u)F[i_n(u)]du
\end{aligned}$$

is the solution of integral equation 13. That is

$$i(t)=\lim_{n\to\infty} i_n(t) \tag{15}$$

The investigation of the convergence of sequence 14 is given in reference 9. The results of this investigation indicate that the sequence converges rapidly in applications of this method of solution to special cases arising from physical problems.

Solution of the Integral Equation by an Operational Procedure

A convenient operational procedure which has been found useful in the calculation of the sequence of functions, $i_n(t)$, is based on the inverse Laplace transform of equation 6, which may be written in the form

$$i(t)=\mathcal{L}^{-1}I(p)=\mathcal{L}^{-1}\frac{E(p)}{Z(p)}-\mathcal{L}^{-1}\left\{\frac{\mathcal{L}F[i(t)]}{Z(p)}\right\} \tag{16}$$

The current $i_0(t)$ is given by

$$i_0(t)=\mathcal{L}^{-1}\frac{E(p)}{Z(p)} \tag{17}$$

Hence equation 16 may be written in the form

$$i(t)=i_0(t)-\mathcal{L}^{-1}\left\{\frac{\mathcal{L}F[i(t)]}{Z(p)}\right\} \tag{18}$$

The sequence of functions, $i_1(t)$, $i_2(t)$... $i_n(t)$ of equation 14 may be conveniently expressed by equations

$$\begin{aligned}
i_1(t)&=i_0(t)-\mathcal{L}^{-1}\left\{\frac{\mathcal{L}F}{Z(p)}[i_0(t)]\right\}\\
i_2(t)&=i_0(t)-\mathcal{L}^{-1}\left\{\frac{\mathcal{L}F}{Z(p)}[i_1(t)]\right\} \qquad (19)\\
&\cdot\\
&\cdot\\
&\cdot\\
i_{n+1}(t)&=i_0(t)-\mathcal{L}^{-1}\left\{\frac{\mathcal{L}F}{Z(p)}[i_n(t)]\right\}
\end{aligned}$$

In practice, it is usually found that the sequence, $i_1(t)$, $i_2(t)$, ... may be more simply computed by equation 19 than by equation 14, because a table of suitable Laplace transforms assists in effecting the required integrations.

A Circuit with a Nonlinear Resistor

In order to illustrate the general method of the foregoing section, it will be applied to obtain the current in the circuit of Fig. 2. This circuit consists of a constant potential E in series with a linear inductor and a nonlinear resistor. It will be assumed that the potential drop across the nonlinear resistor is given by,

$$F(i)=R_0i^2 \tag{20}$$

where R_0 is a constant. If it is assumed that the potential E is suddenly impressed on the circuit at $t=0$, with zero initial current, then the current gradually increases until it reaches a final steady-state value. The differential equation of the circuit is

$$L\frac{di}{dt}+R_0i^2=E \quad \text{for } t>0 \tag{21}$$

In this simple case, the impedance $Z(p)=Lp$, where L is the inductance parameter of the linear inductor. The function $H(p)$ is now given by

$$H(p)=\frac{p}{Lp}=\frac{1}{L}; \quad h(t)=\frac{1}{L} \tag{22}$$

In this case, integral equation 11 reduces to

$$t(i)=\int_0^t \frac{E}{L}dt-\frac{R_0}{L}\int_0^t i^2dt \tag{23}$$

The sequence of functions 14 may be obtained by direct integration, and are given by

$$i_0(t)=\frac{Et}{L}$$

$$i_1(t)=\frac{Et}{L}-R_0\frac{E^2t^3}{3L^3} \tag{24}$$

$$i_2(t)=\frac{Et}{L}-R_0\frac{E^2t^3}{3L^3}+2R_0^2\frac{E^3t^5}{15L^5}-R_0\frac{E^4t^7}{63L^7}$$

$$\vdots$$

Differential equation 21 may be integrated by separating the variables, and writing it in the form

$$t=L\int_0^t \frac{di}{(E-R_0i^2)} \tag{25}$$

If the indicated integration is performed, the current may be shown to be

$$i(t)=\sqrt{\frac{E}{R_0}}\tanh\left(\frac{t}{L}\sqrt{R_0E}\right) \tag{26}$$

If equation 26 is expanded in powers of t, the correspondence between the sequence of functions, $i_1(t)$, $i_2(t)$,. . .and the power series expansion for $i(t)$ is clearly evident. The final steady-state current i_s is given by

$$i_s=\lim_{t\to\infty}\sqrt{\frac{E}{R_0}}\tanh\left(\frac{t}{L}\sqrt{R_0E}\right)=\sqrt{\frac{E}{R_0}} \tag{27}$$

as is otherwise evident from physical considerations.

A Circuit with a Nonlinear Inductor

An important technical problem is the computation of the growth of current in a circuit containing a nonlinear inductor produced by the application of a constant potential source to a circuit such as the one depicted by Fig. 3. This circuit contains a constant potential source in series with a linear resistor and inductor. This combination is, in turn, in series with a nonlinear inductor. The nonlinear inductor consists of a coil of N turns, wound on a magnetic core having a cross-sectional area A and a mean length s. It will be assumed that at $t=0$, the circuit is inert and that the potential E_0 is impressed on the circuit at $t=0$, so that $i(0)=0$.

The differential equation of the circuit is

$$L\frac{di}{dt}+Ri+N\frac{d\phi}{dt}=E_0 \quad t>0 \tag{28}$$

where ϕ is the magnetic flux in the core of the nonlinear inductor. In order to express the flux ϕ in terms of the current i, it is necessary to apply Ampère's law

$$Hs=Ni \tag{29}$$

in suitable units, and to express the magnetization, or B—H curve of the magnetic material of the core in an analytical form. For many practical purposes, the magnetization curve may be represented by the third-order polynomial

$$B=\mu_0H-aH^3 \tag{30}$$

where a is a constant determined empirically, and μ_0 is the initial permeability of the core material, defined by the equation

$$\mu_0=\left(\frac{dB}{dH}\right)_{H=0} \tag{31}$$

If A is the mean cross-sectional area of the inductor core, the flux ϕ may be expressed in the form

$$\phi=BA=A(\mu_0H-aH^3)=\mu_0\frac{ANi}{s}-Aa\left(\frac{Ni}{s}\right)^3 \tag{32}$$

It is useful to introduce the initial inductance of the nonlinear inductor, defined by the equation

$$L_0=\mu_0\frac{N^2}{s}A \tag{33}$$

into the analysis. In terms of this parameter, equation 32 may be written in the form

$$\phi=L_0\frac{i}{N}-c_3i^3 \tag{34}$$

where

$$c_3=Aa\frac{N^3}{s^3} \tag{35}$$

If equation 34 is substituted into equation 28 the result is

$$(L+L_0)\frac{di}{dt}+Ri-Nc_3\frac{d\,i^3}{dt}=E_0 \tag{36}$$

Let L_t be the total inductance of the circuit, given by

$$L_t=(L+L_0)=L+\mu_0\frac{N^2}{s}A \tag{37}$$

and

$$k=Nc_3=Aa\frac{N^4}{s^3} \tag{38}$$

In terms of these parameters, equation 36 may be written in the form

$$L_t\frac{di}{dt}+Ri-kDi^3=E_0 \tag{39}$$

This equation is of the form of equation 1 with

$$Z(D)=L_tD+R \tag{40}$$

and

$$F(i)=kDi^3 \tag{41}$$

In this special case, we have

$$H(p)=\frac{p}{Z(p)}=\frac{p}{L_tp+R} \tag{42}$$

$$h(t)=\mathfrak{L}^{-1}H(p)=\frac{\epsilon^{-bt}}{L_t}$$

where

$$b=\frac{R}{L_t} \tag{43}$$

The integral equation satisfied by the current in the circuit, is in this case

$$i(t)=i_0(t)-\frac{k}{L_t}\int_0^t \exp\,[-b(t-u)]Di^3(u)du \tag{44}$$

where

$$i_0(t)=\mathfrak{L}^{-1}\frac{E_0}{(L_tp+R)}=\frac{E_0}{R}(1-\epsilon^{-bt}) \tag{45}$$

In order to obtain the approximate solution of nonlinear integral equation 44, it is convenient to write it in the operational form of equation 18; it then becomes

$$i(t)=\frac{E_0}{R}(1-\epsilon^{-bt})-\mathfrak{L}^{-1}\frac{[kLDi^3]}{(L_tp+R)} \tag{46}$$

If equation 45 is cubed, the result is

$$i_0^3(t)=\frac{E_0^3}{R^3}(1-3\epsilon^{-bt}+3\epsilon^{-2bt}-\epsilon^{-3bt}) \tag{47}$$

Hence by consulting a table of Laplace transforms,[8] we obtain

$$kLDi_0^3=\frac{kE_0^3}{R^3}p\left[1-\frac{3p}{(p+b)}+\frac{3p}{(p+2b)}-\frac{p}{(p+3b}\right] \tag{48}$$

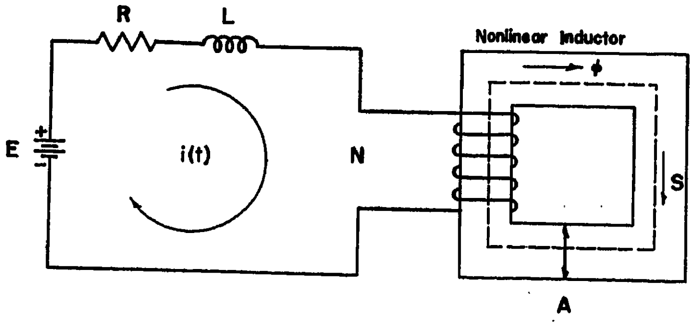

Fig. 3. Circuit with nonlinear inductor

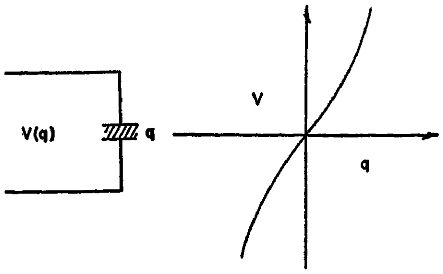

Fig. 4. Nonlinear capacitor and its saturation curve

The second approximation to the solution of equation 46 is given by equation 19; in this case it has the form

$$i_1(t)=\frac{E_0}{R}(1-\epsilon^{-bt})-\mathcal{L}^{-1}\frac{[kLDi_0{}^3]}{(L_tp+R)} \tag{49}$$

By the use of equation 48 we obtain

$$\frac{kLDi_0{}^3}{(L_tp+R)}=\frac{kE_0{}^3}{L_tR^3}\left[\frac{p}{(p+b)}-\frac{3p^2}{(p+b)^2}+\frac{3p}{(p+2b)(p+b)}-\frac{p}{(p+3b)(p+b)}\right] \tag{50}$$

The inverse transform of equation 50 is

$$\mathcal{L}^{-1}\frac{kLDi_0{}^3}{(L_tp+R)}=\frac{kE_0{}^3}{L_tR^3}\times\left[3bt\epsilon^{-bt}-\frac{9}{2}\epsilon^{-bt}+6\epsilon^{-2bt}-\frac{3}{2}\epsilon^{-3bt}\right] \tag{51}$$

If equation 51 is substituted into equation 49 the second approximation for the current in the circuit is seen to be

$$i(t)=\frac{E_0}{R}(1-\epsilon^{-bt})-\frac{kE_0{}^3}{L_tR^3}\times\left[3bt\epsilon^{-bt}-\frac{9}{2}\epsilon^{-bt}+6\epsilon^{-2bt}-\frac{3}{2}\epsilon^{-3bt}\right] \tag{52}$$

The higher approximations may be obtained by computing more functions of sequence 19.

A Circuit with a Nonlinear Capacitor

The dielectric properties of many substances have been discovered to have nonlinear characteristics as a consequence of the alignment of the electric dipoles of their atomic ions.[10] These substances are said to exhibit the ferroelectric effect. If one of these substances is used as the dielectrical of a capacitor, as shown in Fig. 4, the potential difference across the plates of the capacitor produced by a charge separation q will be found to be a function of q, $[V(q)]$ that is not linear. The following analytical expression has been found adequate to represent $V(q)$ for many substances exhibiting the ferroelectric effect.[11]

$$V(q)=\frac{S_0}{a}\sinh(aq) \tag{53}$$

In this expression S_0 is the initial elastance of the capacitor defined by the equation

$$S_0=\left(\frac{dV}{dq}\right)_{q=0} \tag{54}$$

This is the reciprocal of the initial capacitance defined by

$$C_0=\left(\frac{dq}{dV}\right)_{q=0} \tag{55}$$

The constant a in equation 53 is chosen in such a manner so that this expression will give the best fit to the empirical saturation curve $V(q)$ of the capacitor under consideration. It may be noted that the quantity a is a measure of the degree of the nonlinearity of the nonlinear capacitor. That is, if $a=0$, the capacitor is linear and $V(q)=S_0q$.

To illustrate the general procedure in the analysis of a circuit containing a nonlinear capacitor,[11] consider the circuit of Fig. 5. This circuit consists of a linear resistor in series with a nonlinear capacitor and a periodic electromotive force. If the potential drop across the nonlinear capacitor is expressed by equation 53, Kirchhoff's electromotive-force law, applied to this circuit leads to the differential equation

$$R\frac{dq}{dt}+\frac{S_0}{a}\sinh(aq)=E_m\sin(\omega t) \tag{56}$$

where q is the charge separation on the plates of the capacitor. The current of the circuit is given by

$$i=\frac{dq}{dt} \tag{57}$$

In order to completely determine the problem, it will be assumed that at $t=0$, the harmonic potential is impressed on the circuit, and that $q(0)=0$. Let

$$b=\frac{S_0}{R} \tag{58}$$

Equation 56 may be written in the form

$$\frac{dq}{dt}=\frac{E_m}{R}\sin(\omega t)-\frac{S_0}{aR}\sinh(aq) \tag{59}$$

If the term $(S_0q)/R$ is added to both members of equation 59, the result may be written in the form

$$\frac{dq}{dt}+bq=\frac{E_m}{R}\sin(\omega t)+\frac{b}{a}[aq-\sinh(aq)] \tag{60}$$

By the methods of the series-circuit section, it can be shown that the charge separation $q(t)$ satisfies the integral equation

$$q(t)=\frac{E_m}{R}\int_0^t \exp[b(u-t)]\sin(\omega u)du+\frac{b}{a}\int_0^t \exp[b(u-t)]\{aq(u)-\sinh[aq(u)]\}du \tag{61}$$

In order to obtain the approximate solution of equation 61, it is expedient to proceed by an operational method similar to that of equation 19. To do this, introduce the Laplace transform of the charge separation $q(t)$ by the equation

$$\mathcal{L}_q(t)=Q(p) \tag{62}$$

Since $q(0)=0$, the Laplace transform of equation 60 is

$$(p+b)Q=\frac{E_m}{R}\frac{\omega p}{(p^2+\omega^2)}+\frac{b}{a}\mathcal{L}[aq-\sinh(aq)] \tag{63}$$

The inverse transform of equation 63 gives $q(t)$ in the form

$$q(t)=q_0(t)+\mathcal{L}^{-1}\left\{\frac{b}{a}\frac{\mathcal{L}[aq-\sinh(aq)]}{(p+b)}\right\} \tag{64}$$

where

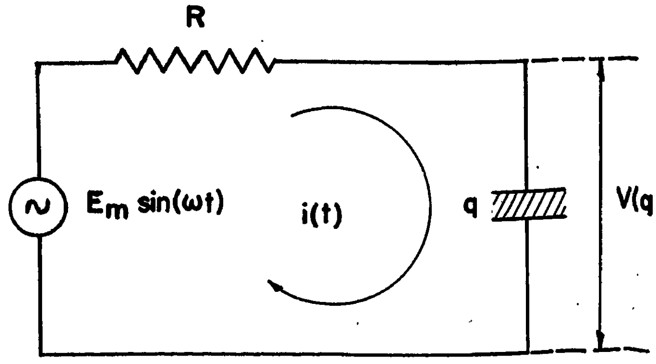
$$q_0(t)=\mathcal{L}^{-1}\frac{\frac{E_m}{R}\omega p}{(p+b)(p^2+\omega^2)}=\frac{E_m}{R}\omega\left\{\frac{\epsilon^{-bt}}{(b^2+\omega^2)}+\frac{\sin(\omega t-\theta)}{\omega\sqrt{(b^2+\omega^2)}}\right\} \tag{65}$$

and

$$\tan\theta=\frac{\omega}{b}$$

Here, $q_0(t)$ is the linear approximation to the function $q(t)$. The second approximation $q_1(t)$ is given by substituting $q_0(t)$ into the right-hand member of equation 64 and is

Fig. 5. Circuit with nonlinear capacitor



$$q_1(t)=q_0(t)+\mathcal{L}^{-1}\left\{\frac{b}{a}\,\mathcal{L}\left[\frac{aq_0-\sinh(aq_0)}{(p+b)}\right]\right\} \tag{66}$$

The function $\sinh(aq_0)$ has the power series expansion

$$\sinh(aq_0)=(aq_0)+\frac{(aq_0)^3}{3!}+\frac{(aq_0)^5}{5!}+\frac{(aq_0)^7}{7!}+\ldots \tag{67}$$

It has been found that for most nonlinear dielectric materials the parameter a is very small. If terms of the order of a^4 and higher are neglected

$$[aq_0-\sinh(aq_0)]\frac{1}{a}=-\frac{a^2}{6}q_0^3 \tag{68}$$

To this order of approximation, equation 66 reduces to

$$q_1(t)=q_0(t)-\frac{a^2b}{6}\mathcal{L}^{-1}\left\{\frac{\mathcal{L}q_0^3}{(p+b)}\right\} \tag{69}$$

THE STEADY-STATE SOLUTION

If the second order approximation to the steady-state response of the circuit is desired, the steady-state linear approximation $q_{0s}(t)$ after the transient term involving ϵ^{-bt} has disappeared may be used. The linear steady-state term is given by equation 65, in the form

$$q_{0s}(t)=A\sin(\phi) \tag{70}$$

where

$$A=\frac{E_m}{R\sqrt{(b^2+\omega^2)}}$$

and

$$\phi=(\omega t-\theta) \tag{71}$$

The second order steady-state approximation is given by substituting q_{0s} in the right-hand member of equation 69 in the form

$$q_{1s}(t)=q_{0s}(t)-\frac{a^2b}{6}\mathcal{L}^{-1}\frac{\mathcal{L}q_{0s}^3}{(p+b)} \tag{72}$$

and retaining the periodic terms. Now

$$q_{0s}^3=A^3\sin^3\phi=\frac{A^3}{4}(3\sin\phi-\sin 3\phi)=\frac{A^3}{4}[3\sin(\omega t-\theta)-\sin 3(\omega t-\theta)] \tag{73}$$

In order to compute the steady-state part of $q_{1s}(t)$ by the use of equation 72, let

$$f(t)=\mathcal{L}^{-1}\left[\frac{\mathcal{L}q_{0s}^3}{(p+b)}\right] \tag{74}$$

Hence

$$\mathcal{L}f(t)=\frac{\mathcal{L}q_{0s}^3}{(p+b)} \tag{75}$$

It can therefore be seen that $f(t)$ satisfies the differential equation

$$(D+b)f(t)=q_{0s}^3=\frac{A^3}{4}[3\sin(\omega t-\theta)-\sin(3\omega t-3\theta)] \tag{76}$$

The periodic part of the solution of equation 76 is

$$f(t)=\frac{3A^3}{4}\frac{\sin(\omega t-2\theta)}{\sqrt{(b^2+\omega^2)}}-\frac{A^3}{4}\frac{\sin(3\omega t-3\theta-u)}{\sqrt{(b^2+9\omega^2)}} \tag{77}$$

where

$$\tan(u)=\frac{3\omega}{b} \tag{78}$$

Hence, the second order periodic or steady-state approximation as calculated from equation 72 is given by

$$q_{1s}(t)=A\sin(\omega t-\theta)-\frac{3a^2}{24}bA^3\frac{\sin(\omega t-2\theta)}{\sqrt{(b^2+\omega^2)}}+\frac{a^2}{24}bA^3\frac{\sin(3\omega t-3\theta-u)}{\sqrt{(b^2+9\omega^2)}} \tag{79}$$

To this order of approximation, the steady-state charge oscillation is seen to contain a third-harmonic component not in phase with the fundamental. The steady-state current is given by

$$i_{1s}(t)=\frac{d}{dt}[q_{1s}(t)] \tag{80}$$

Quasilinear Oscillations and the van der Pol Equation

A very important equation in the theory of vacuum tube oscillators is van der Pol's equation.[11] This equation is usually written in the form

$$\frac{d^2x}{dt^2}+\mu(x^2-1)\frac{dx}{dt}+\omega^2x=0 \tag{81}$$

where μ and ω are constants.

The nature of the solutions of equation 81 for various values of the parameter μ has been exhaustively studied by van der Pol.[12,13] The case for μ a large number is the basis of van der Pol's theory of relaxation oscillations.[13] If $\mu=0$, the van der Pol equation reduces to that of a simple oscillator and the solutions of equation 81 are then of the form

$$x=C\sin(\omega t+\phi) \tag{82}$$

where C and ϕ are arbitrary amplitude and phase constants. If μ is numerically small, van der Pol's analysis indicates that harmonic oscillatory solutions of equation 81 exist, but with a definite amplitude. Such oscillations are known as quasilinear vibrations in the current literature. It is here proposed to study the nature of these solutions by the use of the method of integral equations. In order to do this, it is convenient to recognize that the nonlinear term of equation 81 may be written in the form

$$x^2\dot{x}=\frac{1}{3}\frac{dx^3}{dt} \tag{83}$$

In accordance with this, equation 81 may be written in the form

$$\frac{d^2x}{dt^2}+\omega^2x=\mu\left[\dot{x}-\frac{1}{3}\frac{dx^3}{dt}\right] \tag{84}$$

Let it now be assumed that equation 84 satisfies the following conditions at $t=0$

$$x(0)=a;\quad \dot{x}(0)=0 \tag{85}$$

Introduce the Laplace transform

$$\mathcal{L}x(t)=y(p) \tag{86}$$

The transform of equation 84 with the initial conditions given by equations 85 is

$$(p^2+\omega^2)y=p^2a+\mu\mathcal{L}\left[\dot{x}-\frac{1}{3}\frac{dx^3}{dt}\right] \tag{87}$$

Hence

$$y=\frac{p^2a}{(p^2+\omega^2)}+\frac{\mu}{(p^2+\omega^2)}\mathcal{L}\left[\dot{x}-\frac{1}{3}\frac{dx^3}{dt}\right] \tag{88}$$

The inverse transform of equation 88 may be expressed in the form of the integral equation

$$x(t)=a\cos(\omega t)+\frac{\mu}{\omega}\int_0^t\sin[\omega(t-u)]\times\left\{\frac{dx}{du}(u)-\frac{1}{3}\frac{dx^3}{du}(u)\right\}du \tag{89}$$

If $\mu=0$, the solution of the resulting linear equation is given by

$$x_0(t)=a\cos(\omega t) \tag{90}$$

The second-order periodic solution of equation 81 may be obtained in the following manner, by a sequence similar to that of equation 19. Let the transform of the solution of linear equation 90 be given by

$$y_0=\mathcal{L}x_0(t)=\frac{p^2a}{(p^2+\omega^2)} \tag{91}$$

Let $y_1(p)$ be the transform of the second approximation to the solution of equation 81. This is given by substituting $x_0(t)$ in the right-hand member of equation 88 in the form

$$y_1=y_0+\frac{\mu}{(p^2+\omega^2)}\mathcal{L}\left[\dot{x}_0-\frac{1}{3}\frac{dx_0^3}{dt}\right] \tag{92}$$

We now calculate the functions

$$\dot{x}_0(t)=-\omega a\sin(\omega t) \tag{93}$$

and

$$x_0^3(t)=\frac{a^3}{4}[\cos(3\omega t)+3\cos(\omega t)] \tag{94}$$

If equations 93 and 94 are substituted into equation 92, the result is

$$y_1=y_0+\frac{\mu\omega}{(p^2+\omega^2)}+\frac{\mu\omega}{(p^2+\omega^2)}\mathfrak{L}\left[\left(\frac{a^3}{4}-a\right)\times \sin(\omega t)+\frac{a^3}{4}\sin(3\omega t)\right] \quad (95)$$

The indicated Laplace transforms may be obtained from a table of transforms and equation 95, written as

$$y_1=y_0+\mu\left(\frac{a^3}{4}-a\right)\frac{p\omega^2}{(p^2+\omega^2)^2}+ \frac{3}{4}\mu a^3\omega^2\frac{p}{[p^2+(9\omega)^2](p^2+\omega^2)} \quad (96)$$

A table of Laplace transforms yields the result

$$\mathfrak{L}^{-1}\frac{p\omega^2}{(p^2+\omega^2)^2}=\frac{1}{2\omega}[\sin(\omega t)-(\omega t)\cos(\omega t)] \quad (97)$$

Thus, it is seen that unless

$$\left(\frac{a^3}{4}-a\right)=0 \quad (98)$$

the inverse transform of equation 96 will give rise to a secular term of the form of equation 97, and the solution will not be periodic. Hence the possible amplitudes a of the periodic steady-state solution to this order of approximation are the solutions of equation 98. These are given by

$$a=0 \quad \text{or} \quad a=\pm 2 \quad (99)$$

This is the well-known result for the possible amplitudes of the periodic solutions of equation 81, for small values of μ obtained by van der Pol[12] using another method of analysis. If $a=2$, the second-order periodic solution is obtained by computing the inverse transform of equation 96. This solution is

$$x_1(t)=2\cos(\omega t)+\frac{\mu}{4\omega}[3\sin(\omega t)-\sin(3\omega t)] \quad (100)$$

For small values of μ/ω, the first term of the right member of equation 100 is the dominant one. This is the quasilinear solution of equation 81.

Conclusion

The mathematical technique for the solution of certain nonlinear differential equations of importance in electric circuit theory has as its theoretical basis the theory of Lalesco's nonlinear differential equation.[7] It has been found, however, that in order to obtain practical results in an efficient manner, an operational procedure such as that given in the series-circuit section is preferable to the classical iteration procedure given by equation 14.

Application of the methods given in this paper to the solution of several practical nonlinear problems has indicated that useful results can be obtained with an economy of effort. The method is particularly efficient in the solution of differential equations in which the nonlinear terms are multiplied by parameters whose numerical values are small.

The First-Order Behavior of Separable Oscillators

DAVID C. DE PACKH
NONMEMBER AIEE

Synopsis: The first-order performance of oscillators satisfying Groszkowski's criterion of separability of linear and nonlinear elements can be predicted in the first order with a knowledge only of the Nyquist diagram of the linear portion of the circuit, the amplitude characteristic of the nonlinear portion, and the loop gain. The best form of nonlinear characteristic from the standpoint of frequency stability is one in which the odd-power terms are dominant.

IT IS THE purpose of this paper to present the analysis of electric oscillators whose linear and nonlinear elements are separable in the first order, that is, under the assumption that the deviation of the oscillation from the simple harmonic form is small compared with the total amplitude. Although this criterion of separability is a stringent one in practice because of Miller effect, grid loading, plate resistance variations, and similar phenomena which essentially make the Nyquist[1] diagram a function of the amplitude, it is nevertheless clear that the principles of separable oscillators admit of a simple extension to the nonseparable case in the first order; the only additional requirement is a knowledge of the behavior of the resonant point of the Nyquist diagram with amplitude. This behavior can evidently be obtained with the feedback loop open. The frequency variation imposed by the separable oscillator theory is then added to this variation to give the total frequency behavior. In many practical cases the separability condition is nearly enough satisfied so that, except for the most precise results, the separable oscillator theory can be applied without correction.

This work will be termed a first-order analysis although in actuality second-order effects such as the frequency shift require the retention of terms of the

David C. dePackh is with the Naval Research Laboratory, Washington, D. C.

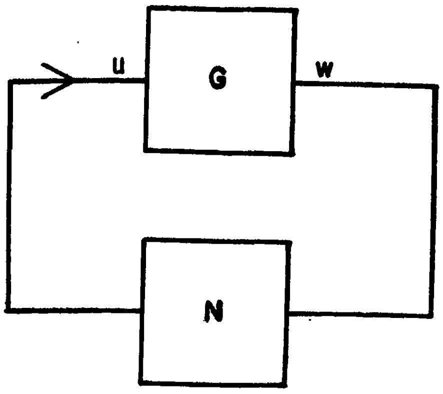

Fig. 1. Feedback loop of electric oscillator. Arrow indicates direction of energy flow

second order of small quantities. The analysis is evidently applicable also to oscillators of any nonelectrical, for example, mechanical, type which can be separated into linear and nonlinear elements whose functions are respectively expressed by a Nyquist diagram and a power series amplitude characteristic.

The problem of electric oscillators has been treated by many authors, and van der Pol[2] has shown how the amplitude may be derived in the first order with a knowledge of the characteristic of the nonlinear element. There is also considerable literature to indicate the effect of the harmonic content of the oscillation on the frequency of the system, at least for ordinary resonant inductance-capacitance circuits or their equivalent as the frequency-determining element. The literature, however, is lacking in a general treatment of the behavior of the system in terms of the nonlinear characteristic and a general form of frequency-determining element, and in general criteria for frequency stability with variation of the feedback. It is true that in the latter connection the knowledge of the frequency behavior in terms of the harmonic content has led certain workers, for example, Groszkowski,[3] to insert filters to remove the harmonics and in that way to arrive at a constant frequency. There are other means to stabilize the frequency by operating on the linear, frequency-determining portion of the circuit, either by making the harmonic responses of the network such that the total frequency shift contributed by the harmonic content vanishes, or by the use of a circuit whose effective Q is high, so that $\partial\psi/\partial\omega$ is large at resonance, where ω is the angular velocity and ψ is the phase on the Nyquist diagram. There is, however, an important criterion relative to the form of the nonlinear characteristic which apparently has not been explicitly given.

Reference 2 indicates by implication what this criterion must be. Van der Pol has indicated that the even-power nonlinear terms in the nonlinear characteristic are almost without effect in determining the amplitude since the power integral for such terms vanishes identically. One may conclude immediately from this observation that in any oscillating system in which even-power nonlinear terms are dominant the amplitude is likely to grow very large, to grow, in fact, until the odd-power content can limit the amplitude. But by this time the even-harmonic content is likely to be so large that the frequency will have undergone a considerable change. It would therefore appear that the best way of maintaining stable frequency behavior is to make the odd-power terms of the nonlinear characteristic dominant. An experimental verification of this conjecture as well as a theoretical one are given herein.

To treat this problem generally it seems appropriate to use the Nyquist diagram rather than to derive results for any specific system. It is plain that since this diagram can be experimentally obtained, and since the oscillating system is assumed to be in the steady state, there should be no need to have recourse to a differential equation.

Theoretical Data

The oscillating system is best thought of as comprising a nonlinear gain G and a frequency-determining linear element N in a closed loop, see Fig. 1. The functions of these two elements are assumed to be separate, which means that the gain G is single-valued in its output w with respect to its input u. Therefore the integral of $w\,du$ over 1 cycle of the oscillation must vanish; thus

$$\oint w\,du=0 \qquad (1)$$

This integral was introduced in a very similar form by Groszkowski.[3] Now suppose

$$u\equiv A\cos\theta+\sum_{n=2}^{\infty}\epsilon_n\cos(n\theta+\phi_n)$$

and

$$w\equiv C[v_0+A'\cos(\theta+\phi)+\sum_{n=2}^{\infty}\epsilon_n'\cos(n\theta+\phi_n')]$$

where C is a constant. The element N will be assumed to have zero response at $\omega=0$, this being the case in nearly all practical circumstances. Hence u is to contain no constant term.

Then carrying out the integration, Equation 1 gives

$$AA'\sin\phi=-\sum_{n=2}^{\infty}n\epsilon_n\epsilon_n'\sin(\phi_n'-\phi_n)$$

θ is of course $\omega_0 t$, where ω_0 is the steady-state angular velocity. The amplitudes and phases of the various harmonics are related through the passive element N in the following way

$$\epsilon_n=C\epsilon_n'|N_n|;\ \phi_n-\phi_n'=\psi_n$$

where $N(\omega)$, the gain of the element N, is given by

$$N(\omega)=|N(\omega)|\epsilon^{i\psi(\omega)}$$

Accordingly

$$\sin\psi_1=-\sum_{n=2}^{\infty}n(\epsilon_n/A)^2(1/\nu_n)\sin\psi_n;$$

$$\nu_n\equiv|N_n|/|N_1| \qquad (2)$$

Since ψ_1 corresponds to the altered fundamental frequency on the Nyquist diagram, equation 2 is analogous to the well-known expressions giving the frequency shift in terms of the harmonic content.

Let us now alter slightly the arrangement of Fig. 1 by multiplying the gain G and dividing the factor N by a constant equal to the scalar gain of N at resonance. This changes the passive element into N', which has unity gain at its resonant frequency. The element N' will be referred to hereafter as the Nyquist. The resulting nonlinear element G' may be divided into a linear factor k and a resid-

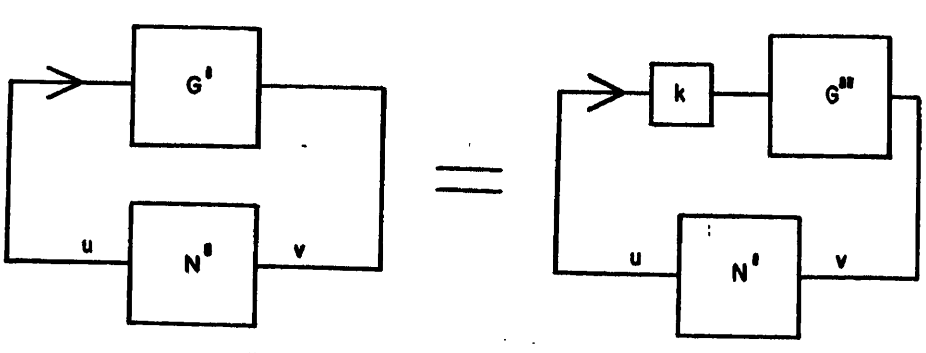

Fig. 2. Equivalent circuits to Fig. 1

ual distorting element G''; see Fig. 2. The characteristic of G' is then expressible as

$$v=ku+a_2(ku)^2+a_3(ku)^3+\dots \qquad (3)$$

and we take $v=w/C$.

If $u=A\cos\theta+\epsilon$, where ϵ represents the harmonic content, we have

$$\begin{aligned} v=kA\cos\theta+&\\ &k\epsilon+\beta_2\cos^2\theta+\beta_3\cos^3\theta+\dots+\\ &(\epsilon/A)(2\beta_2\cos\theta+3\beta_3\cos^2\theta+\dots)+\\ &(\epsilon^2/A^2)(\beta_2+3\beta_3\cos\theta+6\beta_4\cos^2\theta+\dots)+\\ &\dots \end{aligned} \qquad (3\text{A})$$

where $\beta_m\equiv a_m\ (kA)^m$. The expression thus written is arranged in ascending order, since β_m is assumed to be a small quantity of the order of ϵ. Only the first three lines of the expression will be retained.

Before proceeding further, it is worth while to derive a relation of the form

$$\sum_{m=2}^{\infty}\beta_m\cos^m\theta=\sum_{n=0}^{\infty}\gamma_n\cos n\theta \qquad (4)$$

One has

$$\begin{aligned}\cos^m\theta&=[(\epsilon^{j\theta}+\epsilon^{-j\theta})/2]^m\\ &=(1/2^m)\{(\epsilon^{jm\theta}+\epsilon^{-jm\theta})+\\ &\quad m[\epsilon^{j(m-2)\theta}+\epsilon^{-j(m-2)\theta}]+\\ &\quad [m(m-2)/2!][\epsilon^{j(m-4)\theta}+\\ &\qquad\qquad \epsilon^{-j(m-4)\theta}]+\dots\}\\ &=(1/2^{m-1})[\cos m\theta+\\ &\qquad\qquad m\cos(m-2)\theta+\dots]\\ &=(1/2^{m-1})\sum_{k=0}^{[m/2]}B_{km}\cos(m-2k)\theta\end{aligned}$$

where $B_{km}\equiv m!/[k!(m-k)!]$ for $m\neq 2k$, $B_{(m/2),m}\equiv m!/[2(m/2)!^2]$, this case occurring only for m even.

Then

$$\sum_{m=2}^{\infty}\beta_m\cos^m\theta=\sum_{m=2}^{\infty}(\beta_m/2^{m-1})\sum_{k=0}^{[m/2]}B_{km}\times \cos(m-2k)\theta$$

On writing $n\equiv m-2k$ and rearranging the order of summation, one has

$$\sum_{m=2}^{\infty}\beta_m\cos^m\theta=\sum_{m=k}^{\infty}\sum_{k=0}^{\infty}(\beta_{n+2k}/2^{n+2k-1})\times B_{k,n+2k}\cos n\theta$$

$$(\beta_0=\beta_1\equiv 0)$$

Hence in equation 4 γ_n is given by

$$\gamma_n=\sum_{k=0}^{\infty}(\beta_{n+2k}/2^{n+2k-1})B_{k,n+2k} \qquad (5)$$

To find the frequency shift, the coefficient of the quadrature fundamental term must be determined, that is, the coefficient of $\sin\theta$. This term represents a phase shift produced by G' which must be compensated by N' and which accordingly produces a change in frequency.

If σ is the coefficient of $\sin\theta$, then

$$\sigma=(1/\pi)\int_0^{2\pi}v\sin\theta\,d\theta$$

Evidently only the third line of equation 3(A), neglecting all lines beyond the third, can contain $\sin\theta$. The value of the third line is

$$\begin{aligned}-(\epsilon/A\sin\theta)(d/d\theta)&\sum_{m=2}^{\infty}\beta_m\cos^m\theta\\ &=(\epsilon/A\sin\theta)\sum_{n=0}^{\infty}n\gamma_n\sin n\theta\end{aligned}$$

from equation 4. Therefore

$$\begin{aligned}\sigma&=(1/\pi A)\int_0^{2\pi}\left(\sum_{n=2}^{\infty}-\epsilon_n\sin n\theta\sin\phi_n\right)\times\left(\sum_{n=0}^{\infty}n\gamma_n\sin n\theta\right)d\theta\\ &=-(1/A)\sum_{n=2}^{\infty}n\epsilon_n\gamma_n\sin\phi_n\end{aligned} \qquad (6)$$

Now $\sigma/kA=\tan\psi_1\cong\sin\psi_1$, so that equation 6 divided by kA must be equal (in the first order) term by term with equation 2. Therefore

$$\epsilon_n=(\nu_n\gamma_n/k)(\sin\phi_n/\sin\psi_n) \qquad (7)$$

If only the first two lines of equation 3(A) are retained, it is found that

$$\begin{aligned}v&=ku+\sum_{n=0}^{\infty}\gamma_n\cos n\theta\\ &=\gamma_0+(kA+\gamma_1)\cos\theta+\\ &\qquad\sum_{n=2}^{\infty}[k\epsilon_n\cos(n\theta+\phi_n)+\gamma_n\cos n\theta]\\ &=v_0+A'\cos\theta+\sum_{n=2}^{\infty}\epsilon'_n\cos(n\theta+\phi'_n)\end{aligned}$$

neglecting, in the latter relation, the second-order fundamental phase shift. Hence we derive, on comparing the phase angles of the harmonics

$$\begin{aligned}\cot\phi'_n&=\cot(\phi_n-\psi_n)\\ &=\cot\phi_n+\gamma_n/(k\epsilon_n\sin\phi_n)\end{aligned}$$

Combining this with equation 7, we can solve it, finding

$$\cot\phi_n=\cot\psi_n-\nu_n\csc\psi_n \qquad (8)$$

so that

$$\epsilon_n=(\gamma_n\nu_n/k)(1+\nu_n^2-2\nu_n\cos\psi_n)^{-1/2} \qquad (7\text{A})$$

Putting this into equation 2, we have

$$\sin\psi_1=-\sum_{n=2}^{\infty}\lambda_n\gamma_n^2/(kA)^2 \qquad (9)$$

where

$$\lambda_n=n\nu_n\sin\psi_n/(1+\nu_n^2-2\nu_n\cos\psi_n)$$

Evidently also

$$\Delta\omega\cong-\sin\psi_1/(\partial\psi/\partial\omega)_{\psi=0} \qquad (10)$$

For determining the amplitude of oscillation the integral representing the coefficient of $\cos\theta$ in v is required

$$\rho\equiv(1/\pi)\int_0^{2\pi}v\cos\theta\,d\theta$$

If terms through the third line of equation 3(A) are retained, we have

$$\rho=kA+\gamma_1+(1/\pi A)\int_0^{2\pi}\epsilon\sum_{m=2}^{\infty}m\beta_m\cos^m\theta d\theta$$

Define

$$\delta_n\equiv\sum_{k=0}^{\infty}[(n+2k)\beta_{n+2k}/2^{n+2k-1}]B_{k,n+2k} \qquad (11)$$

then

$$\begin{aligned}\rho&=kA+\gamma_1+(1/\pi A)\int_0^{2\pi}\sum_{n=2}^{\infty}\epsilon_n\cos n\theta\times\cos\phi_n\sum_{n=0}^{\infty}\delta_n\cos n\theta\,d\theta\\ &=kA+\gamma_1+(1/A)\sum_{n=2}^{\infty}(\nu_n\gamma_n\delta_n/k)\times(\sin\phi_n\cos\phi_n/\sin\psi_n)\\ &=kA+\gamma_1+(1/A)\sum_{n=2}^{\infty}(\nu_n\gamma_n\delta_n/k)\times(\cos\psi_n-\nu_n)/(1+\nu_n^2-2\nu_n\cos\psi_n)\end{aligned}$$

using equations 7 and 8.

But since $\sin\psi_1$ is of the second order, it follows that $\cos\psi_1$ differs from unity by a quantity of the fourth order. Hence we may put $\rho=A$, and the equation determining the amplitude is thus

$$(k-1)A+\gamma_1+(1/kA)\sum_{n=2}^{\infty}\gamma_n\delta_n\mu_n=0 \qquad (12)$$

to the second order, where

$$\mu_n=\nu_n(\cos\psi_n-\nu_n)/(1+\nu_n^2-2\nu_n\cos\psi_n)$$

It will be seen from equation 5 that γ_1 depends only on odd-order values of β_m and hence of a_m in equation 3. Therefore the first-order limiting is given by

$$\begin{aligned}(k-1)A+\gamma_1=(k-1)A+(3/4)a_3(kA)^3+&\\ (5/8)a_5(kA)^5+\dots=0&\end{aligned} \qquad (13)$$

this being the relation derived by van der Pol[2] and others.

Evidently if only even-order distortion exists, $\gamma_1=0$, and there is no first-order limiting. Suppose

$$v=ku+a_2(ku)^2$$

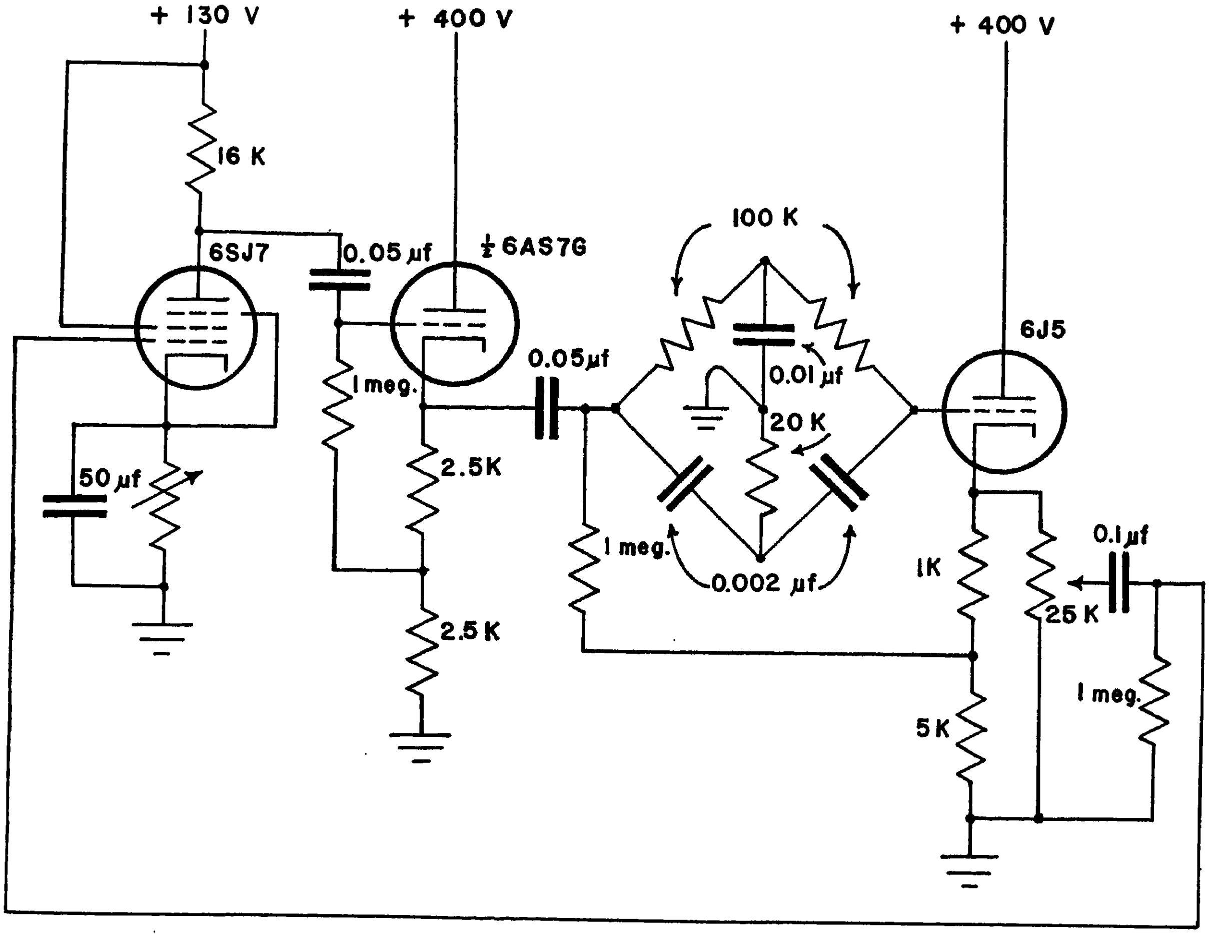
Then $\gamma_2=(a_2/2)(kA)^2$, $\delta=a_2(kA)^2$, the other ordered values of γ_n and δ_n being zero.[2] Then the equation determining the limiting is

$$k(k-1)A^2+(1/2)a_2^2(kA)^4\mu_2=0$$

giving as the nontrivial solution

$$A=(1/k)[-2(k-1)/(k\mu_2a_2^2)]^{1/2} \qquad (14)$$

Fig. 3. Oscillator circuit showing nominal component values of Nyquist



Thus there can be second-order limiting only for $\mu_2<0$, that is, for $\cos\psi_2<\nu_2$. If this condition is not satisfied, there is no limiting in this case. Next suppose

$$v=ku+a_2(ku)^2+a_3(ku)^3$$

This yields the equation

$$(3/16)a_3^2\mu_3(kA)^4+[(3/4)a_3+(1/2)\mu_2a_2^2]\times(kA)^2+(1/k)(k-1)=0$$

for which the solution is

$$(kA)^2=-2[(3a_3+2\mu_2a_2^2)/(3\mu_3a_3^2)]\times\{1-[1-3\mu_3a_3^2(k-1)/k(3a_3+2\mu_2a_2^2)^2]^{1/2}\}$$

If the second term in the radical is small compared with unity, which is true if $k\cong 1$, this solution reduces to

$$A=(2/k)[(k-1)/(-3a_3-2\mu_2a_2^2)]^{1/2} \qquad (15)$$

It may happen in cases of strong second-power distortion that the term $-3a_3$ is not sufficiently positive to make the radicand of equation 15 positive. In this case the first-order theory is no longer adequate to predict the behavior.

The frequency behavior can be determined by equations 9 and 10 once the amplitude is known. For the case of combined second- and third-power distortion.

$$\sin\psi_1=-(1/4)\lambda_2a_2^2(kA)^2-(1/16)\lambda_3a_3^2(kA)^4 \qquad (16)$$

The second harmonic term is seen to be the worst in disturbing the frequency since A is proportional to the square root of the excess gain $(k-1)$, so that the frequency shift varies linearly with the excess gain for second-power distortion but only with its square for third-power distortion. When any even- or odd-power distortion is present by itself, it will contribute a frequency shift proportional to the excess gain, if even, or to its square, if odd, as can be inferred from equations 5, 9, and 12.

The reason for the familiar phenomenon of "dropping in" of oscillators can be readily perceived from equations 15 and 16. In this behavior the transition of the system to the oscillatory state is abrupt and the frequency undergoes a marked decrease. If in equation 15 $\mu_2>0$ and is not small, corresponding to fairly strong response and small phase shift of the second harmonic in the Nyquist, an increase in a_2 for fixed a_3 will increase the limiting amplitude up to a point where the denominator may be quite small, and other forms (fifth and higher powers) of distortion are needed to limit the amplitude. Thus, when a small signal appears, it builds up to a large amplitude, the frequency continually dropping in accordance with equation 16, until equilibrium is ultimately reached because of these higher power terms. This condition is probable in any oscillator whose characteristic has strong second-power distortion such as a triode, or a pentode in class *AB*, *B*, or *C*.

Experimental Data

An attempt was made to verify these predictions with a pentode oscillator operating with plate, screen, and bias voltages such that the cutoff and saturation portions of the characteristic would

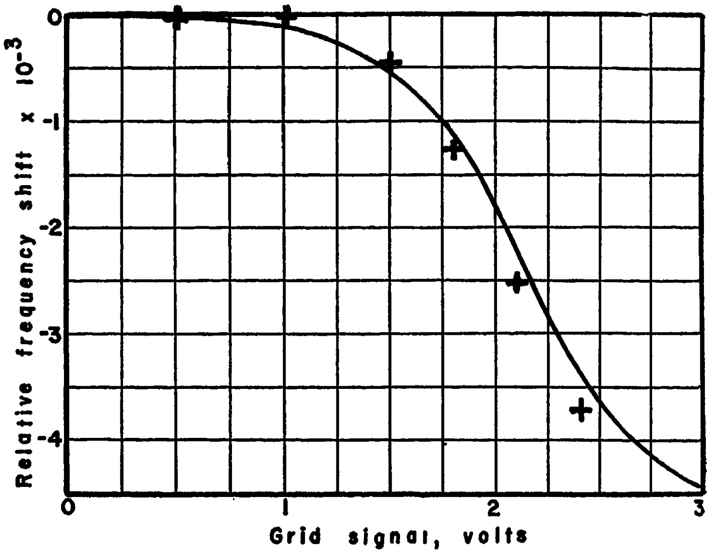

Fig. 5. Measured (+) and calculated (solid line) relative frequency shift as a function of amplitude

be as nearly alike as possible. This generally implies that the average plate voltage is less than the screen voltage and that the load resistance is comparatively low so as to smooth out the saturation characteristic as much as possible. The tube used was a *6SJ7* having a plate load of 16,000 ohms and 130 volts on the screen and as the plate supply voltage. A series cathode resistor was used to adjust the grid bias to the middle of the characteristic at -3.0 volts; see Fig. 3 and Table I.

Using a 7-point Lagrange formula based on $V_G = -3.0$ volts as the center with three 1.0-volt increments in each direction, the total range thus running from -6.0 volts to 0 volts for V_G, one finds

$$-V_L = 77 + 23.95V_G' + 0.1583V_G'^2 - 1.510V_G'^3 - 0.719V_G'^4 + 0.0688V_G'^5 + 0.0604V_G'^6$$

where $V_G' = V_G + 3.0$. We take the normalized unit of amplitude as 1.0 volt, that is, $kA = 1$ implies 1.0-volt signal at the grid. On dividing by the slope of the characteristic at the operating point, we put this relation into the terminology of this paper, thus

Table II. Measured Amplitude and Phase Response of Nyquist of Figure 3

2	2.1	−1.00	
3	3.3	−0.92	$-\psi_n > \pi/2$
4	4.2	−0.85	
5	4.7	−0.80	
6	5.0	−0.72	

$$v = ku + 0.00661(ku)^2 - 0.0630(ku)^3 - 0.0300(ku)^4 + 0.00287(ku)^5 + 0.00252(ku)^6$$

First-order limiting obtains for this characteristic because of the dominance of the third-power term. Neglecting the second-order terms in equation 12, we have

$$kA = \{13.12 - [172 - 557(k-1)/k]^{1/2}\}^{1/2}$$

A graph of this quantity, together with points obtained by measurement, is given in Fig. 4.

In order to obtain freedom from effects on the Nyquist produced by plate resistance changes with amplitude as well as by grid circuit loading which would result from initial velocity effects, etc., as the grid voltage approaches cathode potential, the two cathode followers (*6J5*, ½*6AS7G*) were used to obtain complete isolation of the frequency-determining element. The operating conditions of these are such as to introduce negligible amplitude distortion.

The resonant frequency for the nominal circuit elements both by computation and measurement is 790 cycles per second to sufficient accuracy; the relative responses and sines of the phase shifts for the first six harmonics are given in Table II.

The experimental and calculated values of $[\partial\psi/\partial(\omega/\omega_r)]_{\psi=0}$, ω_r being the resonant angular velocity, agree at approximately -3.7. These figures can be used to calculate the frequency shift by equations 5, 9, and 10. Fig. 5 shows the measured and calculated frequency shifts. Frequency departures were measured by timing beats between the oscillator and a standard. The probable accuracy of the frequency shift measurements due to drift, etc., is about $\pm 10^{-4}$.

The *6SJ7* is not ideally suited to demonstrate drop-in except when underbiased, since the cutoff characteristic is too smooth except for such low gains that the circuit shown fails to oscillate. Accordingly, to secure satisfactory even-power distortion a type *6AB7* was used in the same circuit. The inflexion point of the characteristic was found to be at -1.9 volts bias on the grid, and Fig. 6 shows the relative frequency shift for various values of bias with the circuit generating 1.0 volt of signal measured at the grid.

Conclusion

It is felt that there is adequate experimental and theoretical verification to

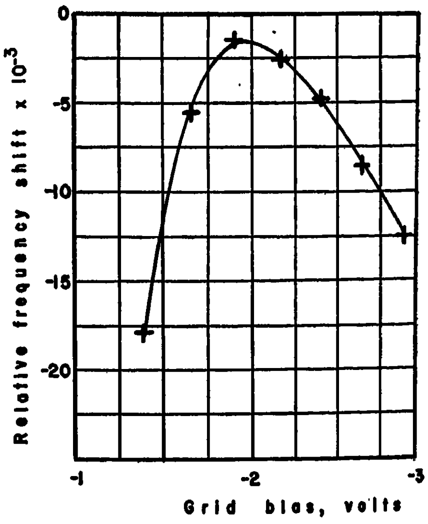

Fig. 6. Measured frequency behavior of 6AB7 oscillator showing effect of even-power distortion away from inflexion point

support the hypothesis that the dominant factor, apart from adjustments of the linear elements, in obtaining frequency-stable and smoothly controlled oscillations in separable electric systems is the suppression of the even-power terms in the amplitude characteristic. Equations 5, 7(A), 8, 9, 10, 11, and 12 provide means for determining the complete behavior of the oscillator, including phase and amplitude of the harmonic content, amplitude of the fundamental, and frequency, given only the Nyquist diagram, the nonlinear characteristic, and the gain.

An Application of Magnetic Amplifier Circuits to Perform Multiplication and Other Analytical Operations

L. A. FINZI
MEMBER AIEE

R. A. MATHIAS
ASSOCIATE MEMBER AIEE

Synopsis: Circuits are described which yield an output voltage proportional to the product or quotient of any number of input voltages. The components used are magnetic cores of grain-oriented nickel alloys, half-wave rectifiers, and linear resistors. Experimental results and some design considerations are given. Circuits of the same kind are also suggested for performing indefinite integration and other analytical operations upon signal voltages which are functions of time.

CONVENTIONAL magnetic amplifiers are well suited to perform mixing of signals as the output depends on the total magnetomotive force of control provided jointly by any number of input windings. Over the linear range of the ampere-turns transfer characteristic, the output is simply proportional to the algebraic summation of signals; other operations can also be performed, in a less straightforward manner, by proper use of nonlinear regions of the characteristic.

The circuits described in this paper, however, operate on somewhat different principles. Their components are single-core amplifiers of the kind described by Ramey[1,2] and utilized in many ways by the same author in digital computer applications.[3]

Although this kind of amplifier is known, a brief discussion of its essential features is given; a proper appreciation of these features is essential for the understanding of the specific applications described further in this paper.

Elementary Single-Core Amplifier

An elementary single-core amplifier is shown in its simplest circuitry in Fig. 1(A). The magnetic core is characterized by a sharply defined saturation at flux levels $\pm\Phi_{sat}$ reached with comparatively small magnetomotive forces, as shown in Fig. 1(B), in an idealization which is adequate for grain-oriented nickel alloys commonly used in high-grade amplifiers. A single winding links this core with N turns; r is the resistance of this winding and R_L is a load resistance. γ and σ are two half-wave rectifiers; it is assumed at first that forward rectifier conduction takes place with negligibly small voltage drops, while infinite resistance is offered to the flow of current in the reverse direction.

In Fig. 1(C), v_g is the voltage of the power supply, or gate voltage; v_s is the signal voltage. For the sake of simplicity in Fig. 1(C) it is assumed that $v_g = V_{g\max} \sin \omega t$, with $\omega = 2\pi f$ = angular velocity of the sinusoidal power source and $V_{g\max} < \omega N \Phi_{sat}$ (that is, application of the gate voltage directly at the terminals of the winding N would not cause saturation in the steady state). Also v_s is assumed to be a full-wave rectified sinusoidal voltage in phase with the gate voltage and with a crest $|V_{g\max}| = k\,V_{g\max}$ where $0 \leq k \leq 1$. This rectified signal voltage is acting constantly against the direction of forward conduction of the rectifier σ.

(Consistent algebraic conventions are established in text and drawings as instantaneous voltages are considered measured from one common reference or ground.)

In positive half-cycles of the power supply voltage the core flux rises from some initial level towards saturation; in this process of varying fluxes the voltage v_g is balanced almost completely by the rate of change of flux linkages $Nd\Phi/dt$ while a very small magnetizing current (dictated by the minor hysteresis loop described) flows with negligibly small voltage drops in R_L and r. At some time during this half-cycle, saturation is reached; the process of flux changes terminates, and in the remaining part of this half-cycle $i = v_g/(R_L + r)$. As v_g becomes zero, i becomes zero, too, and at the end of the positive half-cycle the core is left at the flux level $+\Phi_{sat}$. No current flows in the signal circuit throughout this half-cycle because of the blocking action of the rectifier σ.

In the next (negative) half-cycle v_g reverses its polarity; the rectifier γ blocks any flow of current through the load. But, as v_g now overrules v_s, the rectifier σ becomes conducting and a process of flux changes initiates during which a reversed small magnetizing current flows in the winding. That is, the core flux is being brought down from the level $+\Phi_{sat}$, as the rate of change of flux linkages balances almost entirely the voltage $(v_g - v_s)$. In view of the limitation stipulated for the amplitude of v_g, in no case negative saturation is reached in this half-cycle, that is, the process of flux decay from $+\Phi_{sat}$ extends throughout this presetting half-cycle, at the end of

which a flux level Φ_p is reached, which is

$$-N(\Phi_{sat}-\Phi_p)=\int_{-T/2}^{0}(v_g-v_s)dt=\text{volt-time area } A_{\mathrm{I}}$$

with the notation used in Fig. 1(C).

In the next gating half-cycle the flux starts rising again from this preset level Φ_p under the action of the positive v_g as described initially. This process terminates as a firing time t_f at which saturation is reached, that is

$$\int_0^{t_f} v_g dt = N(\Phi_{sat}-\Phi_p)=\text{volt-time area } A_{\mathrm{III}}$$

From then on and for the rest of the gating half-cycle, the voltage v_g appears across the circuit resistances with a volt-time area of gross output

$$A_{\mathrm{IV}}=\int_{t_f}^{T/2} v_g dt=\int_{t_f}^{T/2}(R_L+r)i dt$$

(The volt-time area of net output into the load R_L is simply $A_{\mathrm{IV}}R_L/(R_L+r)$.) Since $A_{\mathrm{III}}=-A_{\mathrm{I}}$ it follows that $A_{\mathrm{IV}}=-A_{\mathrm{II}}$. Thus the controlling action of the signal voltage acting in one presetting half-cycle upon the output of the immediately following gating half-cycle is fully evidenced.

Although Fig. 1(C) refers to the simple case of a sinusoidal gate voltage v_g and a full-wave rectified sinusoidal signal volt-

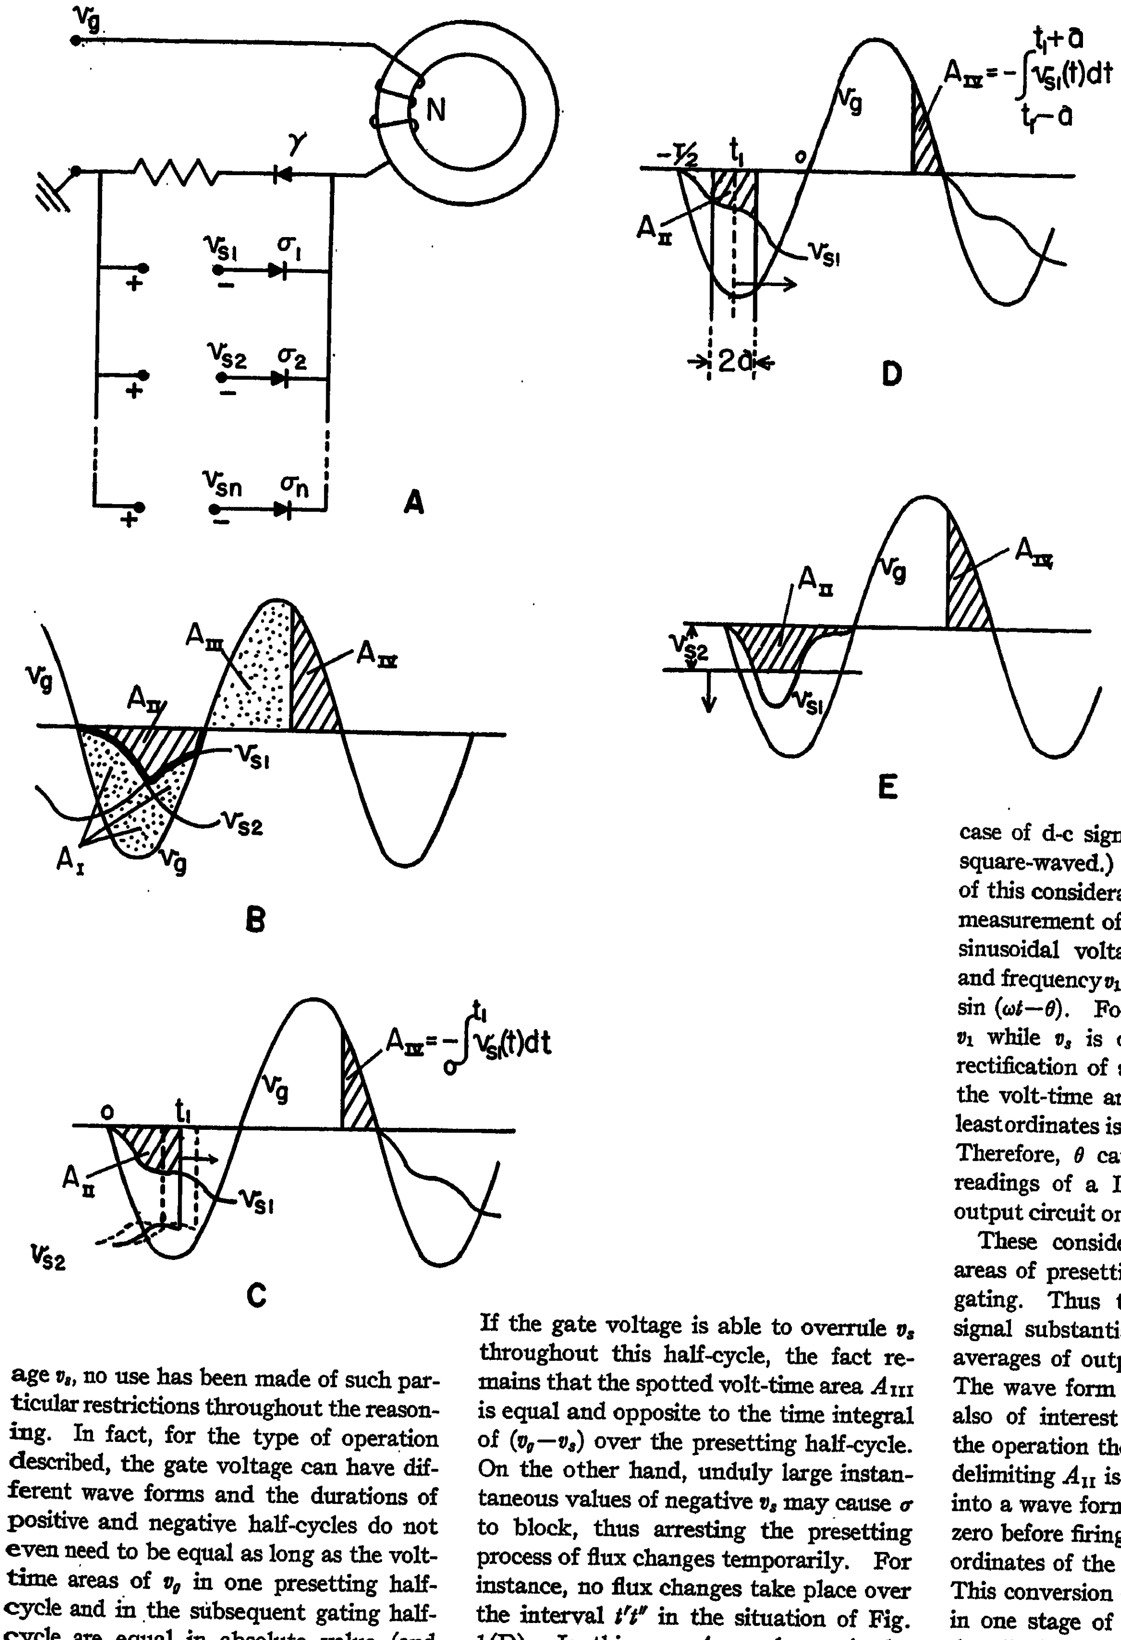

Fig. 2. Multichannel amplifier

age v_s, no use has been made of such particular restrictions throughout the reasoning. In fact, for the type of operation described, the gate voltage can have different wave forms and the durations of positive and negative half-cycles do not even need to be equal as long as the volt-time areas of v_g in one presetting half-cycle and in the subsequent gating half-cycle are equal in absolute value (and less than $2N\Phi_{sat}$).

It is seen also that wave form and magnitudes of signal voltage v_s during a gating half-cycle are of no relevance on the operation as long, of course, as σ is kept blocked. (That is, v_s should not be allowed to become positive but it can well be zero.)

During the presetting half-cycle, the wave form of signal may also be irrelevant. If the gate voltage is able to overrule v_s throughout this half-cycle, the fact remains that the spotted volt-time area A_{III} is equal and opposite to the time integral of $(v_g - v_s)$ over the presetting half-cycle. On the other hand, unduly large instantaneous values of negative v_s may cause σ to block, thus arresting the presetting process of flux changes temporarily. For instance, no flux changes take place over the interval $t't''$ in the situation of Fig. 1(D). In this case A_{II} no longer is the total volt-time area of signal, but rather is the shaded area of the contour of least ordinates (least in absolute value) of both v_s and v_g as shown.

This consideration allows predicting the performance of an amplifier with sinusoidal gate voltage and d-c signals, and explains its lack of linearity. (Linearity, of course, can be obtained in the case of d-c signals if the gate voltage is square-waved.) Also an elementary use of this consideration can be made for the measurement of the phase-angle θ of two sinusoidal voltages of equal amplitude and frequency $v_1 = V_{max} \sin \omega t$ and $v_2 = V_{max} \sin(\omega t - \theta)$. For this, v_g is made equal to v_1 while v_s is obtained from half-wave rectification of v_2. As seen in Fig. 1(E) the volt-time area A_{II} of the contour of least ordinates is then $(\sin \theta/2 - 1)\, V_{max}/\pi f$. Therefore, θ can be obtained from the readings of a D'Arsonval meter in the output circuit on a scale suitably marked.

These considerations relate volt-time areas of presetting to volt-time areas of gating. Thus the action of presetting signal substantially is related to cyclic averages of output currents or voltages. The wave form of the output voltage is also of interest in many instances; in the operation the wave form of the curve delimiting A_{II} is converted in the output into a wave form with ordinates equal to zero before firing and coinciding with the ordinates of the gate voltage after firing. This conversion of wave forms is utilized in one stage of the multiplying circuits described later in this paper.

Multichannel Amplifier

A modification of the previous device is shown in the amplifier of Fig. 2(A), in which many input channels are provided for a corresponding number of signal voltages $v_{s1}, v_{s2} \ldots v_{sn}$. In gating half-cycles the operation is the same as

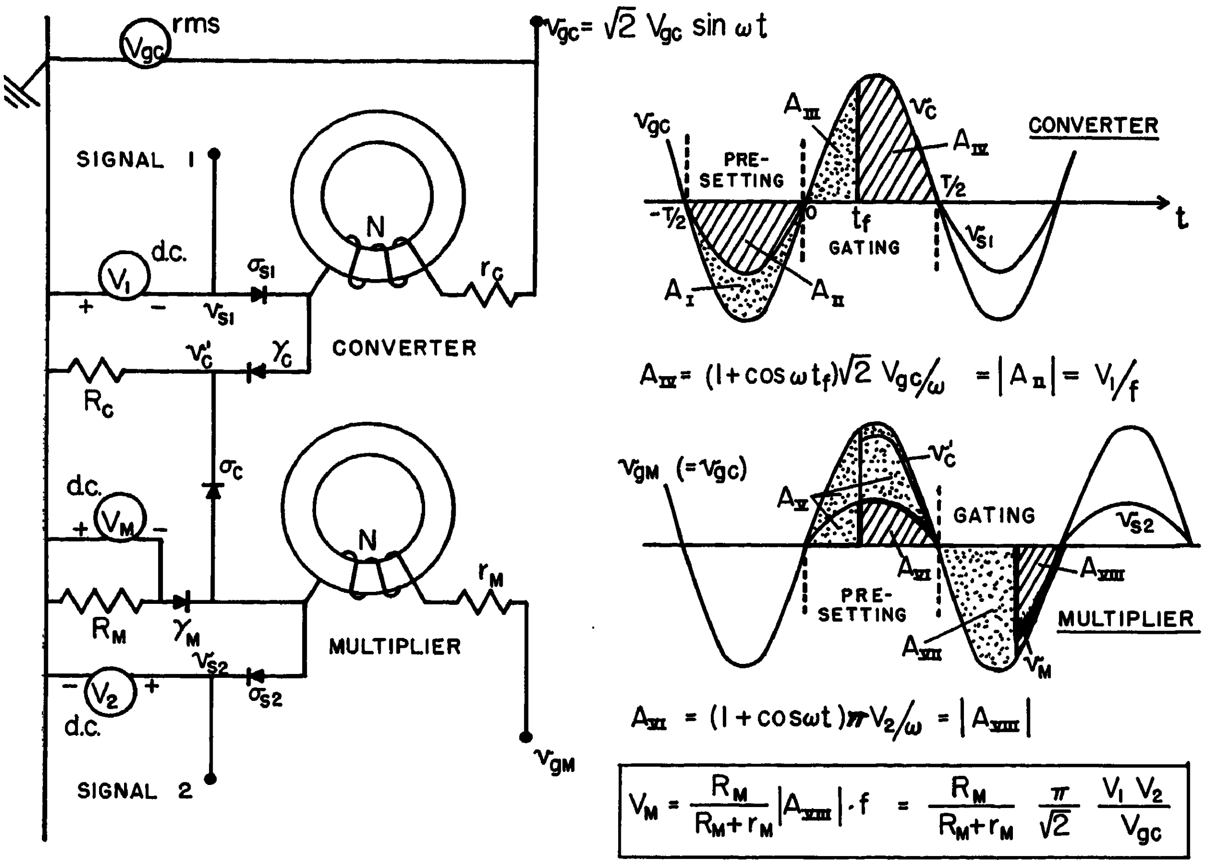

Fig. 3. Basic multiplying circuit

before, the wave forms of the signals being irrelevant as long as proper polarities insure blocking of the corresponding σ rectifiers. On the other hand, during presetting half-cycles the negative voltage v_g overrules whichever signal voltage happens to have the lowest absolute value, while γ and all the other σ rectifiers are blocking. That is, at any instant the rate of change of decaying core flux is dictated by the resultant of the gate voltage and of the weakest signal voltage. Accordingly, a magnetic coincidence counter[8] has been developed under the recognition that no output is found in the gating if even only one of the signal voltages has been zero through the presetting.

More generally it is seen here that the gated output area is equal to the area of the contour of least ordinates of gate and signal voltages during presetting as shown in Fig. 2(B). This general property may have a number of interesting analytical applications. If an assigned voltage $v_{s1}(t)$ is applied periodically in the negative half-cycles in conjunction with a large signal $v_{s2}(t)$ dropping to zero at $t=t_1$ as shown in Fig. 2(C), the reading of a D'Arsonval meter in the output is proportional to the integral

$$\int_0^{t_1} v_{s1}(t)\, dt$$

Thus if t_1 is gradually phase-shifted, a writing d-c meter of adequately large inertia can plot directly the indefinite integral function on a roll of paper moving synchronously with whatever organ controls the scanning phase shift of v_{s2}. (The periodical obliteration of the action of $v_{s1}(t)$ can be obtained and phase-shifted in various other ways, for example, by suitably timed mechanical contactors temporarily short-circuiting the rectifier γ in a single-channel amplifier).

Useful analytical information on the function $v_{1s}(t)$ as shown in Fig. 2(D) can be obtained also by use of a scanning wave v_{s2} of any chosen width $2a$ (or by contactors timely short-circuiting γ, for example at all times but $t_1 - a \leq t \leq t_1 + a$).

On the other hand, gross outputs equal to the areas shaded in Fig. 2(E) result from a scanning with progressively increased direct voltages v_{s2}; thus another type of information on the function v_{s1} is obtained. The simplicity of the circuits and components needed to perform these and similar analytical operations may be an incentive for actual usage in analogue computer studies, for example, as applied to statistical problems.

Multiplying Circuits

Two-Stage Multiplying Circuits

A single-channel amplifier of the type described in the preceding constitutes the converter stage shown in Fig. 3. This stage operates on a sinusoidal gate voltage $v_{gC} = \sqrt{2}V_{gC}\sin\omega t$ with a half-wave rectified signal voltage v_{s1}, of arbitrary wave form. This signal voltage is converted in the gross output voltage v_C absorbed by the resistances $(R_C + r_C)$ in the subsequent half-cycle after firing.

A 2-channel amplifier of the type described in the preceding constitutes the multiplier stage. Its sinusoidal gate voltage is v_{gM}. (For the sake of simplicity v_{gM} is assumed identical to v_{gC} in Fig. 3.) A half-wave rectified sinusoidal signal voltage v_{s2} is one of the inputs, while the other input is the net converter output $v_C' = v_C R_C/(R_C + r_C)$ appearing across the load resistance R_C. In the time interval from 0 to t_f v_C' is zero (or nearly so) and therefore the presetting flux change of the multiplier core is dictated completely by v_{gM}, as the action of v_{s2} is obliterated over this interval. Therefore the total presetting over the half-cycle is limited only by the area A_{VI} of least ordinates, recognized with opposite sign as the area A_{VIII} of gross output of the multiplier in the next half-cycle. The various volt-time areas of the two stages are related easily to the readings of the rms voltmeter V_{gC} and of the d-c voltmeters V_1, V_2, and V_M as shown in Fig. 3, with the result

$$v_M = \frac{R_M}{R_M + r_M}\,\frac{\pi}{\sqrt{2}}\,\frac{V_1 V_2}{V_{gC}} \tag{1}$$

Thus multiplication as well as division is performed by the system.

It can be noted that V_{gC} appears in the denominator because increases of V_{gC} increase t_f and thus reduce the area A_{VI} and A_{VIII}. On the other hand, the crest of the multiplier gate voltage can be varied without any effect of first order on the results because such variations, while affecting the wave form of multiplier output voltage do not modify the volt-time area A_{VIII} and the reading of the meter V_M.

It may be noted also that the two stages do not need to have cores of equal dimensions or magnetic characteristics, and their windings can also have different turns, provided, of course, that in each stage the gate voltage satisfies the condition $V_{g\,\max} < \omega N \Phi_{\text{sat}}$.

The operating range of the device has evident limits; namely $|v_{s1}|$ must be less than $|v_{gC}|$ during converter presetting, and the crest of v_{s2} must be lower than both $\sqrt{2}V_{gC}R_C/(R_C+r_C)$ and $\sqrt{2}V_{gM}$ during multiplier presetting. Different levels of signals can be handled by substituting any one input channel of the converter or of the multiplier with a separate signal winding of suitable turns $N_s \neq N$ in series with one half-rectifier. (The signal applied to any such winding then must act against the presetting action of a voltage $v_g' = v_g N_s/N$ impressed in series in the same winding from the secondary of a transformer with this turns ratio. Such known modifications of the elementary amplifier circuits of Figs. 1 and 2 do not modify in the least the basic operation of the multiplying system described here, and do not need to be examined in detail.)

Also it is recognized that the given signals v_{s1} and v_{s2} act upon the system in two subsequent half-cycles. Hence, a certain cross-correlation lag $\tau = {}^1/_2 f$ is inherent to the multiplication performed. (This lag may be increased, if so desired, for cross-correlation or autocorrelation studies, by the insertion of half-cyclic delay stages[3] between converter and multiplier.) One additional half-cycle lag affects the final output.

These considerations are not necessarily limited to sinusoidal gate voltage and signals. It is sufficient to point out that the circuit of Fig. 3 performs also multiplication of d-c signals if the gate voltages are square waves symmetrical about zero (as obtained from a d-c power source through a rotating commutator); in this case the various volt-time areas A_{I} to A_{VIII} become rectangles and the behaviors of converter and multiplier are even more clearly seen.

MULTISTAGE MULTIPLYING CIRCUITS

The output voltage V_M of the multiplier stage of Fig. 3 has a converted wave form of the same kind as v_c'. This suggests that a second multiplier stage can be added directly to the system of Fig. 3, one of its inputs being $v_M' = v_M$ while the other input is an assigned half-wave rectified sinusoidal signal voltage v_{s3}. The reasoning applied to the volt-time areas of the single multiplier stage of Fig. 3 can be extended to this new stage with the result

$$V_M'' = \frac{R_M''}{R_M'' + r_M''}\left(\frac{\pi}{\sqrt{2}}\right)^2 \frac{V_1 V_2 V_3}{V_{gC} V_{gM}'} \qquad (2)$$

where

V_1, V_2, V_3 are d-c meter readings of the assigned signal voltages
V_M'' is the d-c meter reading of output voltage across the load resistance R_M'' of the second multiplier stage
V_{gC} and V_{gM}' are rms readings of the gate voltages of the converter and of the first multiplier.

This idea can be extended, in principle, to the use of any number μ of multiplier stages, each one of which receives the output voltage of the immediately preceding stage as a converted signal in conjunction with a new half-wave rectified sinusoidal signal independently assigned. The end output metered by $v_{M\mu}$ across the load resistance $R_{M\mu}$ of the last multiplier, is

$$V_{M\mu} = \frac{R_{M\mu}}{R_{M\mu} + r_{M\mu}}\left(\frac{\pi}{\sqrt{2}}\right)^{\mu} \times \frac{V_1 V_2 \ldots V_{(\mu+1)}}{V_{gC} V_{gM}' \ldots V_{gM(\mu-1)}} \qquad (3)$$

where the numerator factors are d-c meter readings of the assigned signals and the denominator factors are rms reading of gate voltages of all but the last stage. The various signals act upon the system in subsequent half-cycles, while one additional half-cycle lag affects the final output. Proper use of the concept of areas of least ordinates must be made to determine the upper limits of signal voltages allowable to control each stage effectively. The total number of stages practically usable in any such system may be limited, of course, by cumulative errors, some of which are discussed later.

EXPERIMENTAL RESULTS AND CRITICAL COMMENTS

Fig. 4 presents some experimental results of operations performed by the circuit of Fig. 3, slightly modified as sketched, with the following components:

1. Magnetic cores, Hypernik V; $DO = 2^1/_2$ inches; $DI = 1^1/_2$ inches; tape height $= 1/2$ inch; number of turns per core $N = 2{,}500$; winding resistances $r_C = r_M = 65$ ohms.

2. Rectifiers: Germanium *G10*, 130 volts rms reverse voltage, 400 milliamperes (later use of selenium rectifiers yielded substantially identical results).

3. Load resistances $R_C = 500$ ohms; $R_M = 410$ ohms.

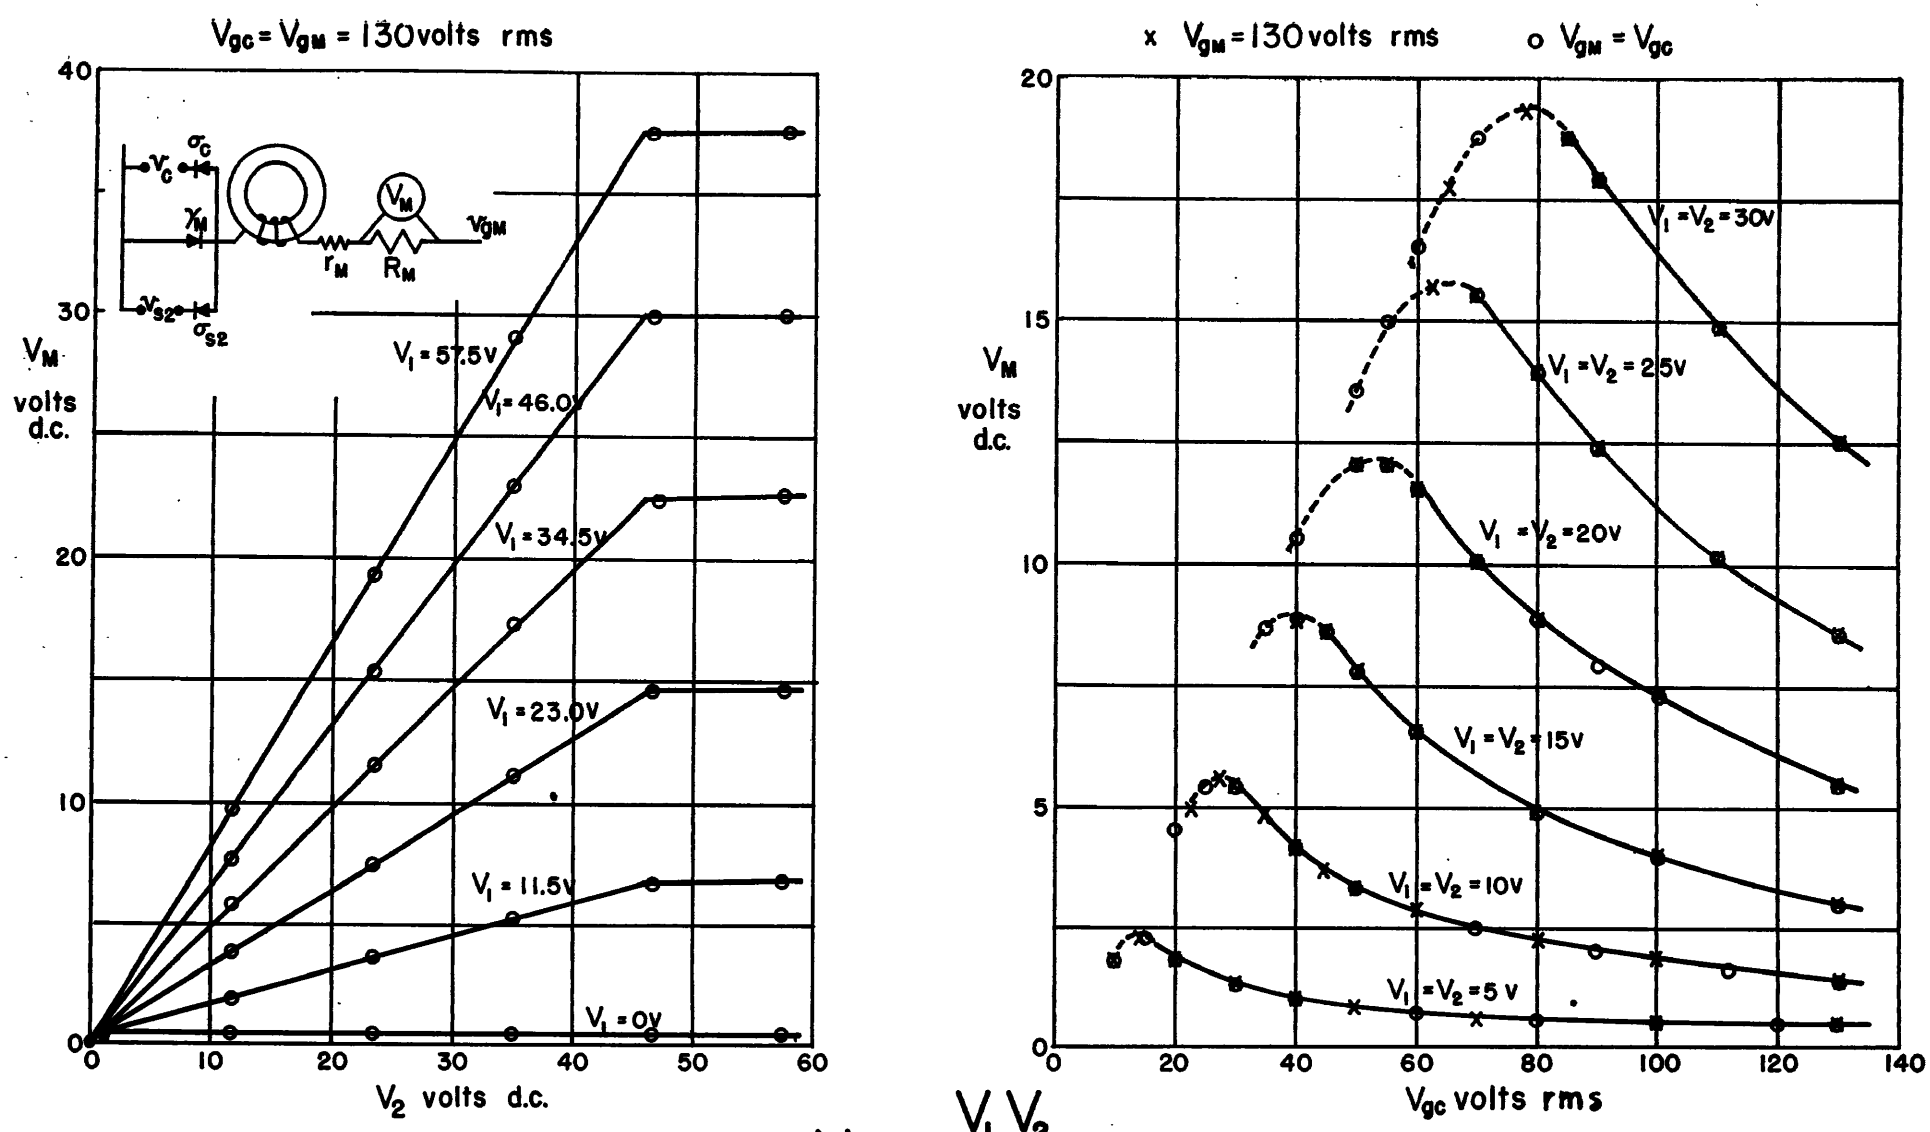
On the left multiplications have been performed by keeping the gate voltages constant, by assigning some fixed value to the signal V_1, and by varying V_2. V_M ceases to increase when V_2 becomes too large to control further the area of least ordinates of multiplier presetting.

On the right, divisions have been performed by varying the converter gate voltage V_{gC} for fixed values of $V_1 = V_2$. The multiplier gate voltage V_{gM} was constant (crossed points) or else was varied together with V_{gC} (encircled points); as should be expected, crosses and circles fall on the same lines. (The rectifier σ_{s1} remains blocked during converter presetting half-cycles when V_{gC} is decreased below a certain value; then the hyperbolic trend breaks as the converted signal v'_C becomes a sinusoidal half-wave of amplitude decreasing with V_{gC}, and the final output V_M also decreases accordingly).

The experimental results show departures from idealized behavior expressed by equation 1. First of all, the multiplier winding after firing possesses residual inductance; hence the metered output is somewhat lower than expected. Practically a calibration of the circuit (simply performed, for example, at some large value of V_1 and V_2) to determine the factor K in the equation written in Fig. 4 disposes of this error quite well at all but low outputs.

In the experimentation it appeared of primary interest to extend the accuracy of equation 1 as far as possible into the region of either signal approaching zero. For this, more careful attention must be given to a different source of errors which really determines the practical design and performance of the system. The simplified reasoning presented has been focussed on voltages acting upon the cores and on their volt-time areas under the assumption that the magnetizing current flowing in the presetting and prefiring intervals is negligibly small. But a closer scrutiny must be given to the voltage drops of these currents through the resistances of their various paths. Of course, in every given numerical situation these voltage drops are known and their influence upon the various phases of the operation is evaluated easily in terms of modified volt-time areas.

Now in the multiplication curves of



$$V_M = K \frac{V_1 V_2}{V_{gc}}$$

Fig. 4. Some experimental results

Fig. 4 it is seen that for $V_1=0$ a certain output V_M, small but not quite zero, was metered. In fact, with $V_{s1}=0$, no firing of the converter occurs in its gating half-cycles, but still the flow of magnetizing current through R_C gives a certain converted signal v'_C to the multiplier; the latter's area of least ordinates A_{VI} is not brought to zero, and the multiplier does fire at some time near the end of its gating half-cycle with an output substantially independent of V_2. A direct use of the original circuit of Fig. 3 had caused an even larger error in the V_M reading because of the drop of prefiring magnetizing current through R_M. To avoid this, R_M was displaced in the position shown in the sketch of Fig. 4; in this manner its drop of magnetizing current over the range of low multiplier outputs nearly averages to zero in consecutive half-cycles. In particular, for any V_1, zero output is truly obtained when $V_2=0$. In the experimentation the rectified signal voltages were obtained from two variable transformers each feeding through a half-wave rectifier into a resistor R_{s1} (or R_{s2}) connected between ground and signal rectifier σ_{s1} (or σ_{s2}). (This is needed to provide a path for the presetting magnetizing currents flowing against the signal voltages.) In the experimental circuit R_{s1} and R_{s2} were chosen as $R_{s1}=R_{s2}=2{,}000$ ohms. As a consequence, at full output the power level of either signal source was about 1/4 of the gross output power. Since it is generally desirable to reduce the over-all signal power requirements, tests were also performed with $R_{s1}=R_{s2}=10{,}000$ ohms, with results not very different from those shown in Fig. 4, except for low values of V_2. (At low values of V_2 the wave form of v_{s2} was significantly distorted from the sinusoidal by the drop of magnetizing current.) Also with $R_{s1}=R_{s2}=2{,}000$ ohms, voltage measurements directly at the transformer terminals corresponded substantially to the readings of the meters V_1 and V_2 across the resistors. This was no longer true for $R_{s1}=R_{s2}=10{,}000$ ohms; in this case the experimental results plotted in terms of transformer voltages departed badly from linearity over the first one-third of the scale of the abscissae.

A more proper design of the circuit components would improve all this as the magnetizing currents (about ±1 milliampere) could be reduced by the use of cores of lesser mean length (the available cores had more than twice the diameter needed to accommodate the windings used.) The voltage drops in question could also be made less significant percentagewise by the use of higher gate and signal voltage levels, allowed by the core cross section but limited in the experimentation by rectifier ratings. And larger power outputs could have been obtained from a reduction of R_M. But the circuit described, while performing the operations assigned remarkably well, is not primarily a power amplifier.

Nevertheless a variety of means is available to circumvent this question. The operation from low-level signal sources can be made possible by means of input cathode followers. Also, if d-c signal voltages (and square-waved gate voltages) are available, no need is felt for the resistors R_{s1} and R_{s2} as the magnetizing current then can flow directly into the signal source.

Finally, one may aim more directly at a reduction of the magnetizing currents in question. Since the magnetomotive force required by a core over intervals of increasing or decreasing fluxes is practically constant, it may not be difficult to provide a large part of it by an auxiliary winding fed from some suitable current source during presetting and prefiring or, more simply, during presetting only. Procedures of this kind are mentioned in the references.

A Transient Analyzer for Magnetic Amplifiers

E. J. SMITH
MEMBER AIEE

Synopsis: The transient analyzer described is a simple and reliable electronic device which operates by generating a number of pulses exactly equal to the number of cycles required for the output current or voltage of a magnetic amplifier to change from its initial value to a predetermined value. The response time in cycles is obtained directly by recording the output of the analyzer with an electronic counter or conventional recording device.

THE RESPONSE TIME of a magnetic amplifier is defined as the time required for the rms or rectified average value of output current or voltage to change a prescribed percentage of the difference between the corresponding initial and final steady-state values. When the magnetic characteristic of the core material approaches the rectangular *B—H*-loop shape, the wave form of the output current exhibits the typical rapid rise as one core saturates at some angle α_{MA}, and sinusoidal form after saturation, until the end of the half cycle. Under these conditions, the peak value of load current is independent of the average or rms value when

$$\alpha_{MA} \leq \frac{\pi}{2}$$

Unfortunately, conventional recording instruments are better suited to the measurement of cyclic peak values, and can be adapted to the measurement of the rms or average value response time only at the expense of considerable inconvenience and difficulty. An electronic cyclic integrator which permits direct measurement of the rectified average value of the output

taken over each cycle has been previously described.[1,2] With this method, the response of the amplifier in terms of cyclic average values is portrayed on the screen of a cathode-ray oscilloscope, is photographed, and the response time determined in the usual manner.

The device to be described in this paper (called the transient analyzer) is also electronic, but is very simple and reliable as compared with the above device, and possesses accuracy of a high order. The output of the transient analyzer is a series of pulses equal in number to the number of cycles required for the load current to change from its initial value to any arbitrarily specified value, called the reference value. The reference may be specified in terms of rectified average or rms values by the use of a suitable meter, by performing a manual adjustment prior to the initiation of the transient.

Description of Transient Analyzer

Principle of Operation

The operation of the transient analyzer is best described by making reference to Fig. 1. The values of control-circuit voltage E_{c1},E_{c2}, or current corresponding to the desired initial and final steady-state values of load current or voltage are first established. The output of the magnetic amplifier is then set at the reference value (that is, 63, 90, etc. per cent of the total change) by applying a suitable signal to the control circuit. Corresponding to the reference value of output, the magnetic amplifier saturates at some angle

$$\alpha_{MA}=\alpha_R$$

α_R is called the reference angle. When the core materials are not ideal the current wave does not jump abruptly at saturation; however, if α_{MA} is taken as the angle of maximum slope of the wave, the operation is the same as though the materials were rectangular.

The transient analyzer generates a voltage pulse of very short duration once every cycle. The phase of this reference pulse is next made to coincide with the reference angle by a manual adjustment. When the output current is less than the reference value

$$\alpha_{MA}>\alpha_R$$

and when the output current is greater than the reference value

$$\alpha_{MA}<\alpha_R$$

(Although these remarks apply only to a single-ended magnetic amplifier, the method itself can be applied to a push-pull amplifier by comparing the saturation angle of one reactor with the reference angle.)

The function of the transient analyzer is to compare the angles α_{MA} and α_R every cycle, and to indicate the result by generating an output pulse every cycle if $\alpha_{MA}>\alpha_R$, but no pulse if $\alpha_{MA}<\alpha_R$ for a build-up transient; and by generating a pulse every cycle if $\alpha_{MA}<\alpha_R$, but no pulse if $\alpha_{MA}>\alpha_R$ for a decay transient. The transient analyzer becomes operative only after the switch initiating the transient is thrown. Therefore, the number of pulses generated by the analyzer after the switch is thrown is equal to the number of cycles required for the magnetic amplifier output to change from the initial value to the reference value. The response time of the magnetic amplifier is obtained directly by counting the number of pulses generated by the analyzer during the transient. An electronic counter of the conventional type (multiple decade counters employing Eccles-Jordan flip-flop circuits, as used in electronic digital computers) was found to be a very convenient means for counting the pulses; however, a standard-type recording oscillograph could be used equally as well, but with perhaps less convenience.

The comparison of the angles α_{MA} and α_R is made during one half of the cycle

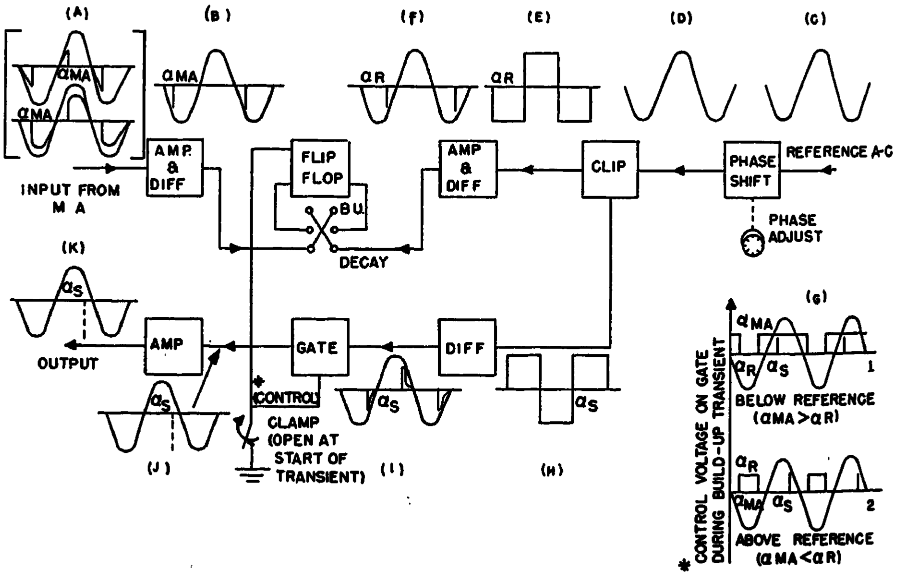

Fig. 2. Block diagram of the transient analyzer, illustrating wave forms at various points

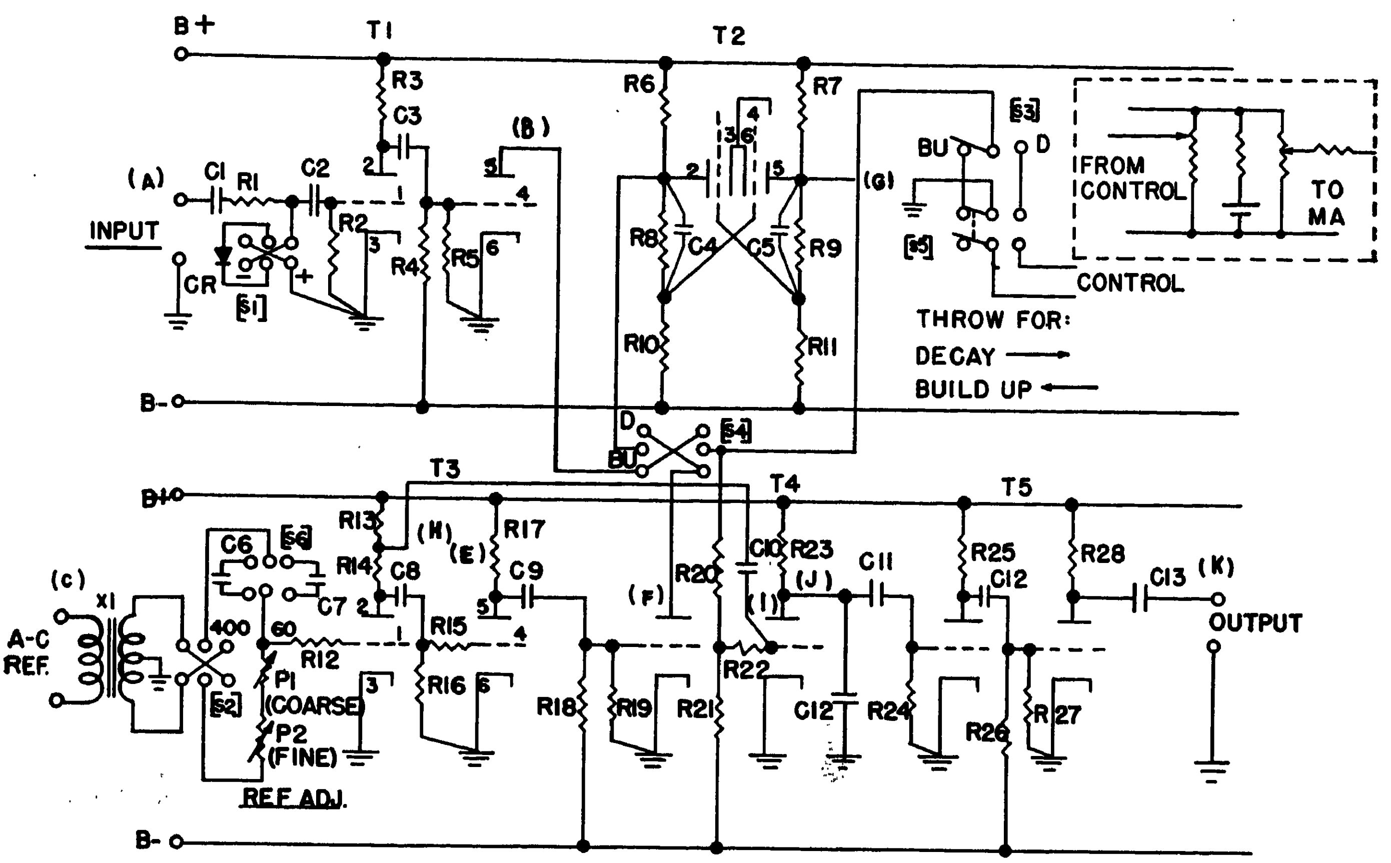

Fig. 3. Circuit diagram of transient analyzer

(the negative half in Fig. 1). If the output of the magnetic amplifier is alternating current, as shown in Fig. 1, the signal into the transient analyzer can be obtained from the load (that is, load voltage). If the signal is full-wave direct current (rectified direct-current), then the signal to the transient analyzer must be taken as the voltage across one reactor winding (see waves in upper left corner of Fig. 2). In any case (that is, full-wave direct current, full-wave alternating current, half-wave, or push-pull alternating current or direct current), the signal can always be taken from a winding of one reactor. The reason for the above is that the analyzer operates by comparing the reference pulse with some negative pulse derived from the magnetic amplifier which occurs only once during a cycle. This requirement is always met by taking the signal from a winding on any core in the amplifier. The input impedance of the transient analyzer is high enough (one megohm) to prevent detrimental loading of the circuits.

The reference pulse phase angle α_R is readily adjusted without the aid of an oscilloscope as follows:

1. The output of the magnetic amplifier is set at the reference value by applying an appropriate steady-state control signal, and observing the output with a suitable a-c or d-c meter.
2. The transient analyzer is unclamped and the phase adjustment varied until pulses are obtained from the output terminals. (The electronic counter counts continuously as indicated by neon bulbs.)
3. The phase adjustment is then varied (coarse and fine adjustments) until the output from the analyzer just ceases. The reference angle α_R is now adjusted properly.
4. The analyzer is again clamped, the counter reset to zero, and the transient initiated by throwing the switch. At the completion of the transient, the reading of the counter is exactly equal to the response time in cycles.

Description of Circuits

The internal operation of the transient analyzer can best be explained by reference to the block diagram of Fig. 2. The input signal A is clipped,* differentiated, and amplified, resulting in a sharp negative pulse of short duration B, which occurs at phase angle α_{MA}. An a-c voltage C having the same frequency as the magnetic supply is passed through a phase shifter, which is equipped with coarse and fine adjustments for varying the phase. The phase shifted a-c wave D is clipped E, differentiated, and amplified, resulting in a sharp negative pulse of short duration F; this is the reference pulse. The phase of the reference angle α_R is determined by the phase adjustments previously described. The two pulses B and F are fed into opposite plates of a conventional Eccles-Jordan flip-flop circuit. The operation of the Eccles-Jordan[3] circuit is such that a negative pulse received at one plate triggers the stage, causing that plate voltage to drop to its low value and the voltage of the opposite plate to rise to its high value. The circuit then remains in this condition until a negative pulse is received at the plate of the second (opposite) tube, at which time the plate voltage values of the two tubes reverse.

The voltage from one plate of the flip-flop circuit G is used to control the gate stage. When this plate is high the gate is open and allows to pass through it a signal appearing at its input terminals I. When this plate is low the gate is closed and the incoming signal I is blocked.

The two input connections to the flip-flop circuit are interchanged for build-up and decay transients. For a build-up transient, the pulse derived from the magnetic amplifier B is connected to trigger the flip-flop in such a direction as to open the gate, and the reference pulse

---

* The negative half cycle is removed if the negative drop in the signal occurs on the positive half cycle (input from a reactor winding) and the positive half cycle is removed if the negative drop occurs during the negative half cycle. See (A) in Fig. 2; for circuit details see Fig. 3.

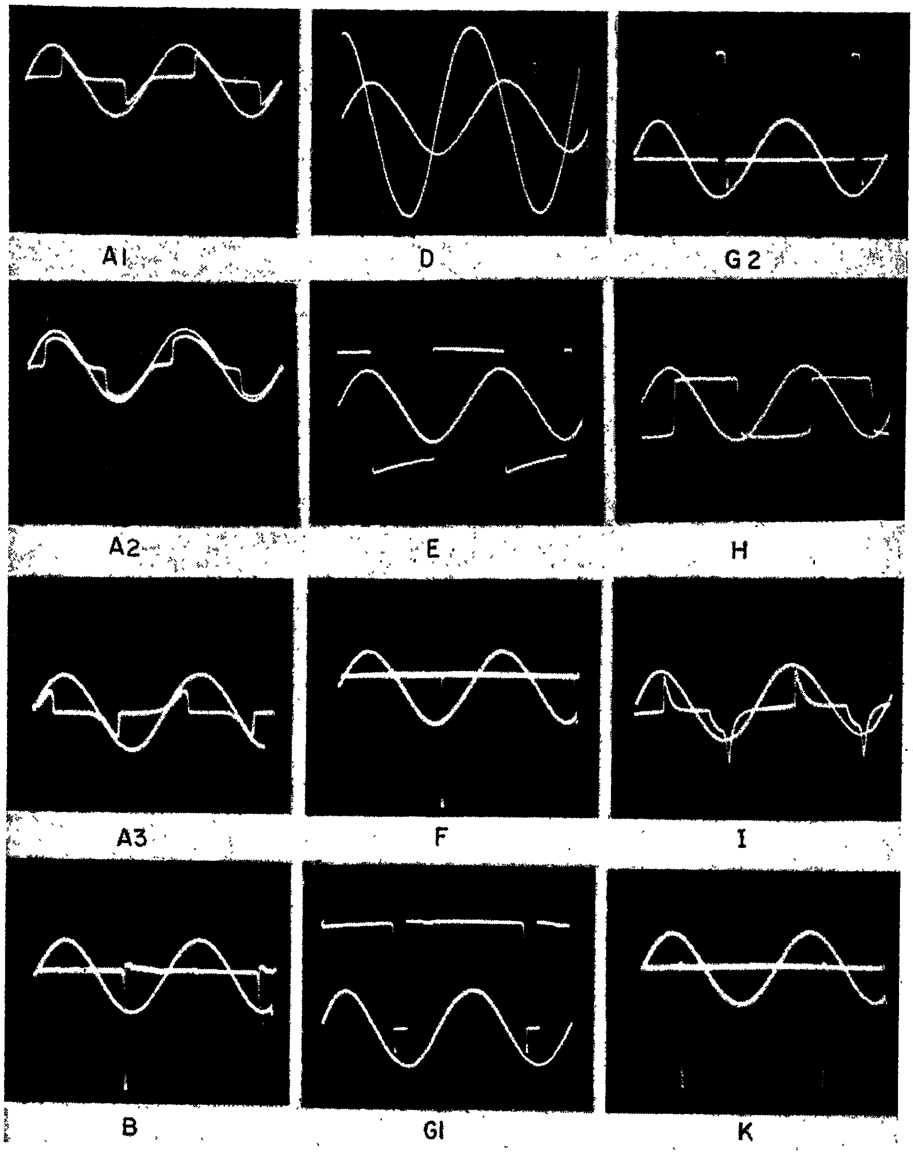

Fig. 4. Oscillograms of voltage wave forms at the various points in the circuit and block diagrams

F is connected in such a direction as to close the gate. The signal input (called the sensing pulse) to the gate *I* occurs at angle α_s, where

$$\alpha_s = \alpha_R + \pi$$

It follows immediately that if *B* occurs after *F*, that is

$$\alpha_{MA} > \alpha_R$$

the gate will be open when the sensing pulse *I* arrives at the input to the gate; therefore, a pulse appears at the output *J* and *K* of the device. On the other hand, during a build-up transient, if *F* occurs after *B*, that is

$$\alpha_{MA} < \alpha_R$$

the gate will be closed when the sensing pulse *I* arrives at the input to the gate; under these conditions, no pulse appears at the output of the transient analyzer. For a decay transient, the roles of the *B* and *F* pulses are interchanged by throwing the reversing switch shown in Fig. 2. The operation of the transient analyzer then proceeds as previously described.

The complete circuit diagram of the transient analyzer is shown in Fig. 3. Conventional pulse-circuit techniques are used; therefore, no detailed description is necessary. The particular circuit design shown is intended primarily for 60 and 400-cycles-per-second operation, but could be modified for higher frequency use with minor changes. Wave forms of voltages at various points in the circuit are shown in Fig. 4. (Oscillograms *B* and *F* are obtained with the tube T_3 removed from its socket.) The letters *A* to *K* refer to the circuit points shown in Figs. 2 and 3. *A1* and *A2* are the output voltages across the load of a Hipernik-V full-wave a-c amplifier for two values of control signal; *A3* is the voltage across the load winding of one reactor corresponding to *A2*. *G1* and *G2* correspond to signals *A2* (or *A3*) and *A1*, respectively for a decay transient in which the reference angle *F* lies in between these two limits. The magnetic amplifier source is 20 volts rms, and is shown in all oscillograms to the same scale.

Operating Experience and Remarks

The primary aim in developing the transient analyzer was to keep the circuitry as simple as possible, and yet provide a device which would be suitable for testing a wide range of magnetic amplifiers. Certain limitations exist; these will be brought out in the following.

The sensitivity of the circuit was found to be sufficient to allow satisfactory operation on signals obtained from typical 10-volt 60-cycles-per-second (supply voltage and frequency) half-wave and full-wave magnetic amplifiers, using Mumetal and Hipernik-V core materials. For much smaller signals, an additional stage of preamplification would be necessary. While there is virtually no upper limit to the amplitude of the signal that can be accepted, it may be necessary to restrict the amplitude in certain cases, where distortions or spurious pulses exist in the output of the magnetic amplifier wave; this can always be done with a high-resistance voltage-divider network.

The logic of the circuit operation requires that the input from the magnetic amplifier be sufficient to trigger the flip-flop stage for all values of α_{MA} realized during the transient. This condition becomes difficult to fulfill when either the initial or final value of α_{MA} approaches π, even though the signal strength may be adequate over the major portion of the transient. While the logic of the design could be changed to take care of this situation, the additional circuit complexity makes the change undesirable and contrary to the original aim of simplicity. Furthermore, the case for which α_{MA} approaches π is a very unusual one, and its exclusion does not impose a serious limitation on the usefulness of the device. At this point it may be asked whether the aforementioned limitation on α_{MA} does not exclude the application of the transient analyzer to push-pull magnetic amplifiers of the null-balance type, in which the initial or final steady-state output is usually zero. The answer is negative, because with such circuits the signal is obtained not from the output, but from a winding on one core. Hence, even at null balance, the signal α_{MA} is not likely to approach π.

The accuracy of the transient analyzer

depends upon how accurately the reference angle α_R can be set according to the procedure previously given. In every case tested, the reference adjustment (the point at which the "counting" just ceases) could be set as accurately as the meter (indicating output current or voltage) could be read.

Appendix. List of Components—Transient Analyzer

Tubes	*T1* to *T5*—*6SN7*
Transformer	*X1*—120 volts primary, 80 volts center tapped secondary, 60 and 400 cycles per second
Potentiometers	*P1*—850 kilohms, 4 watts *P2*—20 kilohms, 4 watts
Crystal Diode	*CR*—*IN34*
Switches	*S1, S2, S4, S5, S6*—double-pole-double-throw, no neutral position *S3*—single-pole-double-throw, neutral position
Power Supply	*B*+, 150 volts, 40 milliamperes *B*−, 100 volts, 10 milliamperes
Resistors	(1 watt, carbon, ±5 per cent)
R13, R14, R28	10 kilohms
R3, R17, R25	18 kilohms
R6, R7	24 kilohms (matched within 2 per cent)

Water Cooling Systems of Mercury-Arc Rectifiers

AIEE COMMITTEE REPORT

Synopsis: This report is intended as a guide on the design, application, and operation of water cooling systems for mercury-arc rectifiers. Its contents are based on the accumulated experience acquired by rectifier manufacturers and users over many years. The report deals with the various engineering and operating aspects of rectifier cooling systems. Several types of water cooling systems are described, and their application is discussed. The various factors influencing corrosion are reviewed. The characteristics of cooling waters are discussed and recommendations are given on the chemical treatment of coolants, the application of antifreeze solutions, and the maintenance requirements of cooling systems. The results of a survey on the operation and maintenance of cooling systems in representative rectifier installations are also included.

THERE are two general types of mercury-arc rectifiers in operation in the United States and Canada: the multianode type, with 6, 12, or 18 anodes with a common mercury cathode in one tank; and the single-anode type, with one anode and its cathode in an individual tank. Nearly all new rectifier installations made in the last 10 years or longer are of the single-anode ignitron or excitron type. For this reason, the report refers primarily to the single-anode type of rectifier; however, its contents apply generally to both types.

A standard rectifier consists of an assembly of 6 or 12 tubes with the auxiliary equipment. The rectifier cooling system, which is the subject of this report, is one of the essential auxiliaries, and its performance is an important factor in the operation of the rectifier.

The flow of current through a mercury-arc rectifier tube is accompanied by a voltage drop called the arc drop, which may have a value in the range of 15 to 25 volts, depending on the tube design and rating. The product of the current and arc-drop voltage is a power loss which is converted into heat. Most of the heat is transferred to the cooled surfaces of the tube by radiation and by condensation of mercury vapor.

For satisfactory operation, the heat generated by the losses has to be removed and the tube temperature maintained in the optimum operating range. The temperature of the cooled surfaces controls the mercury vapor density in the tube. Excessive temperatures are likely to cause arc backs. If the temperature is too low, the arc-drop voltage may increase and voltage surges might be produced due to arc starvation, when the mercury vapor density is insufficient for conduction of the tube current.

Glass-bulb rectifier tubes and some metal-tank tubes are cooled by air forced over the tube surfaces, with a fan or blower. However, most of the rectifiers in the United States and Canada are cooled by circulation of water through water jackets or tubular coils. Some tube designs have copper tubing soldered on the outside surface; others have internal steel coils. Combinations of external and internal coils or of internal coils and external jackets are also used. The water-cooled parts of sealed tubes are usually made of stainless steel.

Rectifier Cooling Systems

The following four types of water cooling systems are used for mercury-arc rectifiers: direct raw water cooling system; direct raw water cooling system with recirculation; heat exchanger cooling

Paper 53-288, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 17, 1953; made available for printing April 27, 1953.

The personnel of the Working Group on Water Cooling Systems of Mercury Arc Rectifiers of the AIEE Committee on Electronic Power Converters are: E. J. Remsheid, *Chairman*, Mrs. B. O. Buckland, A. P. Colaiaco, A. G. Dickinson, G. N. Hughes, J. Klotz (alternate), J. B. Nayler, R. J. Nix, M. W. Rew, Mark Sareault, and Harold Winograd.

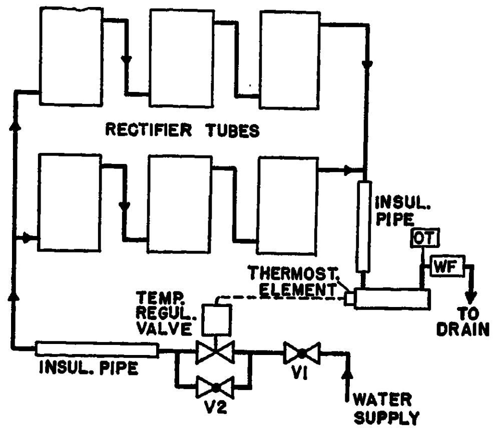

Fig. 1 (left). Direct raw-water cooling system

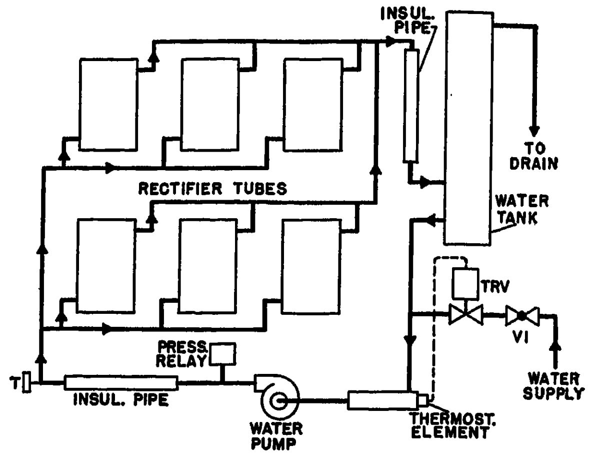

Fig. 2 (right). Direct raw-water cooling system with recirculation

system, using a water-to-water heat exchanger; and heat exchanger cooling system, using a water-to-air heat exchanger.

These cooling systems are illustrated in Figs. 1 through 4. The figures show typical cooling circuits of a 6-tube rectifier, without regard to the type of cooling elements on the tubes or the physical location of the component parts of the system. The cooling circuits are applicable also to rectifiers with a smaller or larger number of tubes. Individual designs of cooling systems may differ from the illustrations in various details.

Direct Raw Water Cooling System

This cooling system is illustrated in Fig. 1. Raw water from an available water supply flows through the rectifier tubes and is discharged to the drain. The flow of water is regulated by an automatic temperature regulating valve, which is actuated by a thermostatic element on the discharge side. The regulating valve conserves water and maintains the tube temperatures in the desired range.

The regulating valve is shunted by the small hand valve *V2* to permit the flow of a minimum amount of water when the regulating valve is closed. This minimum flow is needed for actuating the regulating valve by the thermostatic element, when the water discharge temperature increases and additional water is required. The cooling system is connected to the water supply through hand valve *V1*.

The rectifier tubes are at the potential of the cathode terminal, which is connected to the positive side of the d-c load circuit supplied by the rectifier. With rare exceptions, the positive side of the d-c circuit is insulated from ground. On some applications the negative side is grounded; on others, there is a floating ground connection between the positive and negative poles. For this reason the water connections between the rectifier and the grounded water supply and drain are made through insulating pipes, such as rubber hose or plastic tubing. The insulating connections are made sufficiently long to limit the flow of leakage current from the water to ground to a few milliamperes in order to minimize the electrolysis of the water and the corrosive effect of the liberated oxygen.

For traction systems the negative side of the d-c circuit is usually grounded. This practice has been recommended by the Technical Practices Committee of the National Association of Corrosion Engineers.[1]

To obtain good heat transfer between the cooled tube surfaces and the water, a specified minimum rate of water flow is required for each tube at the rated loads and overloads. To provide the required flow for this type of cooling system without using an exesssive amount of water the tubes are usually connected in series or in a series parallel combination as shown in Fig. 1.

For protection of the tube, an overtemperature relay *OT* on the discharge side and a water flow relay *WF* or a pressure relay are usually provided to give an alarm signal or take the rectifier out of service if the water flow is insufficient or has stopped completely. In automatic stations an electrically operated water valve is used for shutting off water when the rectifier is not in service.

Direct Raw Water Cooling System with Recirculation

This type of cooling system is shown in Fig. 2. The cooling water is recirculated between the rectifier tubes and a water tank by a motor-driven water pump at a constant rate. Raw water is admitted to the cooling circuit by a temperature regulating valve *TRV* as required for maintaining the water temperature in the desired range. The surplus water is discharged to the drain through an overflow pipe on the water tank. When the water temperature is below the setting of the thermostatic element, the regulating valve is closed.

The regulating valve may be connected to admit the raw water to the water tank instead of the piping shown in Fig. 2. The overflow opening in the tank should preferably be located above the highest point of the recirculating system, in order to keep the water passages of the system full and prevent admission of air when the pump is not running.

The rectifier tubes are usually connected in parallel. The water pump should have sufficient capacity to supply the required flow rate of the tubes. The tubes are connected to the grounded part of the cooling circuit through insulating pipes. As an alternative, the insulating pipes may be placed between the regulating valve and the hand valve *V1* on the water supply side, and between the water tank and the drain. The equipment of the cooling circuit would then be at the rectifier potential.

A pressure relay connected to the inlet side of the tubes provides protection against operation of the rectifier without water circulation. The contacts of the pressure relay may be connected in the rectifier control system to prevent starting the rectifier unless water is circulating through the tubes, and to shut it down if the water flow should stop accidentally. A thermometer *T* is provided for indicating the water temperature.

Heat Exchanger Cooling System with Water-to-Water Heat Exchanger

In this cooling system, illustrated in Fig. 3, the rectifier cooling water is circulated between the tubes and the soft-water passages of a water-to-water heat exchanger. The recirculated water is cooled in the heat exchanger by the flow of water from a supply through the raw-water passages. The heat transfer takes place through the walls separating the soft-water and raw-water passages. The heat exchanger usually consists of a copper-alloy tube bundle enclosed in a cast-iron or steel shell. The recirculated water flows through the shell across the tube bundle, while the raw water flows through the tube bundle.

In Fig. 3, the rectifier water circuit is indicated by heavy lines and the raw water circuit by lighter lines. The rectifier tubes are connected in parallel. The water is circulated between the tubes and the heat exchanger at a constant rate by a motor-driven water pump. The flow of raw water through the heat exchanger is controlled by a temperature regulating valve *TRV* in the water supply circuit so as to maintain the rectifier water temperature in the desired operating range. The regulating valve is actuated by a thermostatic element in the rectifier cooling circuit. A pressure relay on the inlet side of the tubes provides protection against operation without water circulation. Thermostats are usually installed on the outlet side of the tubes for overtemperature protection; either a common thermostat or an individual thermostat for each tube is used. A thermometer *T* on the inlet or outlet side of the tubes indicates the water temperature.

A water expansion tank is connected to the rectifier cooling system on the intake side of the pump and is mounted above the highest point of the water circuit. Its purpose is to keep the cooling system full and prevent entrance of air; it serves as a reservoir to permit expansion of the water when hot and to make up for loss of water due to leaks. The expansion tank is provided with an opening to the atmosphere; an overflow pipe may be connected to this opening. The water level in the tank is indicated by a level gauge.

If water from the raw-water supply is used in the recirculating system, a hand valve *V2* may be provided for filling the system or for adding water when necessary.

On some rectifier designs the heat exchanger and other components of the cooling system are mounted on the rectifier assembly at the rectifier potential, as indicated by the dot-and-dash rectangle in Fig. 3. The connections to the grounded water supply and drain are then made through insulating pipes. If the rectifier water is treated with a corrosion inhibitor, it is preferable to maintain the cooling equipment at the rectifier potential, even if this equipment is mounted away from the rectifier, to reduce the leakage current to ground, because the treated water has a much lower resistivity than the raw water. In some installations, it is necessary to ground the cooling equipment to facilitate maintenance and to ensure safety.

Where it is necessary to ground the cooling equipment, the insulating pipes are inserted in the water circuit between the grounded equipment and the rectifier. In such a case untreated distilled water, which has a high resistivity, may be used in the recirculating system, or the insulating connections may be made sufficiently long to keep the leakage current within reasonable limits if the water is treated.

Heat Exchanger Cooling System with Water-to-Air Heat Exchanger

This type of cooling system, illustrated in Fig. 4, is similar to the cooling system of Fig. 3, except that a water-to-air instead of a water-to-water heat exchanger is used. The heat exchanger consists of parallel tubes connected between headers and provided with fins on their outside surfaces. The water passing through the tubes is cooled by the forced flow of air over the tubes, supplied by a motor-driven fan or blower.

One method of controlling the water temperature is to regulate the flow of water through the heat exchanger by a double-valve temperature regulator *TRV* as shown in Fig. 4. One valve *S* is in series with the heat exchanger; the other valve *P* is in parallel with it. The thermostatic element controls the positioning of the valves so that one closes while the other opens, which regulates the proportion of the rectifier water passing through the heat exchanger. The operation of the fan may be controlled automatically by limit switches on the valve operator or by high-low thermostat coordinated with the setting of the temperature regulator.

Another method of controlling the water temperature is to start and stop the fan by high-low thermostats. In some installations several heat exchangers with individual fans are connected in parallel to the water circuit, and the tem-

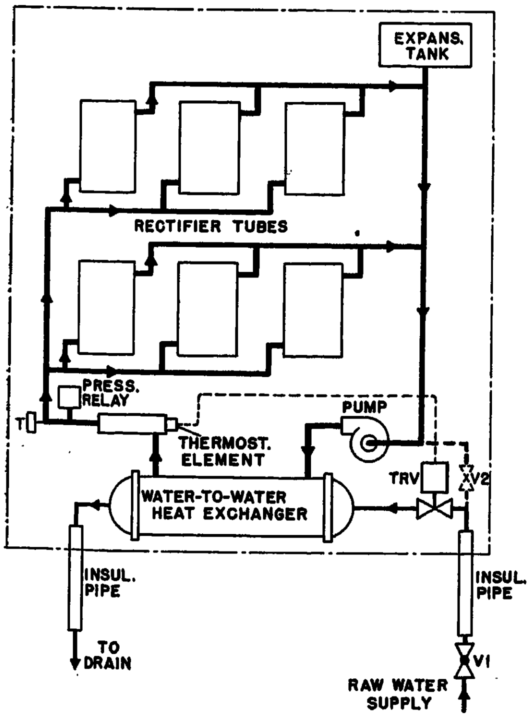

Fig. 3 (left). Heat exchanger cooling system with water-to-water heat exchanger

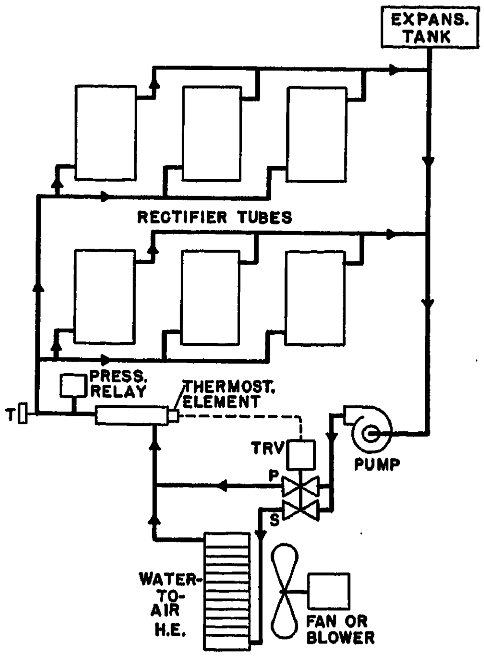

Fig. 4 (right). Heat exchanger cooling system with water-to-air heat exchanger

perature is controlled by the sequential starting and stopping of fans. Still another method of controlling the water temperature is to regulate the flow of air by controlling the speed of the fan motor or the position of air dampers, but this method is rarely used.

To limit the leakage current from ground, it is preferable to insulate the entire cooling system from ground, particularly if the water is treated with a corrosion inhibitor or an antifreeze solution. If the heat exchanger is located away from the rectifier, as is usually done, insulating pipes should be used in the connections of the rectifier cooling system. This provides protection against the flow of power current in case of accidental grounding of the heat exchanger; it also permits temporary grounding for inspection and maintenance. The heat exchanger may also be permanently grounded for safety reasons. In some installations the heat exchanger is placed outdoors.

COOLING OF VACUUM PUMP

The mercury-condensation vacuum pump used with pumped rectifiers and the water-cooled vacuum pipes require a small quantity of cooling water, approximately 1 gallon per minute or less. The vacuum pump requires water of lower temperature than the rectifier, and its cooling circuit is independent of the rectifier cooling system. For efficient operation of the vacuum pump, the cooling water temperature should be below 35 degrees centigrade. Raw water is generally used.

The cooling circuits of the vacuum pump and vacuum pipes are usually connected in series. The connections to the water supply and drain are made through insulating pipes because the vacuum pump is at rectifier potential. A water-flow relay or a thermostat on the vacuum pump is used for disconnecting the pump heater if the flow should stop.

If water of the required temperature is not available a water-to-air heat exchanger or a refrigeration unit may be used for cooling the vacuum pump water in a recirculation system, the choice depending on the ambient conditions.

DESIGN CONSIDERATIONS

The rectifier cooling system should be designed to dissipate the heat generated by the rectifier losses when operating at the rated loads and overloads, under the most adverse specified conditions of the cooling medium, without exceeding the normal operating temperature of the rectifier. The operating temperature, measured on the water discharge side of the tubes, is generally in the range of 45 to 55 degrees centigrade, depending on the tube design and the direct voltage.

The water-to-water heat exchanger should be selected for the highest specified temperature and the lowest specified pressure of the raw water supply. The water-to-air heat exchanger should be selected for the highest specified cooling air temperature. If the water-to-air heat exchanger is placed indoors, provision should be made in the building for the intake and discharge of the required quantity of cooling air. The intake and discharge openings should be far enough apart so that the discharged air will not re-enter through the intake. If ducts are used for the air, the blower should have sufficient capacity to take care of the pressure drop in the ducts in addition to the pressure drop of the heat exchanger.

The water pump should be selected to circulate the required rate of water flow against the total friction head of the cooling circuit. The flow rate is not critical; however, if it is too low the heat transfer in the heat exchanger as well as in the rectifier tubes is reduced. The motor driving a centrifugal water pump is usually matched to the pump so that the motor cannot be overloaded under any flow condition from blocked flow to open discharge. In designing the water circuit, care should be taken to have a positive pressure (above atmospheric) at the pump intake in order to prevent entrance of air through the shaft seal of the pump. To satisfy this condition, the static head from the point of atmospheric pressure (the expansion tank of Figs. 3 and 4) to the pump intake should be higher than the friction drop between these points of the circuit.

In recirculating cooling systems, valves should be provided at the lower part of the circuit for filling and draining the system. Small valves or pet cocks are usually provided on the pump and other parts of the cooling circuit to vent the air trapped when the system is filled. Air in the system can block or reduce the flow of water. Water may be added to the system either by a valve, as shown in Fig. 3 or at the expansion tank.

Valves may be provided in the cooling circuit to permit servicing individual items, such as the water pump, without draining the system. The number of such valves should be kept to a minimum because they increase the friction head. Gate valves should preferably be used because they have less friction drop than globe valves. The latter type is used where the water flow has to be throttled, as in the raw-water supply circuit.

For the cooling systems of Figs. 1 through 3, the size of the temperature regulating valve should be selected to suit the flow requirements at the prevailing water pressures. It should be large enough to permit the required water flow, when fully open, at the lowest operating pressure. However, if it is oversized and permits the required water flow when barely open, it will "hunt" and will not provide satisfactory temperature control. If the pressure of the raw-water supply varies over a wide range, a pressure regulator may be required. Strainers are provided in installations where the raw water contains filterable solids.

For some rectifier applications, water heaters are installed in the cooling circuit to maintain the water temperature within the desired operating range. The control of the heaters should be interlocked with the flow or pressure relay, or the pump motor, so that they can be energized only when there is a flow of water.

When a rectifier is on load, some of the internal parts of the tubes, such as the anodes, attain fairly high temperatures and continue to transmit heat to the cooling water for some time after the rectifier is shut down. For this reason the cooling system should continue to operate for 30 minutes or longer after the rectifier is shut down.

Where an insulating pipe is employed in the cooling system between points having a d-c potential difference, as shown in Figs. 1 through 3, an electrolytic target is sometimes provided at the positive (rectifier) end of the pipe to protect the metallic fitting against electrolysis. A metal rod, conductively connected to the fitting and extending several inches into the insulating pipe, is generally used for this purpose. A rod of copper, stainless steel, or iron, or a rod clad with platinum or other noble metal, may be used, depending upon the application. The target serves as the positive terminal for the leakage current flowing through the water in the insulating pipe. The need of targets depends on the magnitude of the leakage current.

If the electrically operated components of the cooling system (such as the water pump, heaters, and control and protective devices) are maintained at the rectifier potential, precautions have to be taken in regard to the insulation between the rectifier potential and the electric circuits to which these components are connected. The required insulation may be provided within the individual devices or through insulating transformers, depending on the operating voltage.

In a 6-phase double-way rectifier circuit, three tubes have a common cathode connection, while the other three tubes have a common anode connection and their cathodes are at different potentials from all the other cathodes. For this reason each of the latter tubes has to be connected to the cooling system through individual insulation pipes.

APPLICATION

The direct raw-water cooling system, Fig. 1, is the simplest and least expensive of the four types described. Because of the minimum water flow required at all times, the operating temperature of the rectifier tubes is likely to be below the optimum value at light loads, and moisture may condense on the outside tube surfaces when the humidity is high. For applications with a low load factor, the water consumption may be higher than for the other cooling systems, due to the minimum water flow requirement.

The raw-water cooling system with recirculation, Fig. 2, is second in regard to cost. It is less expensive than the heat-exchanger systems because the heat exchanger is omitted; the other components of the system are substantially the same. This is the most economical system in regard to water consumption, and the tube temperatures can be maintained in the optimum range.

Neither raw-water cooling system permits the use of a corrosion inhibitor or an antifreeze solution. The water passages of the tubes have to be cleaned periodically to remove any scale or sediment that may be deposited by the water. Raw-water cooling systems have been applied for rectifier units of lower ratings employing sealed tubes with stainless steel or nonferrous water-cooled surfaces. They can be used only when the raw-water quality conforms with the purity specifications given in the section entitled "Classification of Cooling Water."

Where a heat exchanger is required and a sufficient supply of raw water is available, a cooling system with a water-to-water heat exchanger, Fig. 3, is normally used. This type of heat exchanger occupies less space than a water-to-air heat exchanger, requires no fan, and no provision has to be made for the intake and discharge of cooling air. A cooling system with a water-to-air heat exchanger, Fig. 4, is employed when a sufficient supply of raw water is not available. Both heat-exchanger cooling systems permit treatment of the recirculated water, and the deposition of scale or sediment in the closed system is minimized.

Corrosion

The corrosion of metals may be defined as their destruction by the chemical action of their environment and must not be confused with erosion which is destruction by mechanical means. The rusting of iron is the most common example of corrosion, and sand blasting of iron is an example of erosion.

In the cooling systems normally employed for rectifiers, erosion is usually a negligible factor, whereas corrosion is of prime importance and requires diligent consideration of both design and maintenance of the units to insure a satisfactory service life. The types of corrosion commonly encountered in rectifier cooling systems are: atmospheric, galvanic, electrolysis, and acid attack.

ATMOSPHERIC CORROSION

Atmospheric corrosion or, more commonly, the reduction of iron to iron oxide, will form a thin film of oxide on the iron when exposed to dry air at ordinary temperatures. This film effectively isolates the iron from the oxygen and greatly reduces the rate of oxidation. However, if this film is removed in any way, the oxidation will continue.

Iron in an aqueous solution tends to go into solution as iron ions. However, in doing so, it must displace an equivalent number of hydrogen ions which gather on the surface of the iron as a thin invisible film. This film of hydrogen retards the tendency of the iron to go into solution and thus slows up the reaction. However if this film of hydrogen is removed, either by combining with oxygen or by forming hydrogen bubbles, the reaction will continue, the iron going into solution being thrown down as rust.

In an acid solution, the tendency of the hydrogen to plate out on the iron increases with the acidity and may increase the gas pressure in the hydrogen film sufficiently to form bubbles. This will destroy the protective hydrogen film and permit the iron to continue to go into solution. Thus, corrosion of iron is in general much more rapid in acid solutions than in alkaline solutions.

In a water cooling system which contains a continuous supply of oxygen, iron will combine with the oxygen to form hydrated ferric oxide which will precipitate as brown rust, and corrosion may be quite serious. This can occur in a direct raw-water cooling system, in which the oxygen dissolved in the water is liberated in the water passages. Copper, alloys of copper such as brass, also aluminum, and stainless steel form protective oxide coatings and are much more resistant to corrosion.

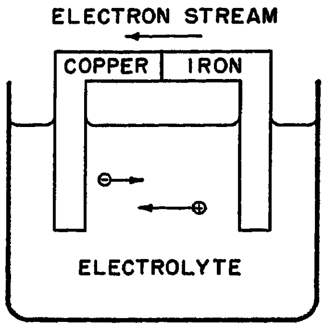

Fig. 5. Galvanic corrosion

In closed or recirculating cooling systems where the supply of oxygen is limited, the oxygen is gradually removed by combining with the iron, or by liberation and escape through vents, and the rate of corrosion is retarded. Also, in a closed system the solution can be made alkaline preventing the destruction of the protective hydrogen film on the iron and further retarding corrosion.

GALVANIC CORROSION

When two dissimilar metals, such as copper and iron, are brought into electric contact and are connected by an electrolyte, a current will flow between them, Fig. 5. The two metals in contact constitute in effect a miniature battery or galvanic cell with the iron as the anode. In the solution, electrons will flow from the copper to the iron and iron ions will flow from the iron to the copper. It is apparent that if this condition is allowed to continue the iron will eventually be eaten away.

Galvanic corrosion has been so very aptly described elsewhere[2] that it is included here.

Galvanic Series—With a knowledge of the galvanic corrosion behavior of metals and alloys, it is possible to arrange them in a series which will indicate their general tendencies to form galvanic cells, and to predict the probable direction of the galvanic effects. Such a series is provided in Table I.

This Table is based on actual corrosion testing experience with numerous corrosives in the laboratory, under plant operating conditions, and on practical results with metals and alloys in long service. This series should not be confused with the familiar "Electromotive Series," which is found in many textbooks and is of value in physical chemistry and thermo-dynamic studies. Let us make this difference a little clearer. The metals in the "Electromotive Series" are arranged according to the potentials possessed by them when immersed in solutions of a definite strength. These solutions are theoretically made up in a concentration containing one mole (a mass numerically equal to its molecular weight) per liter of the same ions as the respective metal immersed in it. The solutions, in other words, must possess an activity of unity. This fact must be borne in mind in using the "Electromotive Series." It is of great theoretical value, but it cannot be relied upon to predict potential differences between metals in the general case. And it certainly cannot be used to predict the amount of accelerated corrosion that will result from contact between two metals. Table I has basic characteristics which make it analogous to the "Electromotive Series," but it also takes into consideration over-all and practical aspects in addition to theoretical principles. The potentials measured in these practical corrosive environments do determine which one of two metals will be anodic and which cathodic.

Table I. Galvanic Series of Metals and Alloys

Corroded End (anodic, or least noble)

- Magnesium
- Magnesium alloys
- Zinc
- Aluminum 2S
- Cadmium
- Aluminum 17ST
- Steel or Iron
- Cast Iron
- Chromium-Iron (active)
- Ni-Resist
- 18-8 Stainless (active)
- 18-8-3 Stainless (active)
- Lead-Tin solders
- Lead
- Tin
- Nickel (active)
- Inconel (active)
- Brasses
- Copper
- Bronzes
- Copper-Nickel alloys
- Monel
- Silver solder
- Nickel (passive)
- Inconel (passive)
- Chromium-Iron (passive)
- 18-8 Stainless (passive)
- 18-8-3 Stainless (passive)
- Silver
- Graphite
- Gold
- Platinum

Protected End (cathodic, or most noble)

It will be noticed that some of the metals in Table I are grouped together. These group members have no strong tendency to produce galvanic corrosion on each other, and from the practical standpoint they are relatively safe to use in contact with each other. But the coupling of two metals from *different* groups and *distant* from each other in the list will result in galvanic, or accelerated, corrosion of the one higher in the list. The farther apart the metals stand, the greater will be the galvanic tendency. This may be determined by measurement of the electrical potential difference between them, and this is often done. But it is not practical to tabulate these differences, because the voltage values for combinations of the metals will vary with every different corrosive condition. What actually determines galvanic effect is the quantity of current generated, rather than the potential difference.

The relative position of a metal within a group sometimes changes with external conditions, but it is only rarely that changes occur from group to group. It will be seen that the chromium-iron and chromium-nickel-iron alloys are in two places in the Table. They frequently change positions as indicated, depending upon the corrosive media. The most important reasons for this are the oxidizing power and acidity of the solutions, and the presence of activating ions, such as halides. Inconel and nickel also occasionally behave in a similar manner, though the variations of their position are less frequent and less extensive. In environments where these alloys ordinarily demonstrate good resistance to corrosion, they will be in their passive condition and behave accordingly in galvanic couples.

Factors Influencing Galvanic Corrosion—The galvanic series indicates only the tendency of the several metals and alloys to set up galvanic corrosion. Actual corrosion cannot proceed unless there is a flow of electrical current. It is basically a question of amperes rather than volts. Just as in ordinary corrosion, the ease with which this current can flow and the magnitude of the current are controlled by a number of basic factors.

These factors are generally discussed under the headings, (1) Conductivity of the Circuit, (2) Potential Between the Anode and the Cathode, (3) Polarization, (4) Relative Cathode and Anode Areas, (5) Geometrical and Relationship Between Dissimilar Metal Surfaces, and (6) Contact Between the Metals.

A practical demonstration of corrosion by galvanic action occurs at the junction of an iron and a copper pipe in a cooling system. As shown in Fig. 6, the iron, or the less noble metal of the two, forms the anode of a galvanic couple and is corroded, with the deepest penetration at the contact point of the two metals.

Aluminum should not be used in a cooling system with copper or its alloys because of their wide separation in the galvanic series. Aluminum, being closer to the anodic end, would be subjected to corrosion.

There are various other causes of corrosion by galvanic currents and these have been listed[3] as follows:

1. Contact with metals.
2. Presence of impurities.
3. Grain boundaries, which are frequently anodic towards grain interiors.
4. Differential thermal treatment, important near welds.
5. Local scratches and cut edges, which are often anodic to the rest of the surface.
6. Differential stress or strain.
7. Differential concentration of salts, especially in the case of copper.
8. Differential aeration.
9. Differential heating.
10. Differential illumination.

Most of these items are not as important to mercury-arc rectifier cooling systems as contact between dissimilar metals. However, differential aeration is one which is thought by some to have a serious influence.

An example of galvanic corrosion by differential aeration is shown in Fig. 7. A small cavity or crack exists in the surface of the metal. Oxygen cannot diffuse readily to the bottom of this crack, whereas there is an abundance of it at the surface of the metal. A current is produced between the aerated surface of the metal (cathodic) and the unaerated crevice which is anodic. Since the attack is concentrated in the small crevice, and assuming that there is an abundant supply of oxygen at the surface, the rate of corrosion will be very great, usually becoming greater as the depth of the pit is increased. Thus, in designing cooling systems it is important to avoid such recesses.

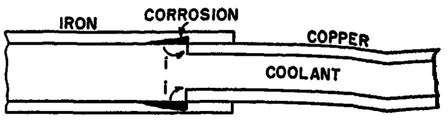

Fig. 6. Galvanic corrosion of water pipe

Corrosion by Electrolysis

In many rectifier installations the negative side of the d-c circuit is grounded or there is a ground connection at some intermediate point between the positive and negative terminals, so that the rectifier tubes operate at a positive voltage with respect to ground. If the coolant supply is grounded, it is brought to the rectifier through an insulating pipe and direct current flows through the coolant to ground. The magnitude of this current is determined by the impressed voltage, the diameter and length of the insulating hose, and the resistivity of the cooling medium.

The metal at the (anodic) positive end of the insulating pipe will be subject to electrolytic attack and may be eaten away to the extent that eventually a leak will result. Another effect of this current is to generate oxygen at the anode and hydrogen at the cathode. The oxygen so generated will tend to aggravate corrosion in other parts of the system.

One method used to prevent damaging electrolytic attack at the anodic end is to insert an electrolytic target which projects into the insulating section of the piping. These targets carry the major portion of the electrolytic current and suffer most of the deterioration, the small leakage current which is carried by the pipe fitting doing negligible damage.

Fig. 8 shows such a target arrangement. The target can be replaced when it becomes so short that it no longer provides adequate protection for the fittings. The rate at which the target wears away is proportional to the electrolytic current. In accordance with Faraday's law, one gram of equivalent (the weight of a sub-

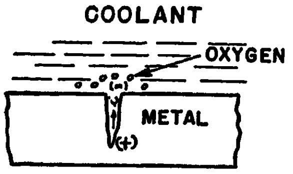

Fig. 7 (left). Galvanic corrosion by differential aeration

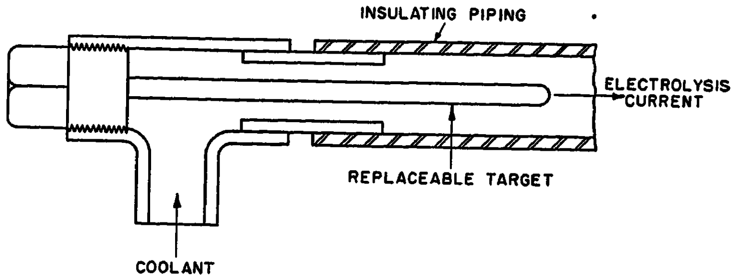
Fig. 8 (right). Electrolytic target



stance displacing or otherwise reacting with 1.008 grams of hydrogen or combining with 1/2 gram atomic weight—8.00 grams—of oxygen) weight of metal will be removed for each 96,500 coulombs (1 coulomb is a current of 1 ampere flowing for 1 second). Thus, 27.9 grams of iron will be corroded for each 96,500 coulombs or approximately 20 pounds per ampere-year. The choice of target materials depends on the degree of protection required, and the coolant being used. Iron, stainless steel, platinum, and copper have been used successfully.

In cases where an inhibitor is used in the cooling system for protection against atmospheric corrosion, the inhibitor usually greatly decreases the resistivity of the coolant with a proportional increase in electrolytic current and wearing away of the target. One commonly used inhibitor is sodium dichromate and borax added to the water in the ratio of 0.5 per cent by weight each. This reduces the resistivity of the cooling water to a small fraction of that of distilled water. However, the protection afforded the rest of the system by the inhibitor more than justifies the additional wear on the targets.

Corrosion by Acid Attack

Most common metals corrode much more rapidly in an acid solution than they will in a neutral or slightly alkaline solution. When a metal is placed in an acid solution it will displace hydrogen ions from the solution and its own ions will go into solution. The noble metals will displace hydrogen ions very slowly, forming a thin film of hydrogen ions on the surface of the metal, which will prevent further dissolving of the metallic ions into the solution, and corrosion is stopped. Metals such as gold, platinum, silver, and copper fall into this category.

The base metals such as iron, zinc, aluminum, and magnesium liberate hydrogen in an acid solution much more rapidly, to the extent that the hydrogen bubbles off in a stream rather than forming a protective film on the metal. This process will continue with the metallic ions continually going into solution, and the parent metal will gradually dissolve away. Metals such as lead, tin, and nickel liberate hydrogen very slowly in acid solutions and corrode very slowly.

A solution which is neither acid nor alkaline, therefore neutral, will have a pH value of 7. A cooling solution with a pH value between 7 and 9 (slightly alkaline) is satisfactory for the cooling systems of mercury-arc rectifiers. It is also important that the cooling medium should not be allowed to become excessively alkaline because metals such as aluminum and zinc, whose oxides are soluble in alkalies, will corrode rapidly in a highly alkaline solution.

Classification of Cooling Water

By the application of filtration, distillation, and chemical treatment, any kind of water can be prepared for a specific purpose. In order to classify raw waters for coolant purposes, factors such as color, pH, turbidity, and chemical analyses should be known. It is not necessary that raw waters, used as rectifier coolants, have a potable bacteriological count. Potable waters are usually free of many troublesome contaminants, but the question of using them as a coolant in many localities is an economic one.

Hardness in waters is caused almost entirely by the presence of calcium and magnesium. To a lesser degree, hardness is increased by minerals such as iron, aluminum, strontium, barium, zinc, and free acids. Hard waters are less corrosive than soft waters, but are more conducive to scaling. In terms of $CaCO_3$ in parts per million very hard waters have a hardness of 201 to 500; moderately hard, 101 to 200; slightly hard, 56 to 100; and soft waters are termed as 0 to 55 parts per million.

Raw-water coolants for power rectifiers are classified as surface waters, ground waters, and purified waters.

Surface Waters

Surface waters are taken from rivers, ponds, lakes, or ocean bays. The quantity of contaminants in such waters is sometimes high, requiring straining or filtration to some degree. At times chlorination is necessary to prevent the growth of bacteria and algae in the finely divided suspended organic matter. Waters pumped from ocean bays are considered brackish because of their high salt content. Desirable low-temperature surface waters are obtained when the intake pipe is at a considerable depth.

Surface waters are applied most frequently as the raw water in cooling systems with water-to-water heat exchangers. Relatively clean surface waters are used in direct raw-water cooling of rectifiers. A high quality potable surface water is obtained from the Great Lakes for many of our larger cities and is well suited for either direct or heat-exchanger cooling or for filling recirculating systems.

Ground Waters

Ground waters are those pumped from the earth, as from artesian wells. Well waters differ greatly in hardness and chemical composition, the differences being due to the different kinds of mineral matter the water contacts while percolating and flowing through the ground.

Like surface waters, ground waters of suitable quality are well adapted to water-to-water types of heat exchangers and for direct raw-water cooling. Ground waters have a desirable characteristic in that the intake temperature is several degrees below the particular ambient.

When applying ground water as a coolant, it is important that the chemical analysis be studied and the possible degree of scaling noted. Chemical analyses are not always available to assist in an appraisal of cooling water. In such cases, an electrical resistivity measurement of the water will provide a satisfactory guide to the total amounts of dissolved solids. Waters having a resistivity of 2,500 ohm-centimeters or higher, when measured at about 25 degrees centigrade, are usually satisfactory as coolants. When desirable, the approximate amount of total dissolved solids in parts per million can be determined by the equation

$$\text{Total dissolved solids in parts per million} = \frac{640{,}000}{\text{specific resistivity in ohm-centimeters}}$$

The recommended quality of cooling water as specified in the American Standards Association Standard *C-34.1-1949*[4] is as follows: Water for direct raw-water cooling systems, where heat exchangers are not employed should have the following purity:

1. A neutral or slightly alkaline reaction, that is, a pH between 7.0 and 9.0.
2. A chloride content of not more than 20 parts per million; a nitrate content of not more than 10 parts per million; a sulphate content of not more than 100 parts per million.
3. A total solids content of not more than 250 parts per million.
4. A total hardness, as calcium carbonate, of not more than 250 parts per million.

PURIFIED WATERS

Distilled water, steam condensate, and properly deionized waters are usually referred to as purified waters. Purified waters are applied specifically in heat-exchanger cooling systems where a coolant of high electrical resistivity is required, as in cases where the water flows through insulating pipes between points of high potential difference.

Waters having a resistivity greater than 30,000 ohm-centimeters are considered purified waters. Steam condensate and deionized water usually have a resistivity of 30,000 ohm-centimeters or higher. Distilled water has a resistivity of 100,000 ohm-centimeters or higher. The resistivity of purified water in a rectifier cooling system is gradually lowered while in use, and the water may have to be replaced periodically if a certain minimum resistance is required.

Chemical Treatment of Rectifier Coolants

Chemical treatment of water in recirculating cooling systems is resorted to for two reasons: 1. To prevent corrosion of metal parts. 2. To prevent freezing of the coolant.

CORROSION INHIBITOR

Various treatments have been tried, but a solution of sodium chromate and water has been found to be the most economical and practical method of preventing the corrosion of the iron parts of a rectifier cooling system. Corrosion is inhibited by the deposition on the metallic surfaces of a dense and adherent protective film of iron oxide and chromic oxide, Cr_2O_3, produced by a simple corrosion reaction. The protective film forms quickly, and the local deposition current gradually decreases as the thickness of the film and its resistance increases. One desirable feature of the protective film is that it is self-healing and will retard any action tending to cause corrosion.

Corrosion inhibiting solutions can be made using either sodium chromate, Na_2CrO_4, or sodium dichromate, $Na_2Cr_2O_7 \cdot 2H_2O$, with either distilled waters or satisfactory tap waters. Such solutions are made as follows:

1. Sodium chromate—Using distilled water, add 0.1 per cent by weight of Na_2CrO_4.
2. Sodium chromate—Using a satisfactory tap water, add 0.5 per cent by weight of Na_2CrO_4.
3. Sodium dichromate—Using distilled water, add 0.5 per cent by weight of $Na_2Cr_2O_7 \cdot 2H_2O$ and 0.5 per cent by weight of borax. Since sodium dichromate tends to increase the acidity of water, the borax is added to increase the alkalinity.
4. Sodium dichromate—Using a satisfactory tap water, add 1 per cent of $Na_2Cr_2O_7 \cdot 2H_2O$ and 1 per cent of borax.

These chromate solutions have proved satisfactory and are recommended in the American Standards Association Standard *C-34.1-1949*.[5]

ANTIFREEZE

Antifreeze solutions are used in recirculating rectifier cooling systems which are exposed to freezing temperatures. This applies most frequently to cooling systems with water-to-air heat exchangers.

There are two general types of antifreeze materials, those with a glycol base and those with an alcohol base. The latter are divided into two classes, methanol base and ethanol base. The glycol base antifreezes have a higher boiling point and are therefore referred to as permanent type antifreezes. Since rectifiers operate at relatively low temperatures, either type of antifreeze is satisfactory. The methanol base types are less expensive and smaller amounts are required for the same temperature protection.

Most commercial antifreezes contain corrosion inhibitors which normally give adequate protection for approximately 3 months. At this time the system should be checked, and if the solution is rusty the inhibitor has lost is effectiveness.

The presence of alcohol in the system without an inhibitor will loosen the protective film of the metallic surfaces. If an alcohol base antifreeze is continued in use after its corrosion inhibitor has lost its effectiveness, an inhibitor should be added. Borax can be used as an inhibitor for an ethanol base antifreeze; a 0.5 per cent solution by weight of borax (0.7 ounce per gallon of solution) is adequate. For a methanol base antifreeze, either borax or sodium chromate may be used as an inhibitor.

The presence of too much inhibitor in the system may prove detrimental and therefore inhibitor should not be added until the self-contained inhibitor in the antifreeze has lost its effectiveness and then only in the amounts specified.

Neither the chromate nor dichromate inhibitors should be used with a glycol or ethanol alcohol base antifreeze because serious corrosion will result.

A commercial synthetic methanol of 99.85 per cent purity (which does not contain any inhibitor) may be used as an antifreeze in a rectifier cooling system in which sodium chromate is used as an inhibitor. The percentage of methanol is determined by the lowest temperature for which protection is required.

Operation and Maintenance

The amount of maintenance a cooling system will require depends much upon the nature of the particular coolant. The more important maintenance items and operating precautions are outlined in the following.

It is necessary to check periodically, at intervals of 6 months or less, the effectiveness of the corrosion inhibitor. This can be done either by checking the electrical resistivity of the coolant or by checking its actual corrosion retarding qualities in an electrolytic cell. The electrolytic cell is provided with two iron wire electrodes with approximately 5 volts d-c potential applied across them. With the electrodes partly immersed in the liquid, electrolytic disintegration of the positive electrode will be noted in a few minutes should the coolant be of a weak concentration. When a sufficient amount of sodium chromate is present, no disintegration will be noted even if the test is continued for many hours. The frequency of the tests will depend upon the amount of make-up water added to the recirculating system, which would naturally weaken the solution.

When the coolant is checked by the resistivity method, it is suggested that all tests be made at a specific temperature. The following values indicate the permissible range when tests are made at a temperature of 25 degrees centigrade:

0.1 per cent solution of sodium chromate, 600 to 800 ohm-centimeters

0.5 per cent solution of sodium chromate, 150 to 200 ohm-centimeters

Because of the nature of a chromate solution, minute water leaks will not seal themselves. It is therefore necessary to make all pipe joints watertight prior to the use of the chromate solution. The cooling system should be inspected frequently for water leaks.

Systems utilizing raw water, such as sealed tube rectifiers or the raw-water side of a heat exchanger, must be cleaned periodically of scale or water sediment. Iron parts of a raw-water system will corrode and in time must be replaced. The cleaning intervals may vary from 3 months to 2 years, depending on the quality of the water.

Excessive amounts of scaling not only will reduce the water flow but will impair the heat-transfer efficiency of cooling surfaces. The removal of scale from a cooling system can be done safely by any of several commercial chemical methods, such as by recirculating solutions of Rodine or oxalic acid.

Cooling tubes of a water-to-water heat exchanger, provided with removable headers, can be cleaned mechanically with wire brushes or metal rods.

It is obvious that all accessory equipment of the cooling system, such as thermal devices, pressure relays, sight gauges and automatic water valves must be maintained in satisfactory working condition. Most of these devices will be conditioned when a cooling system is chemically cleaned. Devices comprising moving parts, such as water pumps, automatic water valves, and fan motors, require special attention.

When a rectifier is in operation, each tube must receive sufficient water to maintain its temperature within the specified operating limits. If the flow of water through an individual tube is too low because of a partial obstruction, it would be indicated by a higher temperature on its water discharge side as compared to the discharge temperature of the other tubes. Air trapped in the cooling circuit may obstruct the flow of water.

For satisfactory protection against freezing, it is recommended that antifreeze solutions be discarded and replaced once each year. Frequent tests of specific gravity should be made to insure adequate protection during the winter months. If electrolytic targets are used, they should be checked periodically and replaced when they become so short that there is danger of electrolysis at the pipe fittings.

All cooling systems have a number of controls to regulate the tube temperature and to act as safety devices. These should be checked once a year for operation and settings.

Survey of Rectifier Cooling Systems

QUESTIONNAIRE RETURNS

A questionnaire on rectifier cooling systems was sent to 81 rectifier users. Returns were received from 32 users, representing 475 operating ignitron, excitron and multianode units. Included in the number are rectifiers operating in all classes of service, both in the United States and Canada. The d-c operating voltages of the various units range from 250 to 1,800 volts. Installation dates of the various units range from 1927 to 1951. The following data reveal the number of rectifier units involved for each specific question asked.

TYPES OF COOLING SYSTEMS

The three usual methods of cooling rectifiers are by raw water, water-to-water heat exchangers, or water-to-air heat exchangers. The number of rectifier units in the survey employing each of the three types of cooling systems is as follows:

Rectifiers cooled by water-to-water heat exchangers, 291

Rectifiers cooled by water-to-air heat exchangers, 174

Rectifiers cooled by raw water (sealed tube units), 10

TREATMENT OF RAW WATER

Chemical treatment of raw water depends specifically on the quality of water and local conditions. So-called hard waters are treated to remove scale-forming materials. Waters having a comparatively low pH value are treated to make them less corrosive. Fungus growth is prevented by chlorine treatment. The number of rectifier units using chemically treated raw water is 86.

Water containing suspended matter requires filtration. The survey indicates that in some cases this is done either by the use of filters or settling tanks.

TREATMENT OF RECIRCULATING COOLANT

Chemical treatment of recirculating coolants is used specifically to retard or prevent the corrosion of iron parts of the cooling system. The survey indicates the following interesting facts regarding the recirculating coolants used in 475 operating units. The percentages of the units employing the various coolants are:

	Percentage
Raw water, untreated	29.0
Distilled water	27.2
Steam condensate	10
Sodium chromate and water	31.5
Other chemicals and water	2.3

Table I. Variance in Cleaning Methods

Loose deposit	48.5
Tubercles	19.3

CLEANING OF COOLING SYSTEMS

To maintain the effectiveness of the heat-transfer surfaces of heat exchangers and rectifier tubes, periodic cleaning is necessary. Rectifier manufacturers have designed the various components of coolant systems to facilitate this maintenance procedure. Because of the difference types of coolants and the specific differences in cooling systems, the cleaning methods employed and the type of sediment removed vary with the installations. This variance is portrayed by the percentages given in Table I, indicating the preferences of various rectifier users.

It is noted from the percentages given in Table I that raw waters containing mineral matter which form loose deposits are often used as rectifier coolants. Fortunately such deposits can be removed most readily by reverse flushing or with compressed air and water. Hard scale is met with in some instances and requires harsher removal methods, such as a wire brush, sand blast, scraper, or chemical means.

When hard scale is encountered, water softening by the removal of calcium and magnesium salts is an economical remedy. The bulk of the calcium salts is usually removed by treatment with lime and sodium carbonate, and the magnesium salts are treated with sodium hydroxide.

Tubercles or large pieces of metal oxides often grow in parts of a cooling system. Water flow loosens these masses, which are then carried through the system until they bind themselves in narrow passages and thus impair the performance of the system. Tubercles of this nature usually form on iron surfaces when untreated water is used. Many tubercles grow to a size 10 to 30 times the amount of metal corroded in producing them. The addition of an alkali to the coolant usually prevents the growth of tubercles.

Electrolytic Targets

The survey indicates that 348 of the 475 rectifier units reported use some form of electrolytic target. The target materials include copper, steel, zinc, copper-zinc alloy, iron, carbon, and platinum. The usual location of such targets is at the rectifier ends of insulating water pipes.

Painting of Vacuum Chambers

Many multianode rectifier users find it desirable to paint the water-cooled tank surfaces periodically. The types of coating applied are Apexior paint, graphite base paint, and aluminum powder mixed in varnish. Such painting, when applied to clean metal surfaces, will give protection from corrosion for approximately 2 years.

Grounding of Heat Exchangers

Approximately 55 per cent of the survey returns indicate a preference for operating the heat exchangers at rectifier potential. This arrangement has several advantages. No insulating water pipes are required between the component parts; also the heat exchanger and rectifier can be mounted on a common base. Thirty-eight per cent of the returns indicate a preference for keeping the heat exchangers at ground potential. One advantage of this arrangement is that some maintenance work can be done on the heat exchanger while the rectifier is energized.

Maintenance

The following items were reported as requiring more than the usual amount of maintenance:

1. Regulating water valves, both motor-operated and bellows-operated.
2. Thermostats.
3. Early deterioration of insulating water pipes, especially rubber hoses.
4. Cooling jackets on mercury-vapor vacuum pumps.
5. Bearings of pumps and fans.

Summary

A study of the questionnaire returns indicates that materials in suspension and materials which are classed as dissolved solids in raw water involve more maintenance hours than do actual corrosion troubles. Such materials cause erosion of pump impellers and piping, deposition of scale and mud in the system, and deposition of a heat-insulating film on the heat-transfer surfaces of heat exchangers and rectifier tubes. Such materials also interfere with the functioning of control devices, cloud gauge glasses, and sight flow indicators. Seasonable changes in the chemical nature of raw waters are also a cause for additional maintenance hours.

It is gratifying to note, however, that cooling systems provided with sodium chromate operate for many years free from corrosion troubles.

Appendix I. Heat Transfer and Fluid Flow

A rectifier functions as an electronic switching device, for it neither generates nor stores energy. The heat liberated comes entirely from the arc loss during conduction between anode and cathode. The thermal capacity in a rectifier tube is low, and the cooling system must be proportioned to dissipate all losses readily whether generated in continuous or intermittent duty.

The required operating temperature and rate of water flow is specified by the tube manufacturer, and the cooling equipment supplied with the rectifier is designed to maintain the prescribed operating temperature. There is an optimum temperature range for satisfactory operation, and the cooling system is designed to keep the temperature within that range. Unlike some other types of electric equipment, the rating of a rectifier is not determined by the temperature rise of the water-cooled parts, and the loading cannot be increased by lowering the temperature below the specified values. Operating at excessively low temperatures can be detrimental to the rectifier.

Scale formation interferes with the water flow, as it restricts the flow area. It also interferes with heat transfer, as it introduces an additional thermal resistance between the water-cooled surfaces and the water. This makes the wall temperature hotter for the same water flow and temperature. The heat-transfer coefficients for scale deposits are given by McAdams.[6]

The greater part of the heat liberated at the anode of a rectifier tube is dissipated by radiation to the cooled surface of the tube. Part of the heat is dissipated by conduction to a radiator or bus terminal connection, which maintains the anode seal at a safe operating temperature. A large part of the heat generated at the cathode is dissipated by condensation of the vaporized mercury at the cooled surface.

Water Cooling

In a water cooling system the water flow required to dissipate the losses can be calculated from the following equation

$$\text{gpm}=\frac{3.8\text{ kw}}{t_{\text{outlet}}-t_{\text{inlet}}}$$

where

gpm = gallons per minute

$$\text{kw}=\frac{\text{arc loss (volts)}\times\text{load current (amperes)}}{1{,}000}$$

t = temperature, degrees centigrade

In some cases, as in a direct raw-water cooling system, the available head of water is one of the system limitations, and thus determines whether the flow paths are to be connected in series or in parallel.

Air Cooling

In an air cooling system the air flow required to dissipate the losses can be calculated from the following equation

$$\text{cfm}=\frac{1{,}750\times\text{kw}}{t_{\text{outlet}}-t_{\text{inlet}}}$$

where cfm = cubic feet of air per minute at sea level.

For air cooling the air velocity must be much higher than the corresponding velocity for water cooling. Consequently, an air system requires a substantial head measured in inches of water.

Conversion Factors

1 kw = 3,413 Btu per hour = 56.88 Btu per minute = 239.1 calories per second
1 Btu = 0.000293 kilowatt-hour = 0.293 watt-hour
1 gpm water = 500 pound-hours
1 cfm air = 4.5 pound-hours
Specific heat of water = 1.0 Btu per pound (degrees Fahrenheit) or calories per gram (degrees centigrade) at normal cooling temperatures
Specific heat of air = 0.24 Btu per pound (degrees Fahrenheit) or calories per gram (degrees centigrade) at normal cooling temperatures
1 pound per inch^2 = 0.434 foot head of water

Frequency Generating Equipment for Million Watt Navy Transmitter

D. G. ROBERTSON
MEMBER AIEE

Synopsis: Novel methods are used to obtain crystal stability and still permit continuous coverage of the frequency range. The type *o-146/FRT-3* Frequency Generator-Monitor described is part of the United States Navy's new model *AN/FRT-3* superpower very-low-frequency transmitter.

THE DESIGN OF frequency generating equipment for a 1000-kw Navy transmitter required the application of new circuits and combinations of circuits to meet the following general specification requirements:

1. The generation of a radio-frequency signal continuously variable from 14.5 to 35.0 kc, with a frequency stability of 0.001 per cent;
2. An on-off keying capability of speeds up to 75 cycles per second without the use of relays when polar or neutral keying signals are supplied;
3. A frequency-shift keying capability, either polar or neutral, with deviations up to plus and minus 25 cycles, at speeds up to 24 cycles per second.

The equipment design to meet these requirements is called the Frequency Generator-Monitor. All components necessary for the proper operation of the frequency generator-monitor are contained in 12 units mounted in the 3-bay rack-type enclosure shown in Fig. 1.

Basic equipment consists of two variable-frequency sources, a master-oscillator, and a monitor. Auxiliary equipment is also supplied to compare the two frequencies. This consists of a deviation indicator and an automatic frequency control. Elements mounted in the left bay and the upper unit of the center bay comprise the master oscillator. The second and third units in the center bay are the deviation indicator and automatic-frequency-control units respectively. The remaining bay constitutes the monitor. Fig. 2 is a block diagram showing the relationships of these four functions.

The master oscillator is comprised of five units:

1. The variable frequency oscillator;
2. The mixer amplifier and keyer;
3. Number 1 and number 2 crystal oscillators;
4. The master oscillator power supply;
5. The frequency shift meter.

Block diagram Fig. 3 shows the relationships of these units and the output and input information associated with each unit.

Radio-frequency voltage to drive the transmitter is generated by heterodyning the 214.5- to 235.0-kc output of the variable-frequency oscillator with the output of crystal oscillators no. 1 or no. 2, and using the difference frequency. The 200-kc output of oscillator no. 1 is used for on-off keying. On-off keying is accomplished without relays by using the keying signals as a direct control on the signal to the transmitter. The 200-kc output of oscillator no. 2, modified by the reactance tube up to plus or minus 25 cycles per second, is used for frequency-shift keying. Relays are used in frequency-shift keying. The keying signals operate the relays and the relay contacts apply control voltage to the reactance-tube grids. The amount of shift is indicated on the frequency-shift meter which compares the frequency of crystal oscillator no. 2 against that of crystal oscillator no. 1.

The monitor also consists of five units:

1. The fixed frequency divider;
2. The frequency generator;

Paper 53-198, recommended by the AIEE Radio Communication Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted December 26, 1951; made available for printing March 30, 1953.

D. G. Robertson is with the Radio Corporation of America, Camden, N. J.

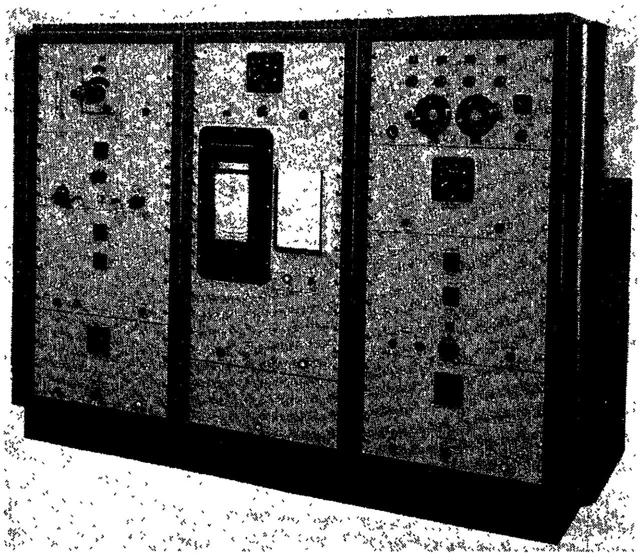

Fig. 1. Frequency generator-monitor

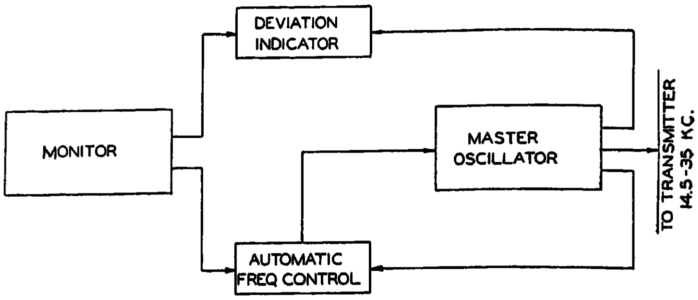

Fig. 2. Block diagram, frequency generator-monitor

3. The frequency increment meter;
4. Crystal oscillators no. 3 and no. 4;
5. The monitor power supply.

Block diagram Fig. 4 illustrates the relationships of these units and pertinent output and input frequencies. The monitor generates its output frequency in an unusual manner, enabling it to maintain a stability within the specified tolerance of 0.001 per cent. It is accomplished through the use of a bridge-stabilized oscillator[1] in conjunction with a binary-type variable-frequency divider. The bridge-stabilized oscillator, crystal oscillator no. 3, provides stability, and the variable-frequency divider permits frequency variation. Fig. 5 illustrates this action. The 200-kc frequency generated by crystal oscillator no. 3 is passed through the fixed-frequency divider to obtain a reference frequency of 100 cycles. The frequency generator, by virtue of its variable-frequency divider, then acts to produce the monitor output signal having the stability of this 100 cycle signal.

The basic monitor frequency is generated by a simple Colpitts oscillator. This oscillator is continuously variable over the range of 645 to 850 kc. The output of this oscillator is fed to the variable-frequency divider, which can be adjusted to divide by any whole number from 6,450 to 8,500 inclusive. For example, if the variable oscillator frequency is 645,000 cycles per second, and the divider is set to divide by 6,450, the output frequency is 100 cycles per second. This signal and the 100 cycle signal derived from crystal oscillator no. 3 are fed into a phase detector. The output of the phase detector acts on a reactance tube coupled to the variable oscillator in such a manner as to compensate for any tendency to drift on the part of the variable oscillator. Thus, the variable oscillator is "locked-in" with crystal oscillator no. 3. By this method frequencies with crystal stability are generated at 100-cycle intervals throughout the range of 645 to 850 kc.

This voltage is fed to a fixed divider having a division ratio of ten. This gives an output of 64.5 to 85 kc, in steps of ten cycles. To derive the final monitor output frequency, this signal is heterodyned with a 50-kc signal derived from crystal oscillator no. 3. The difference frequency of 14.5 to 35 kc, in 10 cycle steps, is thus obtained. In order to obtain continuous-frequency coverage, crystal oscillator no. 4 is switched in place of crystal oscillator no. 3 in the final heterodyne circuit. Oscillator no. 4 is provided with a vernier adjustment to lower its frequency 40 cycles from 200 kc. This results in increments of up to ten cycles in the monitor output frequency. The frequency-increment meter is provided to measure the frequency difference between oscillators 3 and 4. It is calibrated 0 to 10 cycles to be in accord with the monitor output.

The automatic-frequency-control unit, Fig. 5, samples the output signals of both the master oscillator and the monitor. It compares the signals, and when any frequency difference exists, it produces 2-phase power. This power operates a synchronous motor to turn a variable capacitor in the master oscillator's variable-frequency oscillator. By this means, the master-oscillator frequency is continually corrected to give it the stability of the monitor.

Of particular interest is the variable-frequency divider. It consists of a chain of 16 driven flip-flop binary dividers. Each binary consists of two triodes connected to resemble a multivibrator, so that when one triode is conducting, the other is cut off. The constants are so chosen that the circuit is stable in either state of conduction, and the application of a triggering pulse will reverse the cir-

cuit. The application of two pulses of the same polarity causes 1 cycle of operation, giving a divide-by-two circuit which is independent of frequency. Four of these binaries connected in series would ordinarily divide by 16, but when two feedback circuits are properly connected between stages a decade (divide-by-ten) circuit results. In this equipment the 16 binaries are arranged into three decades, followed by four binaries, resulting in a basic division of 10×10×10×16, or 16,000. It can be seen that even though each binary has but two conditions (one triode or the other conducting) there are 16,000 different combinations of these conditions, one for each of the 16,000 input pulses.

To make the chain into a variable divider, one of these conditions is taken as the zero-count point and whenever this particular condition exists a thyratron is fired. The output pulse of this thyratron is called the reset pulse, and is fed through four selector switches to one triode grid or the other of every binary in the dividing chain. If for instance, the selector switches are set to obtain a division of 8,500 the reset pulse is applied to the proper binary grids so that the dividing chain is immediately placed in the same condition as though it had received 7,500 input pulses. From this condition it takes only 8,500 input pulses to bring the dividing chain back to the zero condition. If the reset pulse is taken as the output, there will be one output pulse for every 8,500 input pulses. Under these conditions, an input of 850 kc to the divider will result in an output of 100 cycles. The proper setting of the selector switches permits the choice of any division ratio from 6,450 to 8,500 inclusive.

Fig. 6 shows the frequency-stability characteristics of the master oscillator when operating with automatic-frequency control. It is a representative 1-hour sample of the output frequency as recorded during a 6-hour heat run. Since the horizontal scale is 0.4 cycle per division, and the run was taken at a frequency of 22 kc, the total variation shown is 0.00032 per cent. The specifications require 0.001 percent. Fig. 7 is a sample of a similar frequency versus time run, but with the automatic frequency control feature disabled. In this case the horizontal scale is 5.0 cycles per division instead of 0.4 cycles. The total variation shown is 0.5 cycles, or 0.0023 percent of the 22-kc output frequency. It should be pointed out that the latter is ordinarily considered to be a high degree of frequency stability for transmitters operating in the very-low-frequency band. The master-oscillator output which is used to drive the transmitter is obtained by heterodyning a one-tube variable-frequency oscillator against a one-tube crystal oscillator. To generate the monitor frequency requires the use of some 75 tubes and their associated circuits. Thus in the event the monitor fails, transmitter operation can still be maintained with a useful degree of frequency stability. Achievement of this practical design goal satisfies the important requirement of dependability, which is an essential military characteristic.

Telephone-System Applications of Recorded Machine Announcements

W. BENNETT
MEMBER AIEE

THE BUSINESS of the Bell System is primarily to provide communication services. However, as in any industry, a number of very useful side lines have developed, one of which is in the voice-reproduction field. With the vast growth of the telephone system and the increasing complexity of its networks of lines and switching systems, numerous instances have arisen wherein the general service could be improved or additional services given to telephone users by employing voice-reproduction devices. Some announcement systems, such as the Weather Forecast bureau, provide invaluable service to business men and holiday pleasure-seekers alike. Other systems, such as the use of a machine to quote the delay time for setting up long-distance calls in busy holiday seasons, relieve operators of a tiring task and increase efficiency within the telephone system. The process of providing these added services has, in turn, led to extensive development effort in the recording field by the Bell Telephone Laboratories and an appreciable investment has been made in announcement devices and the associated control equipment.

The applications of voice-recording equipment may be divided into the following four general groups, covered in greater detail below:

1. Announcements Made Direct to and Providing a Distinct Service to Subscribers: The two principal services in this group are Weather Forecast and "Time-of-Day."

2. Announcements Used to Assist Subscribers in Connection With Telephone Service: In this particular group, the principal field of application is in connection with certain Intercept announcements. It is inevitable that some telephone calls will reach vacant or disconnected terminals and it is undesirable, from the standpoint of both the calling subscriber and the telephone company, to permit these calls to be unanswered, since this would waste the time of the subscriber and tie up switching equipment. Therefore it has generally been the practice, until recently, to have an operator answer, or intercept, these calls. Facilities have now been made available to employ a machine for answering these calls.

This classification also includes the emergency announcement system which is used to inform subscribers if some unusual condition prevents normal telephone service.

3. Announcements Employed to Expedite Service and to Assist Operators in the Completion of Calls: The two main fields in this category are the Call Announcer, which has been in service for about 23 years and is used to facilitate the completion of calls from a dial phone to a nondial phone by converting dial pulses into voice announcements; and the Delay Quote system which advises operators of the delay time for completing long distance calls.

4. Announcement or Recording Services for Specialized Purposes: This field is expanding, and already includes price-quotation systems, ticket-reservation systems, various announcement systems, and business aids.

Types of Announcement Equipment

There are three types of voice-reproduction equipment in common use at the present time:

1. The optical method, utilizing a photographic-film record, and having an associated scanning system with photoelectric cells.
2. The magnetic method, using a magnetic pattern set up in magnetic media such as wires, tapes, drums, etc.
3. The mechanical method, in which the recording is engraved or embossed on a recording material.

Careful studies have been made before selecting announcement devices for each application, the optical and magnetic methods having been given the most extensive use in telephone-announcement work.

General Features

Each new announcement system has its individual features and has introduced its own individual problems but, in addition, there are several features common to all.

The transmission considerations on announcement systems are, of course, highly important. Because the speech on announcement systems is one way and the calling subscriber cannot ask the machine to repeat, transmission must, as a first requisite, be loud and highly intelligible, but at the same time the distribution system must not impose a level so high as to create crosstalk on other circuits. The objective is to give a grade of transmission at least equivalent to that obtained on an average telephone call, and suitable machines, amplifiers and networks must be provided with this in mind. Also, when giving an announcement to large numbers of stations simultaneously, provision must be made to prevent conversation between the connected stations. This is accomplished by the use of a low common-impedance output or bus to which the calling stations connect through networks providing a sizable transmission loss. A typical example of this is shown in Fig. 1, where the loss between two simultaneously connected stations is so great that conversation between the stations is impossible.

There is also the problem, in many systems, of connecting calls through to the announcement at the proper time, and of disconnecting them after an interval. The calling subscriber, in general, is allowed to hear the announcement for a long enough time to permit him to absorb the message but, on the other hand, a cutoff interval must be established to avoid prolonged listening which monopolizes valuable trunk and switching facilities. This problem is solved by a suitable switching circuit usually controlled by signals from the announcement machine.

Due to the importance of machine announcements, complete reliability of service is a primary consideration and therefore extensive alarm equipment is provided. Since the announcement machine is the heart of the system, it is the practice to furnish a standby machine with automatic transfer arrangements in the event of failure of the machine serving the load. Arrangements are also generally provided to permit an operator to make announcements if all machines fail.

Description of Systems

WEATHER FORECAST SERVICE

The weather announcement system has proved to be a very popular service since the first installation in 1939. In New York City, for example, the service averaged 71,000 calls per day in 1951. This rate varies extensively and has reached a daily high of about 270,000 calls under severe weather conditions.

The forecast information for this announcement system is received through the co-operation of the Weather Bureau. The information is transmitted over a

direct teletype line to the recording room in a telephone central office. A typical recording room is shown in Fig. 2 with the teletype machine and recording turret. In addition to providing a convenient service to telephone subscribers, this system relieves the Weather Bureau personnel of considerable telephone-answering effort. It is customary to change the announcement at hourly intervals, or more frequently, if necessary, to take care of sudden weather changes.

This service presently uses magnetic-type announcing machines developed for the purpose.[1] The machines and amplifiers function on 110 volts a-c and, therefore, an inverter is provided for use if a power failure occurs. The inverter operates from a 48-volt battery in the telephone central office and produces 110 volts a-c.

The general arrangement of the announcement system is shown in Fig. 3. The trunks from various central offices are ordinarily terminated on the output bus at the main bureau but, if the area served is sufficiently large, subcenters are provided with two cable pairs between the main bureau and the subcenter.

As shown in Fig. 3, the output of the announcement machines is connected to the bus through pattern relays, which are designed to operate in a sequence giving each machine an equal amount of use in the load and standby positions. This pattern is automatically controlled and the proper machines are selected when an erase key in the turret is operated, preparatory to a new recording. While one machine is kept in service, the remaining two available machines are recorded simultaneously, but cannot be put in service until the operator has monitored both.

While the operator monitors the verbal accuracy of the report, a speech monitor circuit checks the volume level and prevents the operator from connecting a machine to the load if specified limits are not met. The operator places the two newly recorded machines in their proper places as the load and standby machines by the operation of a single key. A speech-monitor circuit is connected across the bus as a check of the presence of speech and its volume level. If the volume is too low or if there is no speech, a transfer to the standby machine occurs. As an additional safeguard, such as the remote eventuality of all machines being out of service, the operator will give the announcement herself by plugging her microphone into a manual-announcement jack causing the operation of a pair of manual relays and the manual-service relay. A machine recording may be made during manual announcement by way of contacts *A* shown in Fig. 3.

As stated above, subcenters may be provided, with two cable pairs to the main bureau. Each pair has an amplifier at the subcenter, and the outputs of the two amplifiers are tied together through a bridge circuit, one arm of which is the subcenter bus. If either channel from the main bureau fails, the other can carry the load at the subcenter with a very slight drop in volume. Normally-operated relays are connected across the cable pairs, which will release and cause an immediate alarm if an open line should occur. A relay arranged to operate on speech is connected across the output of each amplifier under control of interrupters and, if the relays fail to operate on each interrupter cycle, an alarm is sounded. The bridge connection between the two channels prevents the output of one working channel from operating the speech-alarm relay of the other channel, if it is out of order.

The announcement given for weather is approximately 25 seconds in length and, therefore, incoming calls are connected through immediately, at any part of the announcement. However, a distributing and timing circuit is provided to control supervision signals in the incoming trunk circuits. After several announcements, the incoming trunk is arranged to send a disconnect signal toward the originating central-office equipment.

TIME ANNOUNCEMENT

Correct time has become a very important item to most of us. Early in telephone history, subscribers acquired the habit of calling the operator for the correct time. This became burdensome to the operator, particularly in the larger areas, and for this reason a number of these areas were arranged with a centralized time-of-day bureau that could be reached by dialing a listed number. In this system, one operator at the central point announced the time at 15-second intervals. This repeated announcement was tedious and operators tired after a short time. Due to the repetitive nature of time announcements, it appeared that the use of a machine announcement system would materially contribute to the convenient and efficiency of the operating personnel and accordingly, it was made available. The service is extensively used. In New York City, the average daily calling rate for 1951 was 68,000. During the annual baseball World Series, the time bureau also carries the inning-by-inning score and in 1951, 1,456,000 calls reached the bureau during the six days of the series.

The machine pictured in Fig. 4 is built by the Audichron Company, Atlanta, Ga., and is presently furnished for time service. The unit shown is equipped with two machines arranged for automatic transfer in the event of failure. However, a single machine has also been made available for use in towns with a small amount of time-of-day traffic.

The machine, which uses the optical method of voice reproduction, is arranged to give a statement such as: "At the tone, the time will be one twenty-two and ten seconds," followed by a short spurt of tone. The announcements are given at 10-second intervals. The machines are driven by 60-cycle commercial power, when it is considered to be regulated closely enough. In other installations, a local power source with closely controlled frequency can be provided. As in the weather service, inverters operating from the 48-volt battery supply 110-volts a-c if a power failure occurs.

The distributing network and subcenter arrangement is similar to that shown in Fig. 3 for that of the Weather Bureau. The general arrangement of a 2-channel time-bureau installation is schematically illustrated in Fig. 5. Here, one announcing machine serves the load, with the other acting as a standby.

If both announcement devices should fail, a visual and audible alarm is given, and a key is operated to transfer the load to a manual-announcement source which employs a third amplifier, not associated with the machines. These announcements may be made from either a microphone and emergency key and lamp box, or from a regular switchboard position, as indicated in Fig. 5. The operator, of course, obtains the time from a clock and the tone spurt is not given.

Inasmuch as a time announcement is short, incoming calls are connected through only between announcements. With machine operation, a short closure of ground on lead *RV* from contact *A* on the machine, preceding each announcement, serves to connect waiting subscribers to the bus. During emergency switchboard operation, an incoming call on a trunk grounds lead *CW*, operating relay *CW* and lighting the calls-waiting lamp in the switchboard. The operator answers the call by plugging a cord in the associated jack, which starts a relay interrupter. This causes the momentary closure of contacts *RV* to connect through the waiting trunks, and then closes contact *AN* which extinguishes the cord supervisory lamp, serving as an indication to the operator to announce the time. A calling subscriber is allowed to listen to several announcements, after which disconnect supervision is sent back to the originating equipment.

Various alarms are provided at the main bureau. These include voice alarms, fuse alarms, faulty distributing-relay operation, and a current-interruption alarm which operates if there is a momentary failure of the 110-volt a-c power, in order to indicate that the time may be slightly off.

Recorded Intercept Announcements

This service is one of the newer users of recorded announcements and will reduce the amount of operator effort in this respect by about 50 per cent.

Calls in the telephone system which are usually intercepted by an operator are those that reach vacant or disconnected terminals, changed number terminals, or lines, in trouble. The calls to vacant or disconnected terminals can be handled by a machine announcement, which advises the calling subscriber that the number he reached has been disconnected and requests him to make sure that he is calling the right number. Calls to changed numbers or to lines in trouble cannot be answered by such a simple statement, and are therefore still routed to an operator who gives definite information regarding the status of the called line.

It has been the practice in large areas to concentrate the intercepting traffic from a number of offices to a single switchboard or desk. Fig. 6 is a functional schematic of the arrangements usually furnished at a central intercepting point, and the trunk equipment at both ends of one trunk from an outlying office to the central point. At the outlying office, the calls to be intercepted are directed to the intercepting trunk by the switching equipment, which also sends signals ahead to indicate the type of answer to be given at the central point. Calls to vacant or disconnected terminals will reach the announcement machine, calls

to lines in trouble will reach an operator's jack and lamp for this service, while calls to changed number terminals will reach another jack and lamp. Referring to Fig. 6, a call to a changed number will cause relay *TRO* of the outgoing trunk to operate and connect battery and ground toward the incoming trunk, but the polarity is such that relay *P* will not operate, and the call is routed to the operator's Regular answering jack and lamp. A call to a line in trouble will operate both relays *TRO* and *RV*, reversing the polarity and causing polarized-relay *P* to operate and direct the call to the operator's Trouble lamp and jack. Calls to either vacant or disconnected terminals cause the momentary operation of relay *M* of the outgoing trunk, applying a 115-volt battery to both sides of the line, which operates the simplex-connected relay *SX* at the incoming end. The operation of relay *SX* sends the call to the announcement machine.

The announcement machines are so constructed that contact *CT* closes during the period between announcements to operate the *CT* relays of the trunks. The pulses from contact *CT* also cause the operation of a counting circuit and, after a predetermined number of announcements, the call is transferred to the operator's Regular jack and lamp, on the assumption that the calling party requires some information in addition to the machine announcement.

The machines used for intercepting service are the magnetic type and are furnished in duplicate, with automatic transfer. In addition to advising the calling subscriber that he reached a disconnected number, he is told that he is listening to a recorded announcement. This latter statement is necessary, since observations have shown that without it, about 40 per cent of the calling subscribers attempt to converse with the machine, believing it to be an operator.

Emergency Announcement System

On rare occasions, magnetic-type announcement machines have been used to advise telephone subscribers if an emergency, such as an air-raid alert, causes the temporary discontinuance of operator service. The method of applying this announcement is interesting due to its simplicity.

In a manual (nondial) central office, the announcement is applied by superimposing it on the battery feed to the line relays.

In any dial central office, some operator services are required, and therefore trunk circuits are furnished from the dial equipment to these operators. Since subscribers are accustomed to receiving audible ringing signals between the end of dialing and the answer of the called party, the trunk circuits have provision for applying audible-ringing signals toward the calling party, through a low capacity condenser (usually 0.02 to 0.04 microfarad), until such time as the call is answered. Under an emergency condition, the recorded announcement is applied by simply disconnecting the ringing from a group of trunks, and transferring the common leads to the announcement bus.

Call Announcer

The introduction of dial-telephone systems could not be accomplished in all central offices at the same time. This situation called for some arrangement for completing calls from dial to manual telephones and, accordingly, an arrangement known as the call indicator was originally provided at the manual office. This system was such that the dialed number would appear before the manual operator as lighted numerals. With further expansion of the telephone system and the introduction of large tandem centers using common control equipment, the call announcer was developed for use at these tandem centers. This machinery brought about an appreciable reduction of equipment and modification needed at the manual office.

If a call is made from a dial area to a line in a manual office, the number dialed is recorded by relay operations. When the operator in the distant manual office is ready to serve the call, the operated relays cause the machine to announce the

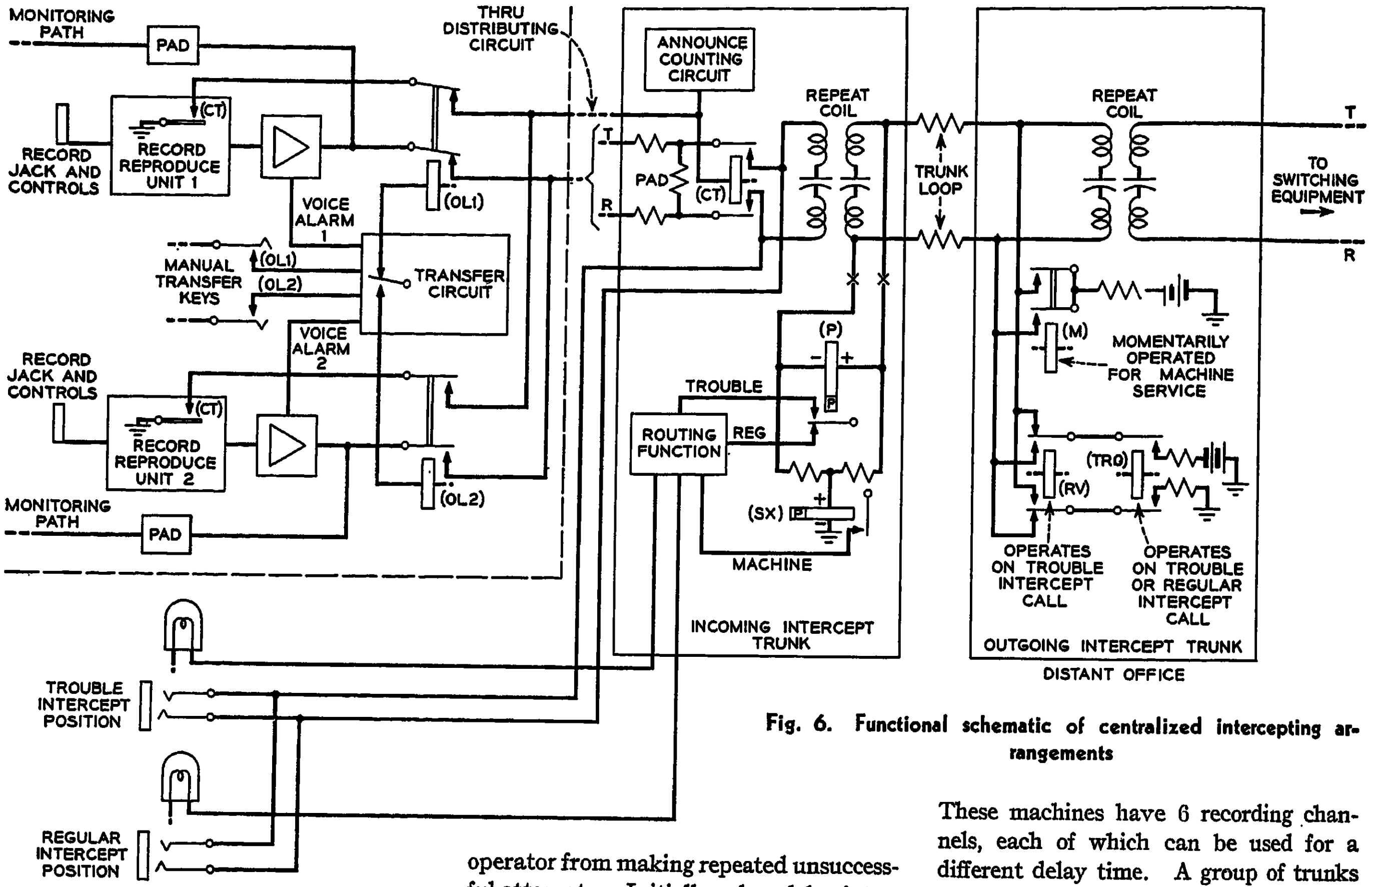

Fig. 6. Functional schematic of centralized intercepting arrangements

digits of the number, in proper sequence, to the distant operator.

The call announcer machine itself is of the optical type, and can announce the digits 0 to 9 and party line letters *W*, *R*, *J*, and *M*. Two machines are ordinarily in use, each carrying half the load, but in the event of a speech failure on one of the machines, an automatic transfer connects all the load to one machine.

Delay Quotations for Toll Calls

As mentioned in the introduction, another newcomer to the machine announcement field is the Delay-Quotation system. This was developed to relieve operators of the repetitious chore of quoting toll-line delay times during periods of heavy traffic such as Mother's Day, Christmas, etc.

The general arrangement for handling these quotations on delayed toll calls is shown in Fig. 7. Referring to this figure, assume that an operator at point *A* dials a call for point *C* via a toll crossbar office at point *B*, and that the switching circuits, testing, find that all trunks from *B* to *C* are busy. If the delay is to be of such length that the usual supervisory signals will not adequately inform the originating operator of the availability of trunks to point *C*, it becomes desirable to quote a period of time before the call can be completed, to prevent the originating operator from making repeated unsuccessful attempts. Initially, when delay intervals became 1/2-hour or more, the delay quotation was handled by patching (at the supervisory panel) the overflow control circuit to a jack appearing before an operator who gave the quotation, but since the development of the machine system, the operators are no longer required to do this. After the patch to the delay-quote jack has been set up, the calls will be directed to overflow trunks, the originating operator hears the quotation, and turns the call over to her own delayed-call operator for completion.

The jacks at the supervisory panel that carry the delay quotations are connected to magnetic-type recorders. These machines have 6 recording channels, each of which can be used for a different delay time. A group of trunks may be patched to any desired delay announcement. Contacts on the machine are provided to give supervisory flashing signals toward an outward operator, before the announcement occurs, to attract her attention in case she has left the connection.

No standby machines are furnished on these installations but, if a voice failure should occur, an alarm is given and the operator can quote the delays.

Specialized Applications

Voice-recording and announcement machines have been put in service for a number of uses as a convenience or important business aid in furnishing particular serv-

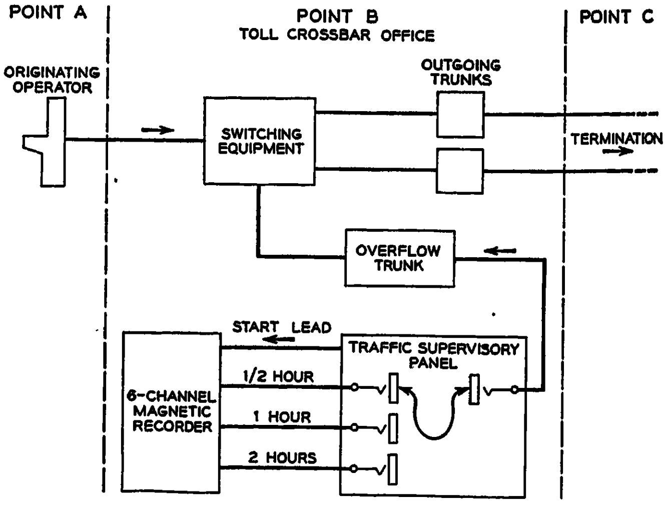

Fig. 7. Diagram of delay-quote system

ices. Several typical applications are described in the following paragraphs.

One of the earliest applications of magnetic type recorders for an announcement system was made in New Jersey in 1937 to give potato growers up-to-the-minute information regarding prices, car movements, loadings, and holdings. To receive this information it was necessary to call a listed number and, since the installation was in manual central-office area, the operator completed the call via a jack to the announcement bus. The system employed two machines, one in service, and the other being held as a spare or for new recordings.

A management announcement system, used on a few trial installations, permits the management of large corporations to disseminate important information to certain groups of employees without these employees leaving their regular work locations. The information is recorded on a magnetic-type machine and interested employees call a number in the company private-branch exchange to hear this announcement. Since it is often necessary to make a new recording without interrupting service, two machines are provided. These machines can also be operated sequentially if a particularly long announcement is needed.

It is planned to provide arrangements at the New York Stock Exchange to give price quotations on some of the most active stocks. The brokers will be able to obtain the latest price by dialing the number listed for the particular stock. The quotations on the announcement machines will be constantly kept up-to-date by recordings from attendants at the trading posts on the floor.

Magnetic-type recorders were also used in a large New York newspaper office in 1937, not as an announcement system, but as recording devices. In this instance, reporters out on assignments, could go to the nearest telephone, call their office and be connected to a recorder on which they would record their reports for later transcription.

There have been other special applications of voice recording equipment, including railroad-reservation information.[2]

Future Development

As far back as the late 1920's it was found that recorded announcements would serve to expedite service as applied to the Call Announcer. This experience indicated that voice recording was a valuable tool in communications. As seen from the foregoing descriptions, a number of other applications have been made with resulting advantages in convenience and services rendered to both subscribers and operating personnel.

At the present stage, various other applications are being explored, more are anticipated within the next few years, and indications are that this field should become increasingly important in the years ahead.

Heating of Fat-Muscle Layers by Electromagnetic and Ultrasonic Diathermy

HERMAN P. SCHWAN
ASSOCIATE MEMBER AIEE

EDWIN L. CARSTENSEN
NONMEMBER AIEE

KAM LI
NONMEMBER AIEE

IN CLINICAL practice, it is frequently desirable to produce heat in the muscular tissue which lies below subcutaneous layers of fat. Until recently short-wave diathermy provided the most satisfactory answer to the general problem of deep heating. However, biophysical research[1] has shown that, when electric currents pass through alternate layers of fat and muscle, the fatty tissue is selectively heated. Although the ratio of heat developed in fat to that in muscle becomes smaller as the frequency increases, even at the highest practical frequencies the ratio is still greater than unity. It was in part to overcome this difficulty that electromagnetic and ultrasonic radiation were introduced as forms of diathermy following the second World War. The heating of homogeneous tissues by radiant energy has previously been discussed.[2] However, the important fat-muscle problem as it applies to the new forms of radiation diathermy has not, up to now, been given quantitative consideration.

Radiation Diathermy

The discussions for heat development in the case of electromagnetic and acoustic radiation are completely analogous. In both cases, radiant energy flows through the tissue and is, in part, absorbed and converted into heat. At the interfaces separating two different tissues, reflections occur giving rise to standing waves which may materially influence the pattern of heat development. In order to obtain a complete analytical description of this problem it will only be necessary to assume knowledge of the complex propagation constants γ which characterize the various media. These propagation constants in turn, are either directly measurable quantities or can be simply related to measurable quantities. The quantitative conclusions of this analysis depend, therefore, upon measurements of the electromagnetic and acoustic properties of the tissues involved. Sources of these data are discussed in subsequent sections.

For the present discussion the conditions found in the body will be idealized, as shown in Fig. 1. Plane waves are assumed incident normally on plane and parallel interfaces, which separate the

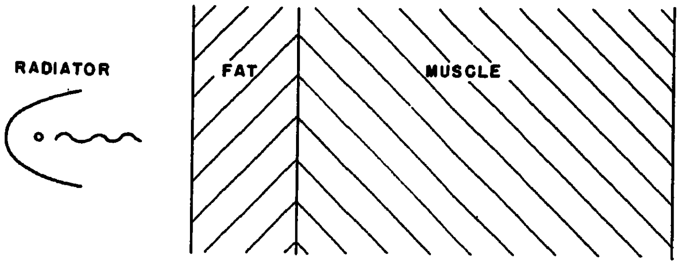

Fig. 1. One-dimensional representation of the fat-muscle configuration as found in the body

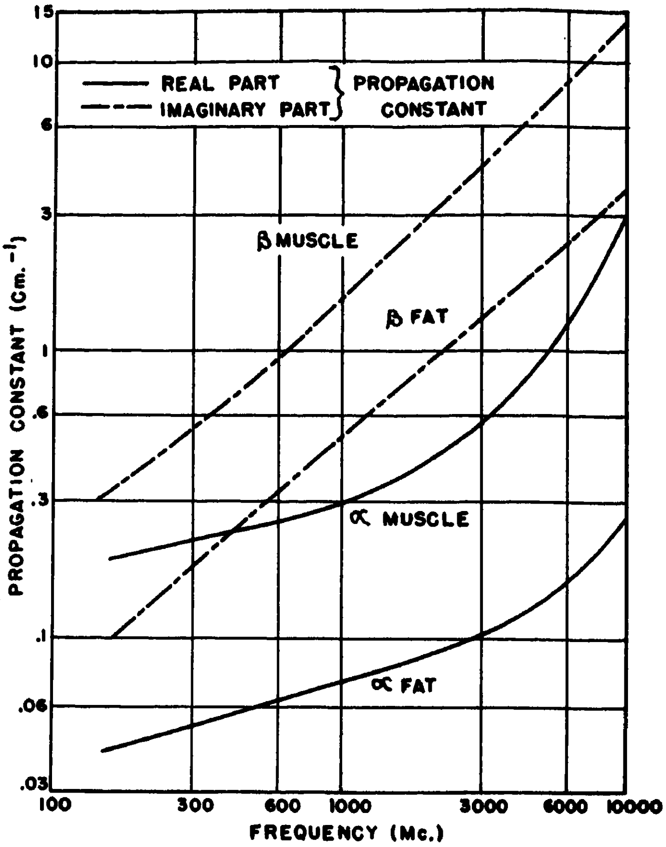

Fig. 2 (right). Electromagnetic propagation constant $\gamma=\alpha+j\beta$ for fat and muscle

layer of subcutaneous fat from the coupling medium (for example, water or air) on one side, and from the semi-infinite region of muscular tissue on the other side. The fat layer is taken to have a thickness d; the layer of muscle is assumed so thick that the waves transmitted into it are completely absorbed. This assumption is justified for most practical cases in view of the high absorption coefficient of muscle tissue, as shown in Figs. 2 and 4. The origin of the space co-ordinates is taken at the fat-muscle boundary and reference fields are defined at this point. For simplicity, the reference field E_0 will be taken as the effective incident wave at the fat-muscle boundary $x=0$. Of course, the effective incident wave is the sum of the initial wave transmitted directly from the generator and all positively directed reflection arising within the fatty layer. However, it can be shown[3] that the reflection factor for this sum is the same as for a single wave. Hence the complete picture can be given in terms of the effective incident wave.

In the following, the symbol E will be used for the electric field in the electromagnetic case, or for excess pressure in the acoustic case, while H will be used interchangeably for magnetic field or particle velocity. The field in fat then consists of incident and reflected waves E_1 and E_2.[4,5]

$$E_f=E_1+E_2=E_0(e^{-\gamma_f x}+pe^{\gamma_f x})$$

$$H_f=H_1+H_2=\frac{\gamma_f}{j\mu_f\omega}(e^{-\gamma_f x}-pe^{\gamma_f x})$$

where

μ = permeability in electromagnetic case and density in the acoustic case
p = the complex reflection factor of the fat-muscle boundary
γ = the propagation constant

The time factor $e^{j\omega t}$ is implied throughout. By applying the boundary conditions[4,5] it is seen that

$$p=\rho e^{j\varphi}=\frac{\dfrac{\gamma_f}{\mu_f}-\dfrac{\gamma_m}{\mu_m}}{\dfrac{\gamma_f}{\mu_f}+\dfrac{\gamma_m}{\mu_m}} \tag{1}$$

The subscripts f and m refer to fat and muscle, respectively. In the electromagnetic case, where it is reasonable to assume $\mu_f=\mu_m=1$ this reduces to the following

$$p=\frac{\gamma_f-\gamma_m}{\gamma_f+\gamma_m}$$

The wave transmitted into the muscle is characterized by

$$E_m=(1+p)E_0e^{-\gamma_m x}$$

$$H_m=(1-p)\,\frac{\gamma_m}{j\mu_m\omega}\,E_0e^{-\gamma_m x}$$

The intensity I, or energy flow per unit area of the beam, is given by the complex product of electric and magnetic fields, complex Poynting's vector, in the electromagnetic case and by the complex product of pressure and particle velocity in the acoustic case.

Writing $\gamma=\alpha+j\beta$ and using $p=\rho e^{j\varphi}$, the intensity in fat is

$$I_f=\frac{1}{2}EH^*=\frac{1}{2}\,\frac{\beta_f+j\alpha_f}{\mu_f\omega}\,E_0E_0^*\times$$
$$[e^{-2\alpha_f x}-\rho^2e^{2\alpha_f x}+j2\rho\sin(2\beta_f x+\varphi)]$$

The asterisk is used to signify the complex conjugate of the number.

The rate of development of heat per unit volume is given by the negative space rate of change of the real part of this intensity,[4] that is,

$$-\frac{\partial}{\partial x}\mathrm{Re}\,I_f=\frac{1}{2}\,\frac{2\alpha_f\beta_f}{\mu_f\omega}\,E_0^2\times$$
$$[e^{-2\alpha_f x}+\rho^2e^{2\alpha_f x}+2\rho\cos(2\beta_f x+\varphi)] \tag{2}$$

In the electromagnetic case, this reduces to

$$\frac{1}{2}\kappa_fE_0^2[e^{-2\alpha_f x}+\rho^2e^{2\alpha_f x}+2\rho\cos(2\beta_f x+\varphi)]$$

where κ_f is the electrical conductivity of fat, since the product $\alpha_f\beta_f=(\mu_f\kappa_f\omega)/2$.

From the continuity of E across the

Electromagnetic Diathermy

Dielectric studies have been carried out above 1,000 megacycles[6-8] and below 100 megacycles[9] for various body tissues. In addition, blood has been investigated[10] in the range 100 to 1,000 megacycles. The mechanism of absorption of electromagnetic energy is well enough understood[11] to be able to state that all tissues with high water content will have properties similar to that of blood in the 100 to 1,000-megacycle range. To complete the picture for fatty tissue, it was necessary to measure the dielectric constant and resistivity of fat in the range 100 to 1,000 megacycles. The methods of measurement will be reported elsewhere. The relative dielectric constant and resistivity in ohm-centimeters for horse and pork fat and muscle are summarized in Tables I and II. Although muscle impedance is remarkably uniform, the range of values for various kinds of fat is of the order of a factor of two. All measurements were obtained at temperatures near 37 degrees centigrade with fresh tissue samples. The data for the water-rich horse fat are used for the numerical calculations which follow.

The propagation constant can be written in terms of these data as

$$\gamma=j(2\pi/\lambda)\sqrt{\epsilon^+}$$

where

$\epsilon^+=\epsilon'-j\epsilon''$ is the complex dielectric constant
ϵ' = the relative dielectric constant
$\epsilon''=60\lambda_0\kappa$
λ_0 = the electromagnetic wave length in air
κ = the electrical conductivity

Values of the attenuation constant α and the phase constant β for horse fat and muscle are given in Fig. 2. From these values it is possible, using equations 2 and 3, to predict the heat development as a function of depth of tissue for a fat-muscle configuration such as shown in Fig. 1.

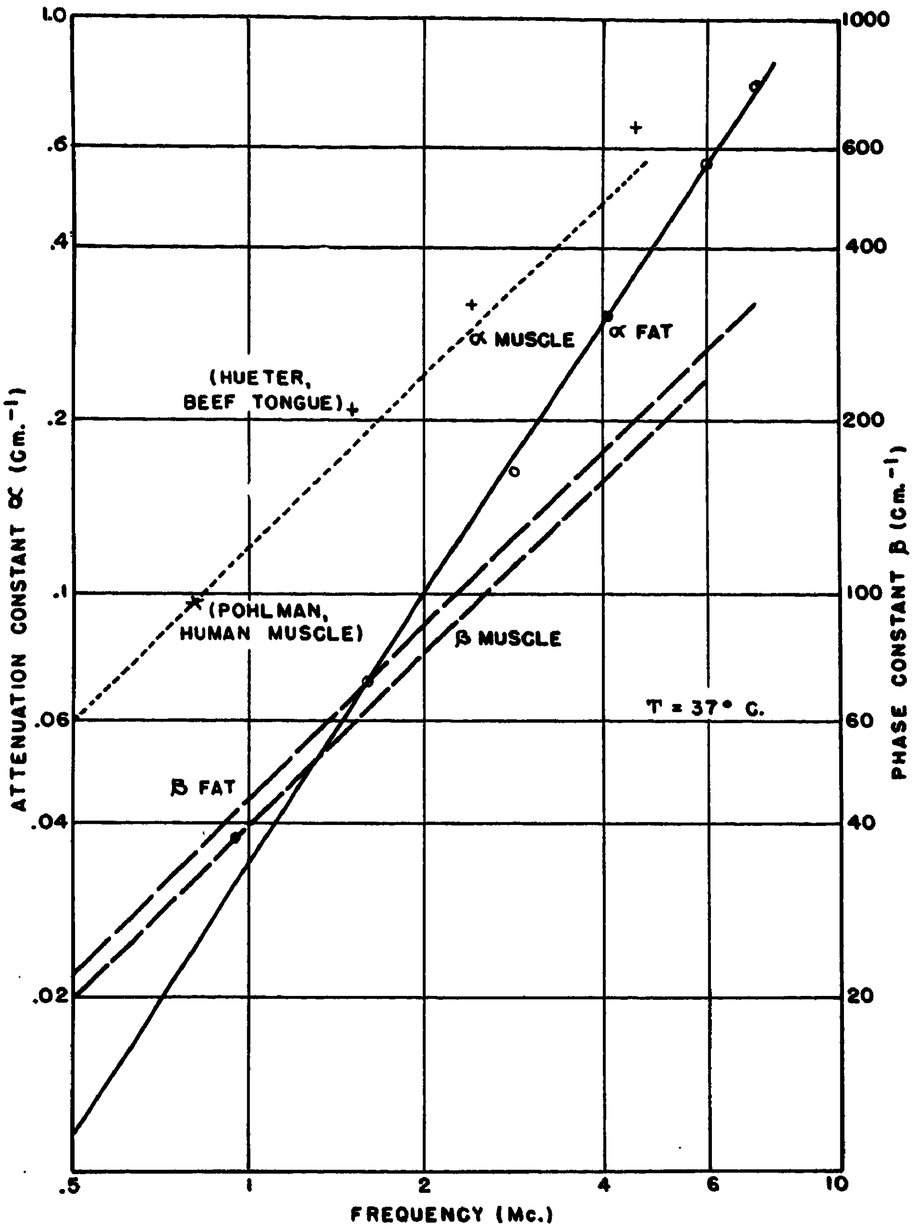

Fig. 4. Acoustic propagation constant $\delta = \alpha + j\beta$ for fat and muscle

The results for frequencies 150 megacycles to 10,000 megacycles are presented in Fig. 3. All values are plotted relative to the heat development in the muscle at the fat-muscle interface. In the electromagnetic case, the reflection factor is high. The magnitude ρ varies from 0.5 to 0.6 throughout the frequency range. This gives rise to a marked standing wave pattern which is predominantly important in determining the heating pattern in the fatty layer. The phase angle is roughly 180 degrees, which tends to minimize heat development in fat near the boundary. It is apparent that the lower frequencies are indicated for a high depth of penetration of energy into the muscle and low heating of the fatty layer. The advantage of radiation diathermy is illustrated by the fact that even at 3,000 megacycles, where the depth of penetration in muscle is very small, it is still possible to get some energy into the first centimeter of the muscle layer even though it is covered by as much as 2 centimeters of fat. The curves, however, show that lower frequencies are much more effective in providing deep heating.

Ultrasonic Diathermy

In the acoustic case, free-field methods are ordinarily used to determine the propagation constant directly. Comparatively little information is available in literature regarding the ultrasonic properties of tissue. Hueter[12] has shown that the absorption of muscle tissues is a linear function of frequency. Pohlman[13] gives a value for the absorption coefficient of human muscle at 800 kc. For the absorption constant of muscle α_m in Fig. 4, a linear curve has been drawn through Pohlman's 800-kc value. Also shown are Hueter's values for beef tongue. Other muscle tissues which he measured have higher absorption coefficients. Ludwig[14] gives the value 1.68×10^5 centimeters per second for velocity of sound in beef muscle.

Essentially no information is available in the literature on the acoustic properties of fatty tissue. To carry out this study, measurements of the absorption and velocity of sound were conducted on fresh pork fat. The corresponding propagation constants for temperatures of 37 degrees centigrade are given in Fig. 4. It will be noted that the absorption in fat has approximately a 1.5 dependence upon frequency in the range from 1 to 7 megacycles. Since depths of penetration of the order of 4 centimeters are desirable for deep heating the frequency range near 1 megacycle is indicated for ultrasonic diathermy.

The density of the fatty tissue used in the measurements was approximately 0.93. Ludwig[14] gives a value of 1.06 for the density of muscle tissue. From these data and the propagation constants it follows, by equation 1, that only roughly 2 per cent of the incident energy is reflected at a fat-muscle interface in the acoustic case. Furthermore, the wavelength is of the order of 1 millimeter; hence any spatial fluctuations of heat development caused by standing waves would be so close together that they would be smoothed out by heat conduction. Using the values given in Fig. 4, the heat development for a fat-muscle configuration is computed by equations 2 and 3, and presented in Fig. 5, for frequencies of 1 megacycle and 2 megacycles.

Conclusions

Perhaps more important than heat development per unit volume is the total rate of heat development in the fatty layer, as compared with that in the muscle. This information is obtained simply by integrating equations 2 and 3. With thickness of the fatty layer as a parameter, the ratio of heat developed in a layer of fat to that in a semi-infinite region of muscle is shown for the electromagnetic case in Fig. 6 and for the ultrasonic case in Fig. 7.

If it is arbitrarily assumed desirable to generate at least three times as much heat in the muscle as in the fat, then frequencies of roughly 500 megacycles in the

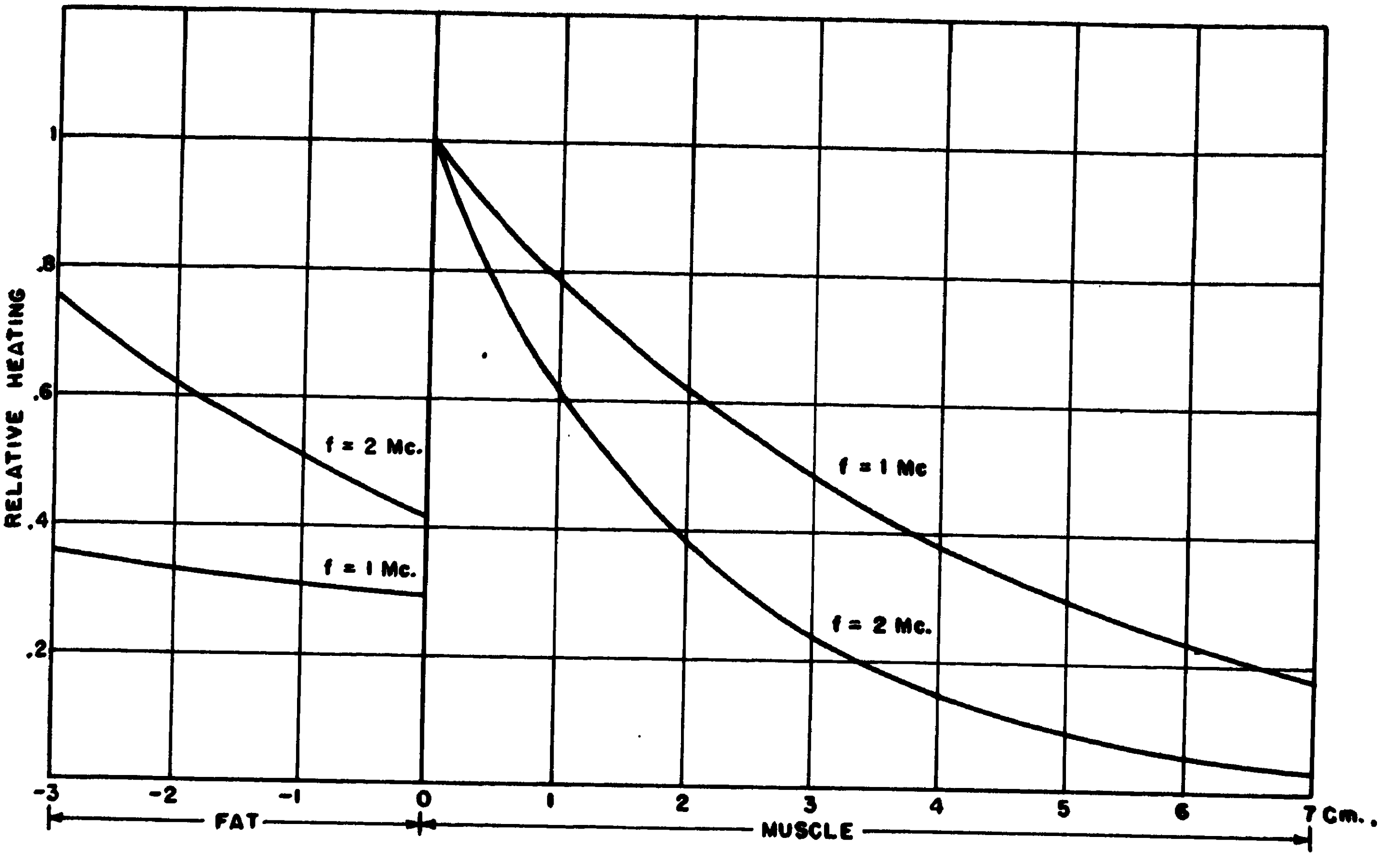

Fig. 5. Heat development per unit volume in the ultrasonic case. (All values are relative to heat development in muscle at the interface)

electromagnetic case and 1 megacycle in the ultrasonic case should be used. In short-wave diathermy the ratio of heat developed in fat to that in muscle decreases with increasing frequency. Just the opposite is true for radiation diathermy, where lower frequencies are recommended for selective heating of muscle. With short-wave diathermy, the fatty layer in a series fat-muscle configuration is always selectively heated. However, with both forms of radiation diathermy it is possible, by proper choice of frequency, to penetrate the fatty layer and dissipate a large fraction of the total energy in the underlying muscle.

Problems to Consider in Applying Selenium Rectifiers

J. GRAMELS
ASSOCIATE MEMBER AIEE

THE PROPER selection of selenium rectifier stacks for d-c power supplies in large scale industrial or military projects usually requires considerably more information than can be obtained from a manufacturer's catalog. The most important problem in applying selenium rectifiers arises in connection with the life requirements for the application. Test data indicate that the life expectancy of selenium rectifiers is affected by the different manufacturing techniques used by the suppliers. With the present art of manufacture, the life expectancy tends to decrease as the cell voltage rating is increased. In addition, the life is affected by the current density and the temperature at which the selenium cells are operated.

The selection of selenium rectifier stacks for use in d-c power supplies involves several important considerations, as follows:

1. Circuit requirements must be carefully analyzed so that allowances may be made for variations in the voltage-current characteristics of each manufacturer's product, as well as for variations that exist for the same stacks processed by different manufacturers.

2. The equipment engineer must anticipate the differences in mechanical details of the same stack assembled by different suppliers. Unfortunately, there is no standardization in the selenium industry regarding mechanical details such as the over-all length and height of the stack, and particularly the type of mounting.

3. The engineer must take into account the magnitude of the changes in the voltage-current characteristics of the rectifier stacks over the specified temperature range of his project. At very low temperatures, output voltages may be 5 to 10 per cent lower than at normal room temperatures. For high-temperature operation, the stacks must be properly derated for both current and voltage, to prevent overheating and rapid failure.

4. Unless otherwise specified, rectifier stacks are coated with various types of paints and varnishes for protection against moisture in normal conditions of humidity. For military projects and other applications where selenium rectifiers may be exposed to high humidities, fungus, salt, or other corrosive atmospheres, the rectifier stacks must be provided with a more suitable type of protective coating or finish. These finishes are available from most manufacturers.

5. Selenium rectifiers age with time. Compensation for this aging should be provided if load requirements warrant. The project engineer should determine what life he expects or requires of the application. For military applications life requirements may vary from minutes to thousands of hours. On other applications, such as telephone and elevator installations, it is desirable to design selenium rectifiers for life expectancies of 10 to 20 years or more.

Electrical Ratings

The electrical ratings of selenium rectifiers are based on their voltage, current, and thermal characteristics. All three of these characteristics must be considered carefully for initial design purposes, as any one can affect life expectancy.

Voltage Ratings

The voltage rating is usually expressed as the reverse voltage rating. It is the maximum rms sine-wave voltage above which an excessive reverse current would flow and overheat the cell, causing breakdown. However, the important consideration establishing the rating is the peak voltage applied to the cell. If the applied voltage differs significantly from a sine-wave, it is important that the peak voltage shall not exceed 1.41 times the rated rms voltage.

When selenium cells were originally manufactured in this country, their rms voltage ratings ranged from 14 to 18 volts. Ratings later increased to 26 volts, and at the present time the goal appears to be 33 volts or higher. One manufacture has already successfully produced 33-volt cells for several years. An-

Paper 53-215, recommended by the AIEE Metallic Rectifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted October 24, 1952; made available for printing April 14, 1953.

J. Gramels is with the Bell Telephone Laboratories, Inc., New York, N. Y.

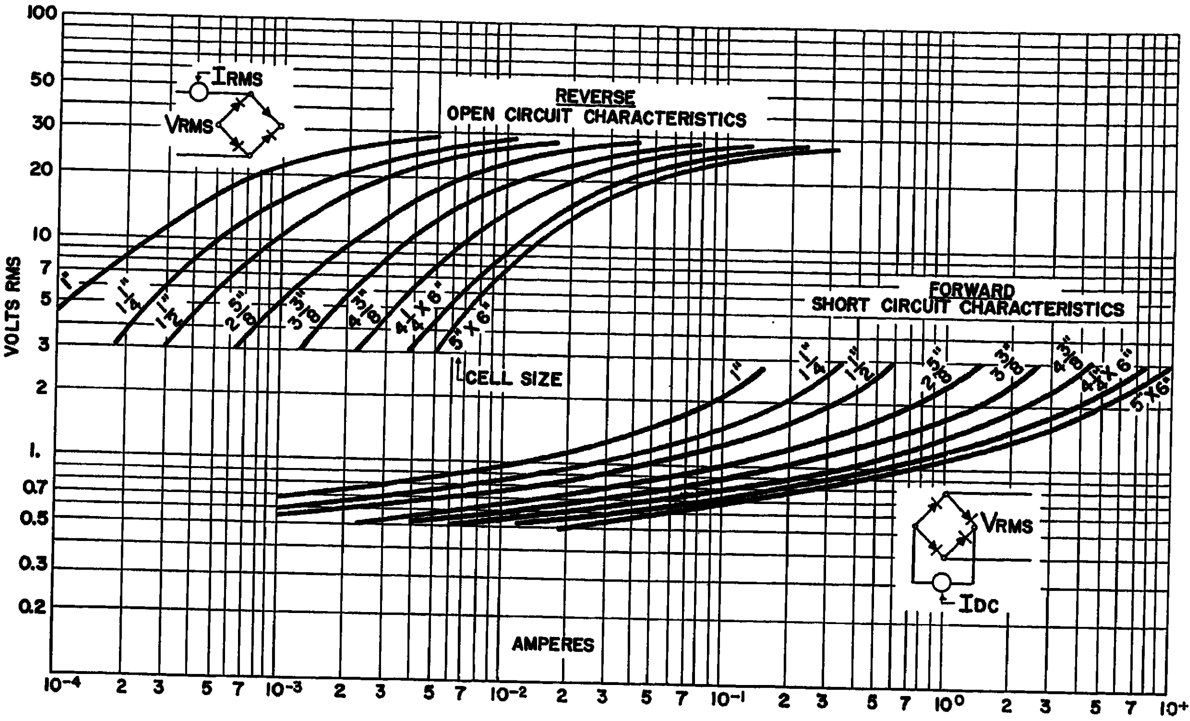

Fig. 1. Typical dynamic voltages current characteristics of 4-1-1B stacks with 26-volt cells

other manufacturer recently has announced a 40-volt cell. Cells rated at 70 volts have been produced in the laboratory. For uncritical applications, such as low cost radio and television sets, some manufacturers process cells rated at 45 volts rms. Generally, in such applications, a high quality produce cannot be expected and the units are likely to have a relatively short life.

Current Ratings

The current rating of selenium cells is based upon a normal current density of 0.32 ampere per square inch of active rectifying surface for a single-phase full-wave rectifier operating into a resistance load. Most manufacturers produce sizes varying from round 1/4-inch-diameter cells to 5- by 6-inch rectangular cells. Larger cell sizes are available from some manufacturers.

Thermal Ratings

The selenium rectifier is a thermal, as well as an electrically rated device. The voltage and current ratings are usually based upon operation of the rectifier stack in a normal ambient temperature of +35 degrees centigrade. It is important to note, however, that for selenium cell applications, ambient temperature is defined as the temperature immediately surrounding the stack within the equipment enclosure, not the temperature area where equipment is installed. Above +35 degrees centigrade ambient, the voltage or current ratings, or both, must be reduced. Rectifier stacks operating at rated current and voltage into a resistance load have temperature rises ranging from 15 to 35 degrees centigrade. The temperature rise depends upon the manufacturing techniques used by the various companies as well as the spacing of the selenium cells on the assembled stack. For long life expectancy, the actual cell temperature should not exceed +75 degrees centigrade.

Selenium rectifiers can be operated at cell temperatures above 75 degrees centigrade, but aging accelerates with temperature and excessive temperatures will result in rapid failure.

A special problem today is the application of selenium rectifiers to high temperature military uses. Many military projects are requesting designs to operate at ambient temperatures of +70 to +90 degrees centigrade. Unfortunately, reliable information about rectifier operation and life expectancy under these conditions is rare and generally not available. Statistical data should be accumulated and development studies should be undertaken to determine:

1. The life expectancy of selenium rectifiers when operated at the manufacturer's rating in ambient temperatures up to +100 degrees centigrade.
2. Whether, at these high temperatures, longer life can be obtained if the voltage and current ratings are reduced.
3. What voltage and current ratings can be applied to obtain longer life.

Voltage-Current Characteristics

To demonstrate the nonlinear characteristics of selenium rectifier cells, Fig. 1

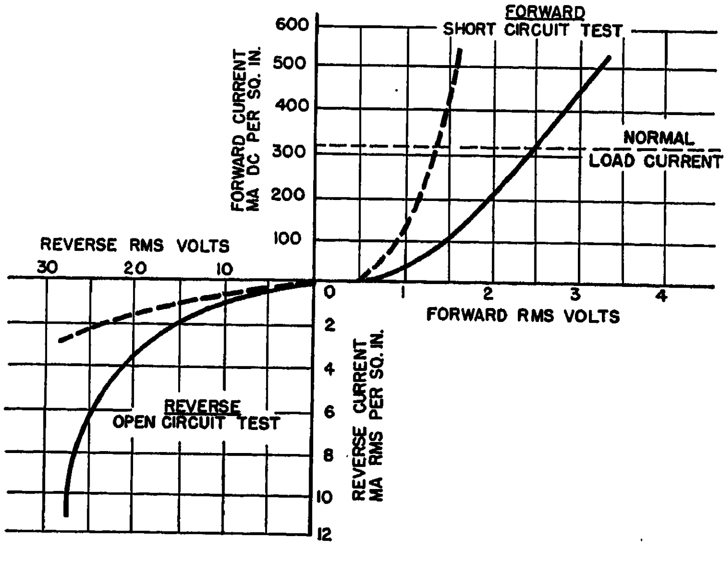

Fig. 2. Typical dynamic voltage-current characteristics of 4-1-1B stacks with 26-volt cells processed by two different suppliers

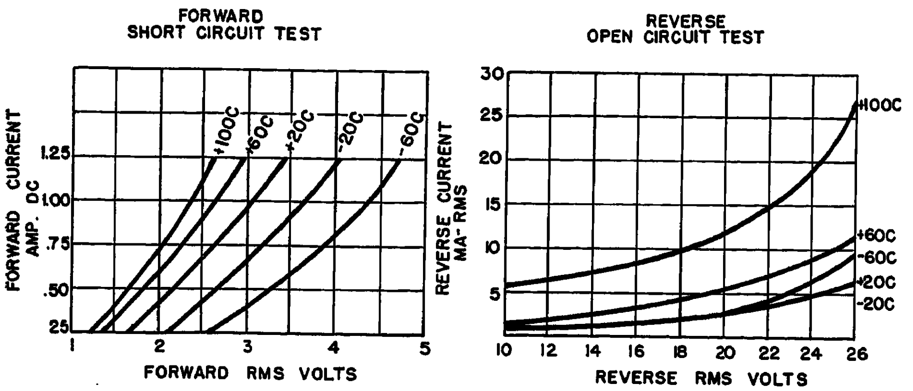

Fig. 3. Ambient temperature characteristics of 4-1-1B stacks with 2-×2-inch 26-volt cells rated at 1.0-ampere d-c

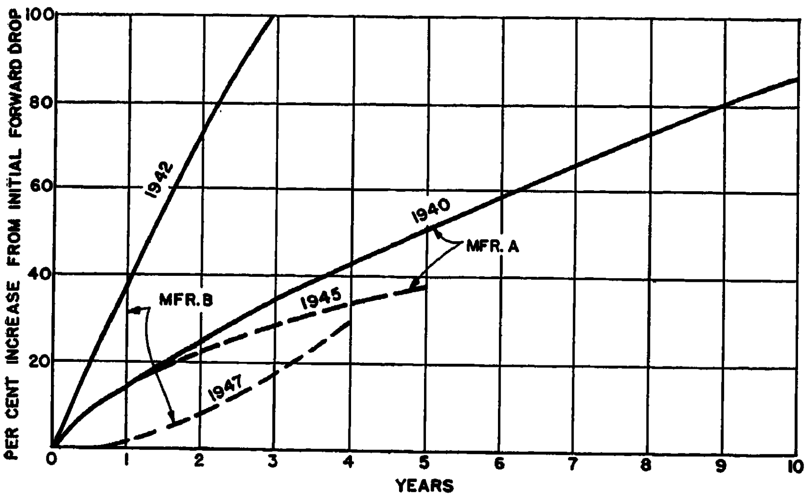

Fig. 4. Forward aging characteristics cell rating, 18 volts rms

illustrates representative dynamic voltage-current characteristics taken at room temperature for typical cell sizes rated at 26 volts, rms.

These data and subsequent results are plotted on the basis of unit type *4-1-1B* rectifier stacks. These stacks are single-phase full-wave rectifier circuits with a single selenium cell in each of the four rectifying elements. Tests were made with 60 cycle sinusoidal supply voltage. The forward voltage drop is expressed as the rms volts required to produce a specified current in a moving coil d-c ammeter connected directly to, and short-circuiting the output terminals of the rectifier stack. The reverse current is measured by applying a specified rms voltage to the a-c terminals with the d-c terminals open, and noting the rms input current after a period of 5 to 10 minutes has been allowed for the current to stabilize.

It should be emphasized that these data are merely typical characteristics. Selenium cell manufacture requires individual testing of each cell before assembling into a stack. Cells are graded by their electrical characteristics. Large variations exist between the lowest and highest grade. Each manufacturer sets up his own standards regarding the variations of characteristics in a given grade. More than one grade of cell may be assembled in a rectifier stack. Differences as great as ±50 per cent in the forward voltage drop at rated current are not uncommon. In the reverse direction, a larger spread exists in the reverse current, particularly in cells or stacks made by different suppliers.

Fig. 2 shows dynamic characteristics plotted on a linear scale to illustrate variations of the forward voltage and reverse current characteristics of selenium rectifier stacks that are processed by two different suppliers. Variations of this magnitude exist, not only from supplier to supplier, but also in a particular supplier's rectifiers. For a fixed a-c input voltage to these rectifier stacks operating into a resistance load, these differences in the forward voltage drop can vary the d-c output voltage ±5 per cent from the mean value. If this cannot be tolerated, selenium cells have to be carefully graded and selected to obtain uniformity, or other circuit adjustments have to be provided. Special selection of cells, obviously, will increase the cost of the product.

Selenium rectifiers, unlike most metal conductors, have a negative temperature

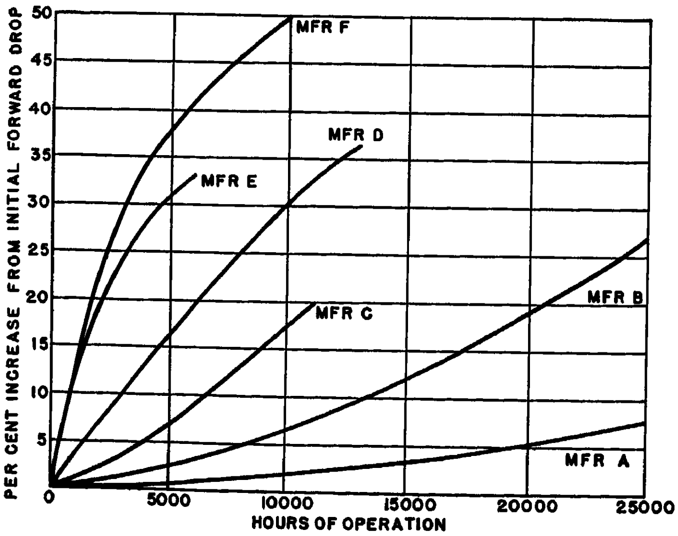

Fig. 5. Forward aging characteristics of various suppliers 26-volt cells

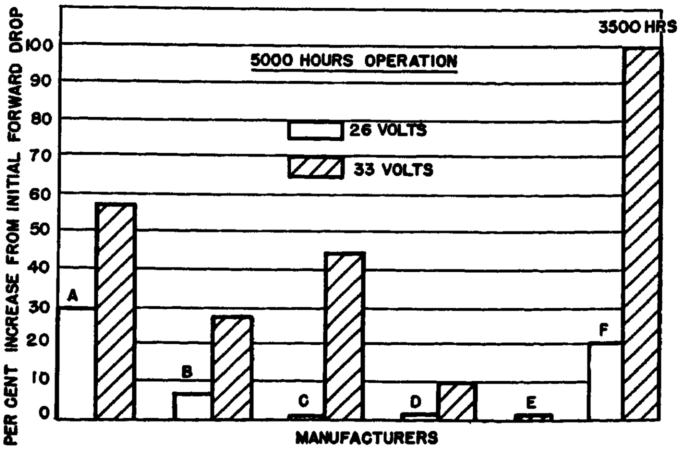

Fig. 6. Forward aging characteristics comparison of 26- and 33-volt cell ratings

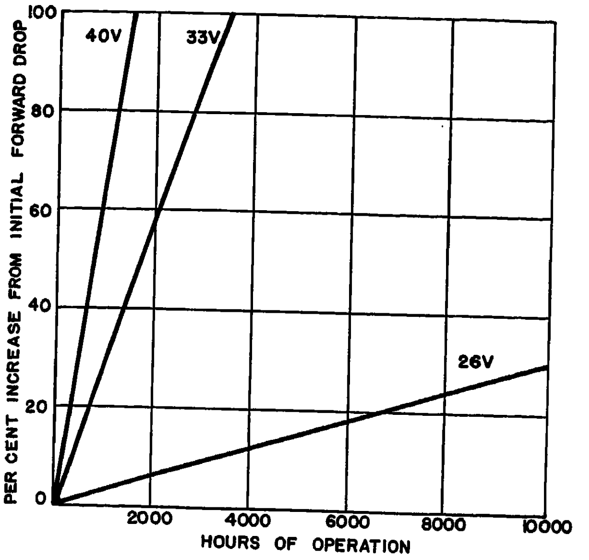

Fig. 7. Forward aging versus cell voltage rating

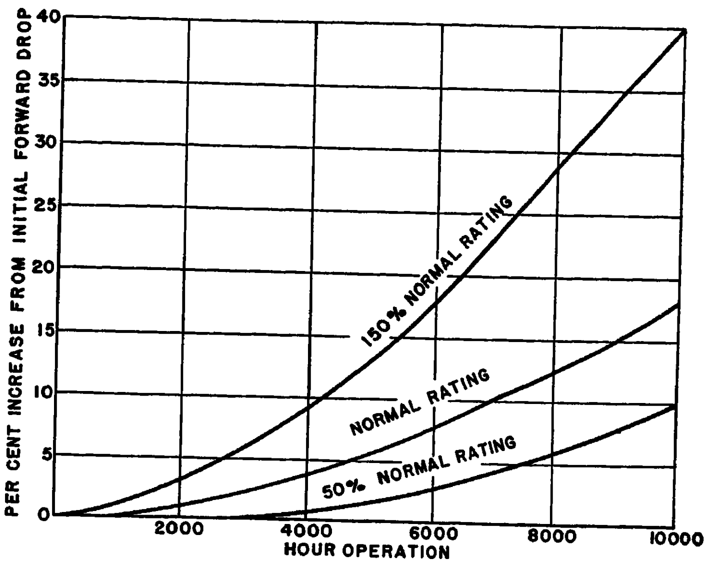

Fig. 8. Effect of load current on forward aging

coefficient of resistance in the forward direction. The forward voltage drop at a specified current decreases as the ambient temperature increases, shown in Fig. 3. In the reverse direction, the reverse current decreases as the temperature is lowered to approximately −20 degrees centigrade. Below this temperature, there is no apparent change in the current except at the higher voltages. At the higher voltages, the current again tends to increase.

Aging

Selenium rectifiers are subject to aging. The important factor in selenium rectifier aging is the increase in the forward voltage drop which results in a decreased d-c output. For normal rectifier applications, aging of the reverse current is not critical. If the rectifier circuit conditions require that the output voltage must be maintained over a period of time, provisions must be made to supply additional a-c input voltage to the rectifier stack as it ages. One or more taps on the associated transfer can compensate for this change. For example, on a rectifier stack operating at its rated d-c output current and voltage, it is considered good practice to design for a 100 per cent increase in the initial forward voltage drop of the stack. This requires approximately a 10 per cent increase in the a-c input voltage to maintain the initial d-c output. At this point, the a-c input voltage usually reaches the maximum reverse voltage rating. A further increase in the a-c voltage may result in overheating and rapid failure.

The extent and rate of aging of selenium rectifiers cannot be determined mathematically. Aging characteristics must be determined by actual test involving lengthy time-consuming projects. To determine whether a given rectifier stack will give satisfactory performance for 5 years, as an example, tests would have to be conducted for this period. Aging can be accelerated by operation at high temperatures or at load currents above normal, but no accepted correlation exists between this type of aging and that obtainable under normal operating conditions.

The following aging data were obtained on sample rectifier stacks obtained from different manufacturers in this country. The samples were set up on life test racks as single-phase full-wave rectifiers and were operated continuously at normal room ambient temperatures. For the duration of the tests, the a-c input voltage to the stacks was kept constant at approximately 10 per cent below the maximum rms voltage rating. The stacks operated into a resistance load. The resistance was selected so that the rectifiers operated at rated d-c load currents. The resistance was not changed thereafter.

Long-term forward aging characteristics of selenium rectifiers assembled with cells rated at 18 volts rms are shown in Fig. 4. After 10 years, or approximately 90,000 hours, continuous operation, the forward drop on one supplier's product increased approximately 90 per cent. A second supplier's product increased 100 per cent in 3 years under similar operating conditions. Further development programs by each manufacturer resulted in improved aging qualities as indicated by tests made on stacks obtained at a later date.

By introducing changes in their manufacturing techniques, the industry eventually increased the voltage ratings to 26 volts rms per cell. This change in processing, however, raises the question, how has the operating life been affected? Fig. 5 clearly illustrates that although many manufacturers are commercially producing 26-volt cells, the life expectancy is vastly different from the six suppliers' stacks that were investigated.

In order to save space, weight, and critical materials, manufacturers are attempting to produce cells with still higher voltage ratings. Obviously, the higher the voltage rating, the fewer cells are required in series for a given a-c input voltage. Most companies have had a 33-volt cell development program under way for some time, but again the problem of aging must be considered. Fig. 6 compares the forward aging of 26- and 33-volt cells after 5,000 hours of operation. It is evident that in all cases except one, the 33-volt cells age substantially faster than the 26-volt cells. The exception is the product of one manufacturer who has not produced 26-volt cells but has commercially processed 33-volt cells for several years. Again, there is a wide difference in the rate of aging.

It should be emphasized that the data on the 33-volt cells, with the one exception, were taken on experimental stacks obtained from various companies while they were still in the research and development stages of processing the 33-volt cell. Undoubtedly, improved aging qualities have been incorporated in their more recent manufacture.

Fig. 7 shows clearly what happens to the aging rate as manufacturers attempt to increase still further the voltage ratings. These data are based upon 26-, 33-, and 40-volt cells made by one supplier. The aging rate is accelerated greatly as the voltage rating is increased.

All the foregoing aging data were taken on stacks operated at rated load currents. A longer operating life may be expected if selenium rectifiers are designed to operate at lower load currents. As shown in Fig. 8, the aging at 50 per cent normal current rating is about one half that at rated current. Above normal rating, the aging is accelerated to a greater degree.

The behavior of the reverse current during these aging studies indicates that the reverse current generally decreases slightly during the first few months of operation and remains substantially constant thereafter. The rectifiers of a few manufacturers, however, show the opposite effect. The current rises slightly before leveling off. For normal d-c power applications, these changes are insignificant.

Conclusion

The procurement of selenium rectifiers and their application for use in d-c power supplies for large-scale industrial or military projects requires considerably more information than can be obtained from a manufacturer's catalog. The performance of a rectifier stack in a short-term laboratory set-up should not be the only basis for selection. Circuits initially can be adjusted to accommodate any manufacturer's product, but the extent and rate of aging are important factors. Rapid aging requires periodic circuit adjustments and more frequent replacement of the stacks.

Aging appears to be directly related to the manufacturing process used. Selenium rectifiers properly designed and conservatively rated can be expected to give satisfactory performance for 10 to 20 years. The quality of selenium rectifiers cannot be judged solely on the basis of initial electrical characteristics. Test data on actual performance over an extended time are essential. New developments or changes in cell processing techniques require at least 10,000 hours of continuous testing to establish the aging rate. Even this is no guarantee that the rate will not be accelerated thereafter. Only long-term studies can determine the ultimate life of selenium rectifiers. The project engineer must determine whether suitable operating life of a particular manufacturer's product will meet the requirements of his application.

No Discussion

40- to 4,000-Microwatt Power Meter

R. W. LANGE
NONMEMBER AIEE

Synopsis: This paper describes a 10-kilomegacycle power meter using a bead thermistor for a power detector and having full scale sensitivities from +6 decibels referred to 1 milliwatt (dbm) (4,000 microwatts) to −14 dbm (40 microwatts) selected in 2-decibel (db) steps. Absolute calibration from built-in d-c standards is provided.

Ease of operation at high sensitivities is accomplished by the improvement in zero stability resulting from: 1. Better temperature compensation by closer proximity of temperature and power measuring thermistors; 2. Selection of thermistor pairs after aging; 3. Adjustment of circuit parameters to compensate for manufacturing variations in thermistor parameters; and finally 4. Deriving entire thermistor bias power from a stabilized bridge oscillator.

MICROWAVE power measurements have been described in the technical literature for measuring powers from kilowatts to a fraction of a milliwatt. High powers may be measured conveniently by calorimetric methods; low powers by bolometric methods.

The power meter to be described is of the bolometric type. It extends the accuracy and convenience of measuring in the milliwatt range into the microwatt range.

Bolometer Bridge Circuit

A simplified block diagram is shown in Fig. 1. This is a temperature-compensating direct-reading bridge using a self-balancing oscillator. A brief review of the operation of this circuit follows.

The bolometer detector is a thermal resistor known as a bead thermistor, matched to terminate a transmission line with low reflection. It is shown in this figure as the element marked *RF*. It is the only element in the *RF* resistance bridge subjected to the microwave power.

Directly below the ground plane is the compensating bridge, or *COMP* bridge. Idealized, this bridge is the mirror image of the *RF* bridge except that the *COMP* thermistor is not subjected to the microwave power. The two bridges connected in series provide the load on the amplifier. The output of the *RF* bridge is connected in the proper phase to the input of the amplifier. The thermal resistor in the bolometer detector is used as the regulating element in a conventional bridge-regulated oscillator, holding the resistance of the thermistor very close to the bridge-balancing value. The oscillator power varies with the ambient temperature of the thermistor. Consider the operation before application of microwave power. In the idealized case where the two thermistors have identical characteristics and operate at the same ambient temperature, the identical bridges are simultaneously balanced.

With the application of microwave power to the *RF* thermistor, the *RF* bridge is automatically balanced as before by a reduction in the oscillator power equal to the applied microwave power. This same reduction in oscillator power is applied to the *COMP* bridge and, since no microwave power is applied

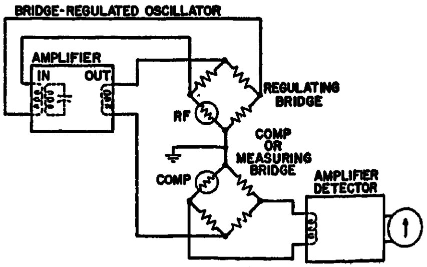

Fig. 1. Bolometer bridge circuit

Paper 53-281, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted February 18, 1953; made available for printing April 29, 1953.

R. W. LANGE is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The author acknowledges the pioneering design of temperature-compensating bolometer bridge circuits and of the basic principles of this power meter by E. W. Houghton and his associates, also the work on stabilization of bead thermistors by C. B. Green and his associates, all of Bell Telephone Laboratories.

to the *COMP* thermistor, this bridge operates at an unbalance proportional to the microwave power applied to the *RF* thermistor. The unbalance voltage of the *COMP* bridge is amplified and detected and read directly as power on a calibrated d-c meter.

Improved Bolometer Detector

The microwave heart of the power meter is the bolometer detector. A cutaway view is shown in Fig. 2. There is the need to operate the thermistors, even thermistors with identical characteristics, at the same ambient temperature. A typical thermistor will have a power temperature coefficient of 100 microwatts per degree centigrade. If we wish to measure 40 microwatts, it is desirable to hold the error in the power indication arising from the random ambient temperature difference of the *RF* and *COMP* thermistors to 2 microwatts or less. This corresponds to an ambient temperature tracking of 0.02 degree centigrade.

In the detector of Fig. 2 the thermistor beads are nearly superimposed. This places the beads at essentially the same ambient temperature. The leads to the beads are similar to give like heat conduction, thereby better ambient temperature tracking. Any residual difference in the thermal conductances of the thermistors to the surroundings appears as a difference in the power-temperature slopes and is corrected, as described later, by the circuit parameter R_∞. The *RF* thermistor is coupled in the usual manner to the TE_{10} mode of the wave guide. The *COMP* thermistor is not coupled to the TE_{10} mode and therefore does not absorb microwave energy. This design has contributed materially to improve the ambient temperature tracking of the beads, making the 40-microwatt sensitivity practical.

General Thermistor Characteristics

The next practical consideration is that thermistor beads do not have identical characteristics. Some of the electrical characteristics are:

1. Aging.
2. The absolute bias power needed to operate the thermistor at a particular resistance for a stated temperature.
3. The power-temperature characteristic which is the relationship between bias power and temperature with resistance a parameter.
4. The resistance-power characteristic which is the relationship between resistance change per unit applied power with temperature a parameter.

There are two approaches toward causing thermistor beads to have effectively identical characteristics. First, manufacturing them alike and, second, adjusting circuit parameters to fit each thermistor. Both approaches are used. The thermistor beads are manufactured and aged with a high degree of control. They are then selected as pairs having like characteristics and similar aging tendencies. These pairs are mounted and matched in the microwave power head.

Circuit Description

BRIDGE CIRCUIT

For the discussion on adjustments of the circuit parameters, refer to Fig. 3 which shows the circuit in greater detail. The amplifier section of the bridge-regulated oscillator must provide stable gain and deliver the total power required to operate the two bridges. The amplifier is stabilized by negative feedback and is operated from a regulated power supply. Both thermistors are biased entirely by the oscillator power.

CIRCUIT PARAMETERS FOR ACCOMMODATING THERMISTOR

The *RF* thermistor is held at the resistance required to match it into the bolometer detector. A typical matching resistance value is 125 ohms. The *COMP* thermistor is held at a resistance determined by R_c. This value is derived as follows: In Fig. 4 the power-temperature characteristics of a pair of thermistors are shown. At temperature t_0 no bias power is required to operate thermistor *RF* at 125 ohms; t_0 is around 300 degrees Fahrenheit, well above the maximum ambient operating temperature. At lower temperatures bias power must be added to maintain the resistance at 125 ohms since at t_0 no heating power is applied. For this particular thermistor operating at 125 ohms the thermistor bead must be held constant at temperature t_0, and this temperature is attained by the combination of ambient temperature and total bias power. The *COMP* thermistor, which is the second one of the pair, requires a temperature t_1 to reach a resistance of 125 ohms. Since the two thermistor beads are at the same ambient temperature and have like heat conduction properties, they can be made to temperature-track over a large operating range by shifting the compensating thermistor characteristic to temperature t_0. To do this the *COMP* thermistor operating resistance corresponding to t_0 becomes higher than 125 ohms, say, for this example, 140 ohms. The circuit parameter R_c, which is one arm of the compensating bridge, is made 140 ohms for this particular thermistor, thereby balancing this bridge when the *COMP* thermistor is 140 ohms. R_c is individually determined for each thermistor pair.

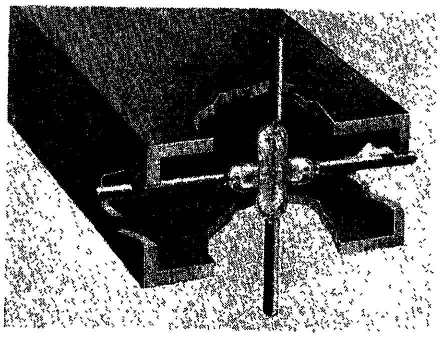

Fig. 2. Bolometer detector

Next, observe that the slopes of the two curves are different. This means that for any increment in temperature the *COMP* thermistor requires a greater change in bias power from the oscillator to maintain its resistance than does the *RF* thermistor. The circuit parameter R_∞ provides that the ratio of the two required powers is the same as the ratio of the slopes of the power-temperature characteristics. This division of oscillator power is made by the variable shunt around each bridge. R_∞ is adjustable for each thermistor pair.

AMPLIFIER-DETECTOR

Three of the four characteristics of thermistors have been accounted for. In considering the fourth, recall in the review of this general type of power meter that the *COMP* bridge operates at an unbalance proportional to the microwave power applied to the *RF* thermistor. This unbalance is dependent on the resistance-power coefficient of the thermistors. To use practical thermistors the circuit must provide an absolute power calibration and adjustments of the amplifier detector sensitivity. Since the thermistor is unaware of its source of heat, the absolute power is conveniently supplied from the d-c calibrating circuit. This circuit consists of a selected network of precision resistors to derive calibrating powers in the range 40 to 4,000 microwatts from the d-c power supply. The sensitivity of the amplifier-detector is adjusted by varying the cathode feedback in the preamplifier, or the zero-db adjust control, which is adjusted for each thermistor pair.

The amplifier-detector is a 3-stage

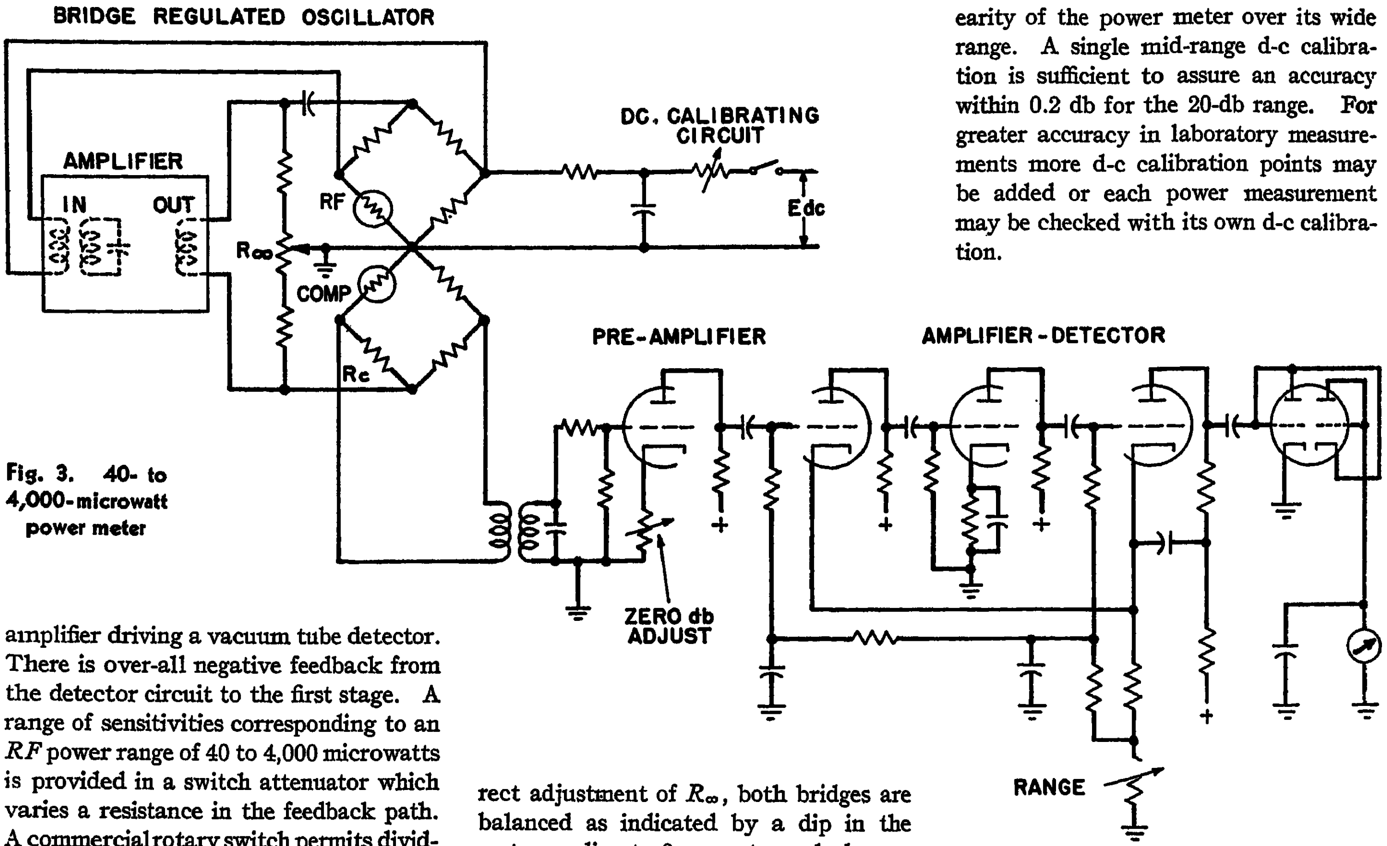

Fig. 3. 40- to 4,000-microwatt power meter

amplifier driving a vacuum tube detector. There is over-all negative feedback from the detector circuit to the first stage. A range of sensitivities corresponding to an *RF* power range of 40 to 4,000 microwatts is provided in a switch attenuator which varies a resistance in the feedback path. A commercial rotary switch permits dividing this range into 2-db steps from −14 to +6 dbm. This range switch is shown functionally in Fig. 3 as the variable resistor designated *RANGE.*

Operating Procedure

There are three simple calibrating steps before applying and measuring the microwave power. First, the supply voltage is adjusted to the calibrate value as marked at full scale on the meter. Second, with the calibrate switch in the adjust ∞ position, R_∞ is adjusted for a meter indication of ∞. (With the correct adjustment of R_∞, both bridges are balanced as indicated by a dip in the meter reading to 0 current, marked as ∞ on the meter scale.) Third, the calibrate switch is operated to apply a known d-c power to the *RF* thermistor. The zero-db adjust control is adjusted to give a full-scale meter indication of 0 db. The actual full-scale power sensitivity is indicated on the range switch. This completes the calibration.

For measurement, the calibrate switch is operated to the measure position. The microwave power under test is applied to the *RF* thermistor. The sum of the meter indication and the setting of the range switch gives the measured microwave power in decibels referred to 1 milliwatt. The meter scale is calibrated in 0.1-db intervals to 2 db and 0.5-db intervals to 6 db, so power ratios 6 db below 14 dbm, that is −20 dbm, or 10 microwatts, may be read directly.

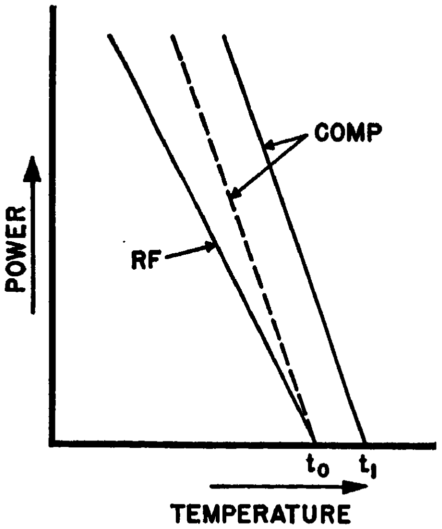

Fig. 4. Power-temperature thermistor characteristics

Stability

The stability of the power meter after an initial warm-up of less than 2 hours is such that for the next 4 hours the drift on the most sensitive scale of −14 dbm is of the order of 1 microwatt. The stability is of the same order with 3 per cent changes in filament and plate voltage. However, these voltages can be regulated quite readily to cause negligible drift.

Linearity

Selection of impedance of the bridge circuits and use of feedback around the amplifier detector contribute to the linearity of the power meter over its wide range. A single mid-range d-c calibration is sufficient to assure an accuracy within 0.2 db for the 20-db range. For greater accuracy in laboratory measurements more d-c calibration points may be added or each power measurement may be checked with its own d-c calibration.

Performance on Continuous-Wave and Pulse Power

Power measurements on continuous-wave signals have been checked against a thermistor detector operating in a simple d-c bridge circuit where the microwave power is the difference in d-c bias power delivered to the thermistor with and without microwave power applied. The two power meters were in agreement within 0.05 db.

Power measurements were made using pulse signals from magnetrons. Pulse lengths of 0.25 to 0.5 microsecond and repetition rates from 500 to 2,000 cycles were used. Power measurements were compared with the d-c thermistor bridge and also with a water load calorimeter. The correlation of the three power measurements was within 0.25 db.

Conclusion

This direct-reading power meter has proved to be a stable, sensitive tool for both laboratory and field use. The basic circuit is suitable for operation with an extension of the design of the improved bolometer detectcr to other frequency bands. These same considerations apply to using hot-wire, or barretter, thermal resistors.

Mathematical Descriptions of Core Losses

J. W. HALE

F. R. RICHARDSON
NONMEMBER AIEE

Synopsis: This paper presents results so far achieved by the writers in endeavoring to gain an understanding of the factors controlling a-c core losses in modern magnetic materials. Losses have been measured on a number of cores over a range of frequencies and at flux densities in the middle portions of the magnetization curves. Theoretical and empirical relations have been derived to connect the dynamic losses to the static losses and other determining factors.

It has been found that in those cases where the combined effect of gauge, frequency, flux density, permeability, and conductivity is sufficiently severe the skin effect during the major part of each cycle reaches a maximum value which is limited by practical saturation of the material near the surfaces of the laminations. A theoretical equation describing eddy currents accompanying this limiting flux distribution gives good agreement with losses measured under these conditions. This equation is analogous to one offered previously by Ganz.[1]

In cases where this limiting flux distribution does not prevail, eddy losses are of greater practical importance, and are more complicated. Data for these cases have been studied by means of dimensional analysis. By dividing the materials tested into groups with similarly shaped magnetization curves, significant correlations have been obtained between parameters embodying the classical variables which are known to influence core losses. It has been found that there also exists in each group a previously unidentified material variable of major importance, and it is suggested that this is domain size. In making this interpretation, the writers rely on the explanation of the eddy current anomaly of Williams, Shockley, and Kittel.[2]

Data are presented which indicate that core losses in modern magnetic materials would be reduced 40 per cent or more if the static hysteresis losses could be kept the same while reducing the domain size to that which exists in ingot iron.

IT HAS been known for many years that observed losses in ferromagnetic laminations are greater than the losses calculated by standard methods.[2] This discrepancy has been referred to as the eddy current anomaly. In the case of 0.014-inch oriented silicon steel at 60 cycles per second, it amounts to about 40 per cent of the observed losses. Stewart[3] has found that refinements in the standard calculations to account for nonuniform permeability and skin effect have not succeeded in explaining the discrepancy. More recently, Williams, Shockley, and Kittel[2] have made a study of losses in a single crystal of silicon steel, and have shown that there is no anomaly in this special case where eddy currents can be accurately calculated on the basis of the actual domain structure. They suggest that classical eddy current equations fail chiefly because flux changes in laminations are treated as being continuous instead of discretely located at moving domain walls.

Because standard calculations fail to describe core losses in modern magnetic materials, no mathematical relations have been presented which quantitatively evaluate the effects on core losses of material variables such as gauge, resistivity, or permeability. It was to gain such quantitative understanding of core losses and to secure knowledge of possible unrecognized material variables that this study was undertaken.

Empirical Relations Describing Core Losses

The method of dimensional analysis outlined by Buckingham[4] has been applied to core loss measurements to obtain empirical relationships describing core losses when flux distribution in laminations is not limited by saturation. In this approach, three independent dimensionless parameters have been derived from core losses and the six classical physical factors known to influence them. Core loss data collected on a number of magnetic materials over a range of frequencies have been used to evaluate these parameters. Two advantages are gained from this method of attack:

1. The presence or absence of a correlation between these three parameters indicates respectively the absence or presence of additional important factors which influence core losses.

2. Since one of the three parameters is constant within certain groups of materials, a 2-dimensional plot of the other two parameters shows the effects on core losses of all the independent classical variables within limits where a correlation exists.

The seven classical variables which would be contained in a complete physical equation describing core losses are as follows:

P_c = core losses, watts per cubic centimeter
f = frequency, cycles per second
B_0 = operating flux density, gausses
ρ = resistivity, ohm-centimeters
d = lamination thickness, centimeters
μ = static permeability, gausses per oersted
J_0 = area of static hysteresis loop, joules per cubic centimeter per cycle at B_0

Three independent dimensionless parameters which embody these variables are

$$\frac{P_c}{fJ_0},\ \frac{fB_0^2d^2}{\rho J_0},\ \frac{\bar{\mu}_0 J_0}{B_0^2}$$

Since μ is not a single-valued function, it is necessary to assign an average value to it. $\bar{\mu}_0$ is the permeability averaged with respect to flux density from 0 to B_0. B_0 is the average flux density that exists in a lamination at the instant of zero voltage.

Values of $(\bar{\mu}_0 J_0)/B_0^2$ for the materials tested are given in Table I. It can be seen there that the values of this parameter divide the materials into two distinct groups, the members of group I all having values close to 1.0×10^{-8} and the members of group II having values close to 1.5×10^{-8}. The members of group II are all materials with rectangular hysteresis loops. The constancy of the parameter in either group is the result of the general similarity in shapes of magnetization curves and hysteresis loops that exists in each group. Within each group, the average permeability is so closely related to the hysteresis loss and flux density that it need not be treated as an independent variable. Therefore, within each group, a correlation between P_c/fJ_0 and $(fB_0^2d^2)/\rho J_0$ will show the effects on core losses of all the independent classical variables; and the absence of a correlation between these two parameters will demonstrate the presence of additional important material factors which influence core losses.

The range of flux densities over which the close relation between permeability and hysteresis exists is limited to the middle portions of magnetization curves, where magnetization proceeds by irreversible domain wall movements. For exam-

ple, this is from about 1,000 to 15,000 gausses in oriented silicon steel.

Empirical plots of P_c/fJ_0 and $(fB_0^2d^2)/\rho J_0$ are shown in Figs. 1, 2, and 3. Data for members of group I are given in Fig. 1; data for heavier gauge members of Group II are given in Fig. 2; and data for the lighter gauge members of group II are given in Fig. 3. The exact materials, flux densities, and frequencies covered in each plot are given in Table II. It will help in understanding these curves if it is noted that P_c/fJ_0 is the ratio of dynamic loss per cycle to static loss per cycle, and therefore must approach unity for small values of $(fB_0^2d^2)/\rho J_0$. Also, higher values of P_c/fJ_0 indicate higher relative losses.

In examining Fig. 1 it can be seen that a good correlation between the parameters exists for all the materials included there except ingot iron, and this clearly does not fit. It follows from the reasoning already presented that the significance of the correlation lies in its indication that no important variable besides those in the parameters acts to differentiate losses in the various materials included there. Conversely, the divergence of the ingot iron data demonstrates that some unknown material factor acts to differentiate its losses from those of the other materials in group I. Since only ingot iron losses are approximated by standard calculations, it is the authors' conclusion that this unknown material variable is responsible for the eddy current anomaly.

If the explanation of the eddy current anomaly[2] is accepted, then it can be reasoned that this unknown variable is domain size. For if the domains became very small, the conditions of the classical equation would be approached, and the losses would approximate those derived from the standard calculations. Also, the larger the domains, the greater the deviation from the assumed classical conditions, and the greater the eddy current anomaly. Photomicrographs of domain structures in 25-mil ingot iron and 12-mil oriented silicon steel, both taken at 200 diameters, are presented in Fig. 4 to demonstrate qualitatively that a large difference in domain size exists between these two materials.

From the principles of physical similarity described by Buckingham,[4] it follows that if domain size is a major variable influencing core losses, then the ratio of domain width to lamination thickness must remain constant to have a correlation between the parameters P_c/fJ_0 and $(fB_0^2d^2)/\rho J_0$. Therefore, the grouping of points shown in Fig. 1 suggests that those materials included there embody significant uniformity of effective domain size, and that this decreases proportionately with lamination thickness. The materials which show this correlation have in common, in addition to similarly shaped magnetization curves, the property of being single-phase alloys

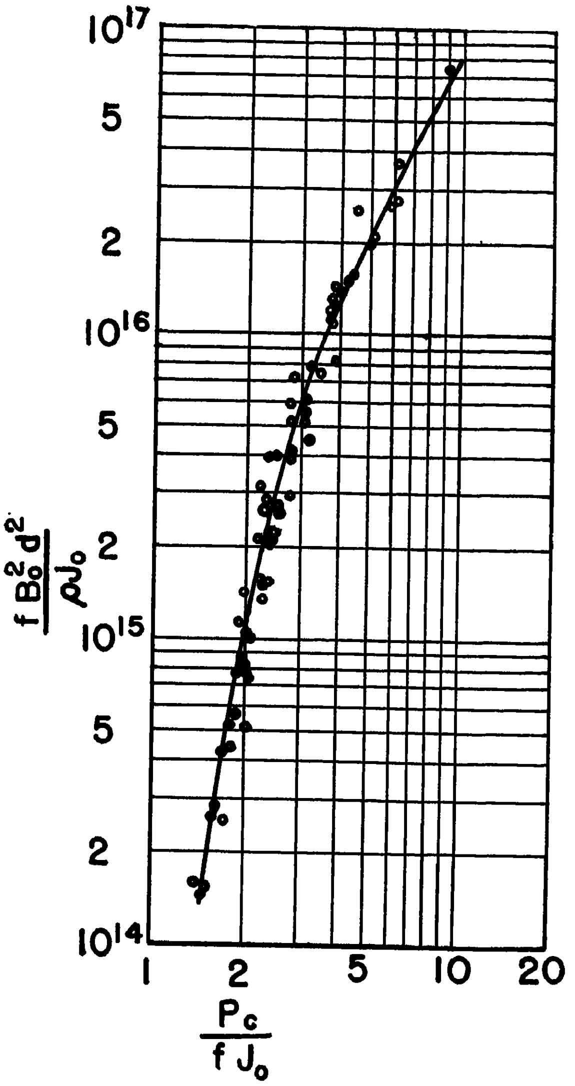

Fig. 2. Measured values of the dimensionless parameters for the 3-, 4-, 5-, and 10-mil materials of group II

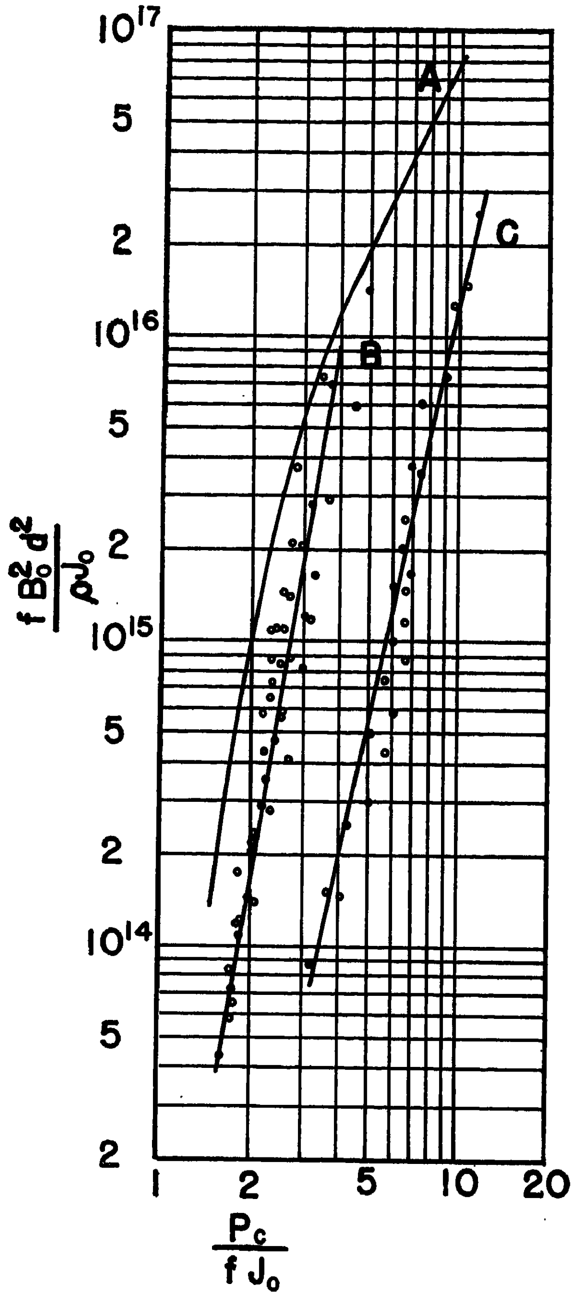

Fig. 3. Measured values of the parameters for the 1- and 2-mil materials of group II. Curve A is from Fig. 2. Curve B is for customarily annealed materials, and curve C for magnetically annealed Deltamax

undergoing no allotropic transformations, and have been high-temperature annealed.

In comparing the two curves in Fig. 1, it can be seen that the ratio of a-c to d-c loss per cycle for ingot iron is 40 per cent less than that for the other materials in group I. This indicates that if everything else could be kept the same in these metals while reducing the effective domain size to that which exists in ingot iron, then their losses would be reduced 40 per cent.

The effect of domain size also is a convenient and reasonable explanation for the displacements of loss curves which will be noted among the materials of group II plotted in Figs. 2 and 3. The heavier-gauge materials plotted by themselves in Fig. 2 form a good pattern, but the lighter-gauge materials in Fig. 3 form a parallel curve displaced slightly in the direction of higher losses. This could be a manifestation of a change in the ratio of domain width to lamination thickness, the domain width not decreasing as rapidly as the gauge. It fulfills a prediction that the eddy current anomaly may be greater in thinner sheets.[2]

The difference in losses of magnetically annealed Deltamax from that given ordinary furnace cooling, also shown in Fig. 3, is especially interesting, since it seems to be a case where core losses are increased by a factor of two through a treatment which presumably changes little, other than in the coarseness of the domain structure. Attempts by the authors to observe the domain structures in this material with powder patterns have not been successful.

If domain size can be accepted as being responsible for shifts in the parametric curves within each of the two groups of materials, then domain shape may be the factor differentiating losses between the two groups. This idea is strengthened by the fact that the rectangular hysteresis loops characteristic of the materials in group II are attributed to their special domain structures.

Although the empirical curves given in this paper have already been of considerable help in interpreting core loss phenomena, they constitute the beginning of a study, rather than the end. The relations may become valuable for estimat-

ing losses of untested materials when the limits of their use are more completely established. Accepting the importance of domain size and shape, the range of applicability of the relations will depend upon 1. the regularity within groups of magnetic materials of the ratio of domain width to lamination thickness, and 2. the number of significant kinds of domain configurations that exist in magnetic materials.

The Importance of Skin Effect

Skin effect in a magnetic lamination is the unequal magnetization through the thickness of the lamination which results from the fact that eddy currents shield central portions of the material from the full effect of the magnetizing force. It is always present under dynamic conditions of magnetization, but is small at very low frequencies, and becomes greater at higher frequencies. The actual patterns of flux distribution which occur during a cycle have a primary effect on the magnitude of the eddy current losses.

Dimensional analysis is based on the concept of physically similar systems.[4] If the groupings of parameter values presented in this paper are true correlations and not mere coincidences, then within limits where a correlation holds, fixing the value of either parameter fixes the geometrical pattern of flux change in a lamination at each instant of each cycle. Thus, it can be seen that changing any of the independent variables changes the amount of skin effect. This results in softening the influence on core losses of every one of the classical variables, from what it would be if the flux configuration remained constant.

This softening influence of skin effect can be made apparent by equating the straight-line portion of the correlation in Fig. 1.

$$P_c=\frac{(4.35)B_0df^{3/2}J_0^{1/2}}{10^8\rho^{1/2}} \tag{1}$$

This equation holds reasonably well over a range of conditions where eddy losses change from about 50 per cent to more than 95 per cent of the core losses.

At the upper end of the range, eddies constitute nearly the entire core loss, and thus approach the condition of varying with 1. the three halves power of frequency; 2. the square roots of hysteresis loss and conductivity; and 3. directly with gauge. The effect of hysteresis loss on eddy currents is a result of its close association with permeability, and is a manifestation of its influence on flux configuration.

At the lower end of the curve of Fig. 1, the eddy currents become independent of the hysteresis loss, because here the influence of skin effect is negligible. Without the softening influence of changing flux configurations, the eddy losses approach the condition of varying with 1. the squares of frequency, flux density, and gauge, and 2. the reciprocal of resistivity.

It is worth noting that over the range of conditions where equation 1 holds, the frequency variation of losses is independent of the hysteresis loss; and this therefore cannot be evaluated by standard core loss separation tests under conditions where equation 1 applies.

All the statements concerning the influence of variables within the range of equation 1 also hold qualitatively for any other range of conditions where core losses are governed by a straight-line parametric relation. The influence of skin effect is more pronounced among materials of group II. For example, the lower portion of the correlation for the lighter gauge materials of group II plotted in Fig. 3 is

$$P_c=\frac{(8.4)f^{7/6}J_0^{5/6}B_0^{1/3}d^{1/3}}{(1,000)\rho^{1/6}} \tag{2}$$

Whether the empirical curves are straight or not, their slopes are such that within limits where the correlations hold, the effects on core losses of the variables other than hysteresis are never more severe than as indicated in equation 1.

Losses Accompanying the Limiting Flux Distribution

If any one of the materials in Figs. 1, 2 and 3 is given a series of tests at successively higher frequencies, eventually the losses begin to increase with the square of the frequency. When this happens, the parameters no longer fit the empirical curve to which the particular material belongs. This failure of the correlation results from the fact that the skin effect increases with increasing frequency until saturation of material near the surfaces of the laminations prohibits the flux configurations demanded by the parametric relation.

It has already been pointed out that, within limits where a correlation holds, fixing the value of either parameter fixes the flux configurations that occur during each cycle, and that this condition is necessary to and responsible for the correlation. It has also been noted that skin effect increases from negligible amounts at small values of the parameters to ever-increasing amounts at higher values. More skin effect means that for a given average flux density, the actual density at the surface of a lamination is higher. It follows that if the combination of skin effect and operating flux density is made sufficiently severe, saturation of part of the lamination will occur, and then the correlation between the parameters will fail.

The authors have developed theoretical eddy current equations based on a limiting flux distribution, and have found that they adequately describe losses when the empirical relations fail because of saturation. This limiting flux distribution represents the maximum possible skin effect, and was first described by A. G. Ganz[1] as a basis for calculating eddy currents in pulse transformers. It consists of regions of saturated material extending inward from the surfaces of the laminations, and separated from material saturated in the opposite direction by surfaces parallel to the lamination surfaces. Magnetization proceeds inward by movement of the separating walls. Simple mathematical analysis is possible to determine eddy currents accompanying such changes in magnetization. The derived equation for average alternating current eddy losses accompanying this limiting flux distribution is as follows

$$P_e=\frac{(\pi)^2}{(4)(10^{16})}\;\frac{f^2B_0^2d^2}{\rho}\;\frac{B_0}{B_a} \tag{3}$$

where

P_e = eddy current losses (watts per cubic centimeter)

B_a = available flux (95 per cent of static induction at 10 oersteds)

The definition of the available flux here is necessarily somewhat arbitrary.

Brailsford[5] has pointed out that skin effect may give increased hysteresis loss. The hysteresis losses accompanying this limiting flux distribution would be

$$P_h=fJ_a\frac{B_0}{B_a} \tag{4}$$

where J_a is the static hysteresis loss

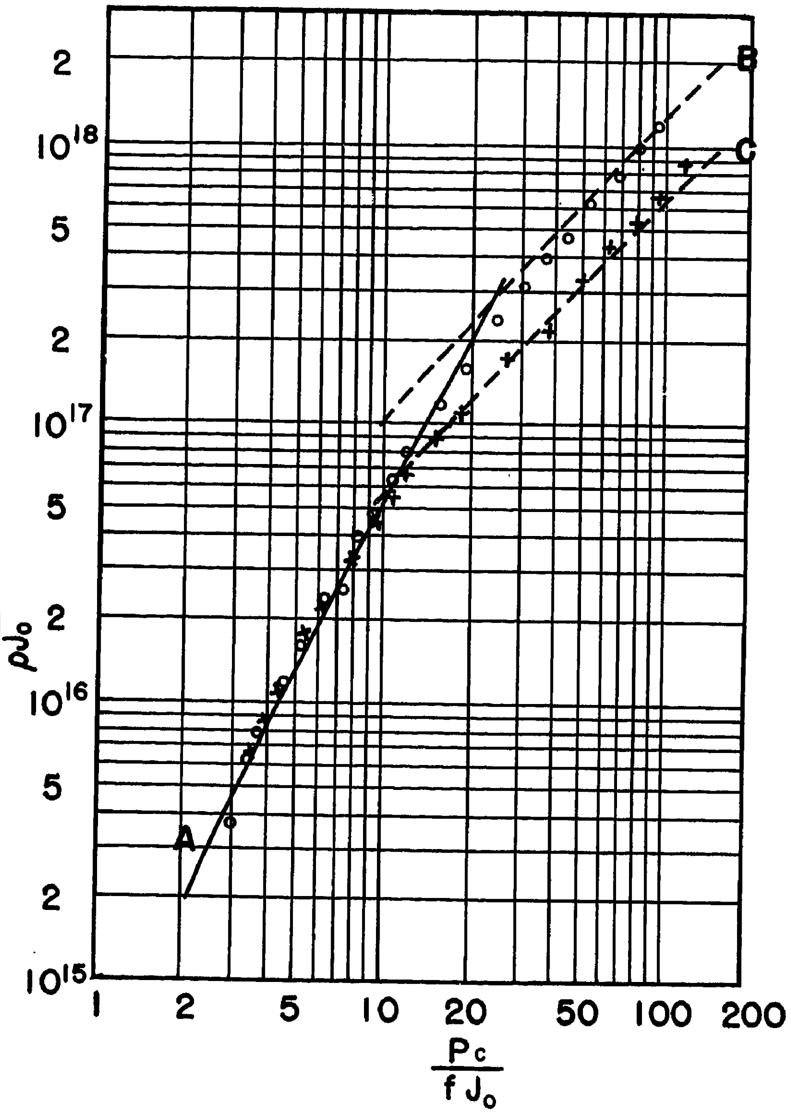

Fig. 5. Theoretical limiting losses in 15-mil oriented silicon steel. Curve A is the empirical relation from Fig. 1. Curves B and C are values of equation 7 for oriented silicon steel at 5,000 and 10,000 gausses respectively. Circles are measured values at 5,000 gausses, and crosses are measured values of the parameters at 10,000 gausses

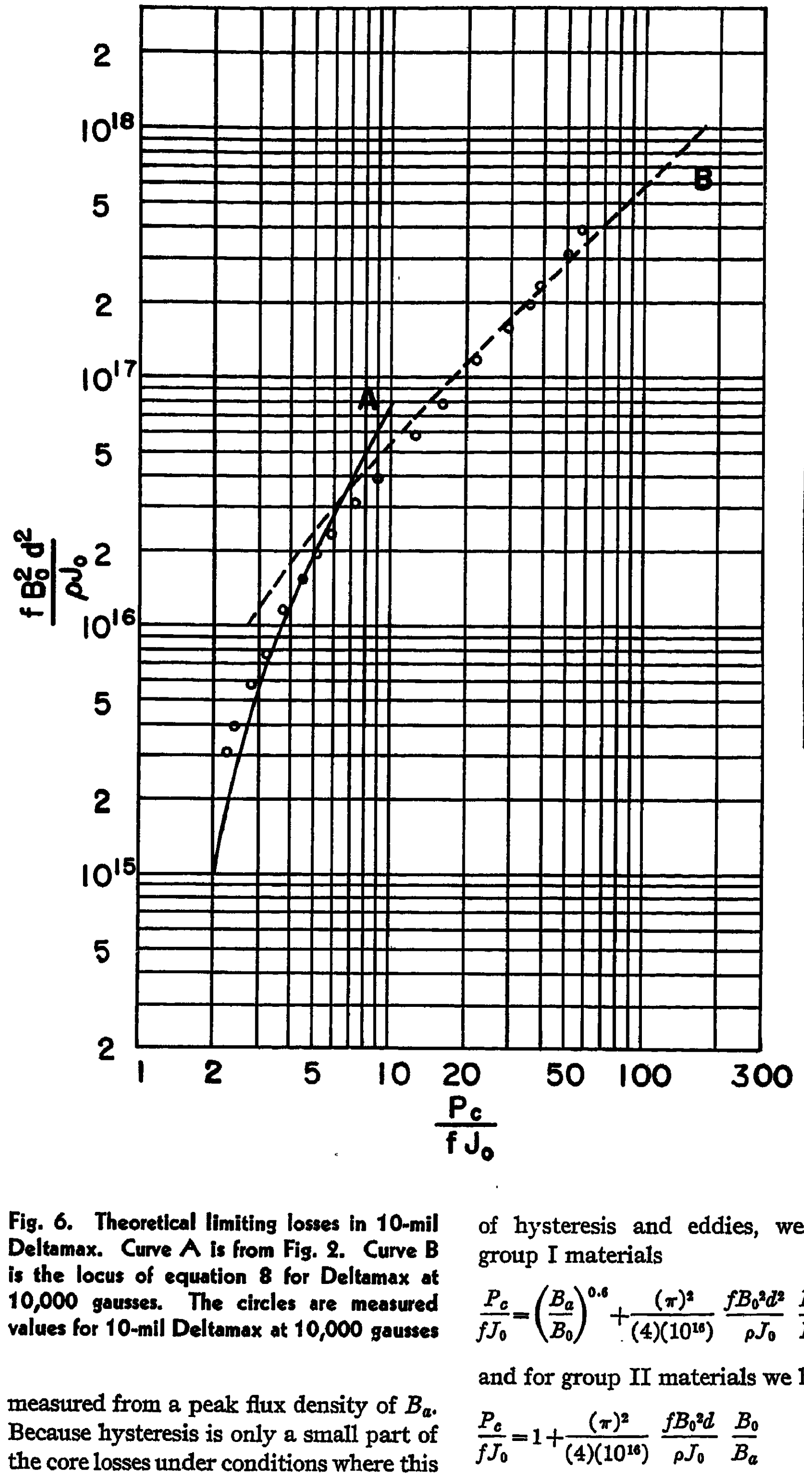

Fig. 6. Theoretical limiting losses in 10-mil Deltamax. Curve A is from Fig. 2. Curve B is the locus of equation 8 for Deltamax at 10,000 gausses. The circles are measured values for 10-mil Deltamax at 10,000 gausses

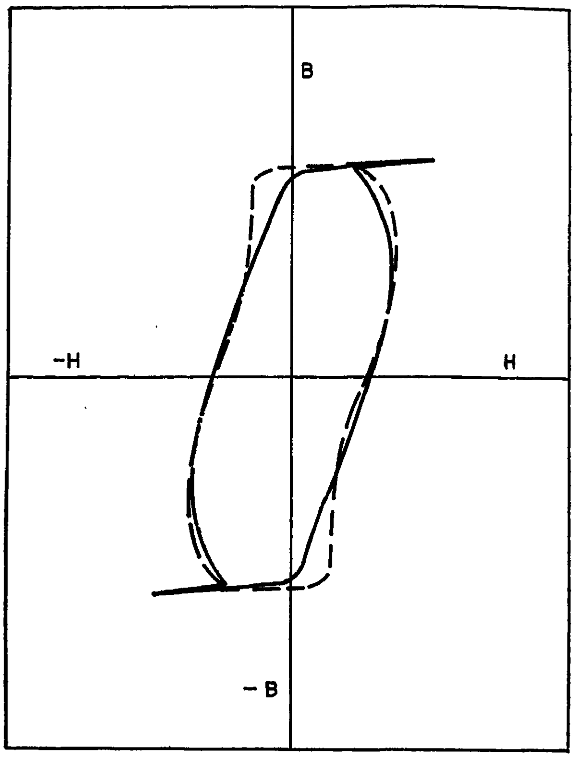

Fig. 7. A comparison of the shapes of an experimental a-c hysteresis loop (broken line) and a theoretical one (solid line). These are for 10-mil Deltamax operating at 400 cycles per second

measured from a peak flux density of B_a. Because hysteresis is only a small part of the core losses under conditions where this limiting flux distribution exists, it is sufficiently accurate to consider the static hysteresis losses in group II materials as varying with the first power of flux density, and in group I materials as varying with the 1.6 power of flux density.

This gives for hysteresis losses in group I

$$P_n = fJ_0\left(\frac{B_a}{B_0}\right)^{0.6}. \tag{5}$$

and in group II

$$P_n = fJ_0 \tag{6}$$

Then, taking the total losses as the sum of hysteresis and eddies, we have for group I materials

$$\frac{P_c}{fJ_0} = \left(\frac{B_a}{B_0}\right)^{0.6} + \frac{(\pi)^2}{(4)(10^{16})}\,\frac{fB_0^2d^2}{\rho J_0}\,\frac{B_0}{B_a} \tag{7}$$

and for group II materials we have

$$\frac{P_c}{fJ_0} = 1 + \frac{(\pi)^2}{(4)(10^{16})}\,\frac{fB_0^2d}{\rho J_0}\,\frac{B_0}{B_a} \tag{8}$$

Comparison of experimental losses with values from equations 7 and 8 are given for 15-mil oriented silicon steel in Fig. 5, and for 10-mil Deltamax in Fig. 6. It can be seen that as frequency is increased in each case, the losses follow the appropriate empirical curve until the limiting loss is approached, and that they then begin to increase in accordance with equations 7 and 8.

Materials operated under conditions where this limiting flux distribution prevails show distinctively shaped dynamic hysteresis loops as seen in Fig. 7. This oscillogram was supplied by H. W. Lord, who first noted and called the authors' attention to these loops. It was taken on 10-mil Deltamax at 400 cycles per second. The same analysis used in deriving equation 3 gives the following equation for the instantaneous magnetizing force

$$H_e = \frac{(\pi^2)fd^2B_0^2(\cos\omega t)(1-\sin\omega t)}{(10^9)\rho B_a} \tag{9}$$

where

H_e = magnetizing force of eddies, oersteds
$\omega = 2\pi f$
t = time, seconds

This equation holds only over the range of $\omega t = 90$ degrees to $\omega t = 270$ degrees, and where the instantaneous flux density is $B = B_0 \sin \omega t$.

A comparison of the shapes of the experimental loop and a synthetic one made as the sum of the static loop and calculated eddy currents is given in Fig. 7. The corners of this loop indicate that the limiting flux configuration is not reached immediately at the start of each half-cycle, and this results in losses slightly higher than theoretical.

Moly-Permalloy and Mumetal both show measured limiting losses which are about 20 to 30 per cent higher than the losses calculated from equation 7. This is partly because the residual induction (B_r) in each of these metals is only 70 per cent of the available induction (B_a).

For these materials, substitution of

$$B_a' = \frac{B_r + B_a}{2}$$

for B_a in equation 7 gives closer agreement with measured values.

The effects of material variables on eddy losses accompanying this limiting flux configuration are evident in equation 3. Because frequency gauge, and resistivity do not influence the flux distribution, their effects are neither softened nor amplified. However, since the relative depth of flux change is proportional to the operating flux density and inversely proportional to the available flux, the losses vary with the cube of the operating density instead of the square, and vary inversely with the available flux. This latter gives another possible control over eddy losses through better materials.

Domain size is not a factor determining losses accompanying this limiting flux configuration, because magnetization proceeds along moving walls which are equivalent in every material, regardless of the basic domain structure.

The existence of this limiting flux distribution demonstrates that when the pattern of flux change in a magnetic lamination is known, a-c core losses can be calculated with good accuracy. This is in agreement with the findings of Williams, Shockley, and Kittel[2]. Thus, it tends to corroborate their idea that classical eddy current equations fail because they ignore domain configurations; and it tends to strengthen the idea offered in this paper that the unknown material variable found in the empirical plots is domain size.

Conclusions

When the combined effect of frequency, gauge, flux density, permeability, and conductivity is sufficiently severe, the configuration of flux change in a lamination reaches a limiting condition representing the maximum skin effect. The losses which accompany this limiting flux distribution agree well with calculated values.

When flux distribution is not limited by saturation, the core loss behaviors of the materials tested fall into two groups. Members of each group are characterized by similarly shaped magnetization curves.

Within each group, significant correlations have been found between parameters embodying the classical factors known to influence core losses. However, there exists in each group an additional material variable; and it is suggested that this is domain size.

These correlations suggest that significant regularity of effective domain size exists within groups of magnetic materials.

Test data indicate that core losses in modern magnetic materials would be decreased 40 per cent or more by reducing the effective domain size to that which exists in ingot iron, while keeping other factors the same.

Electron-Tube Voltmeter Concepts in the Mid-Frequency Range

GEORGE B. HOADLEY
MEMBER AIEE

FROM TIME to time the AIEE sponsors papers of a tutorial nature designed to expound some phase of electrical engineering for the benefit of the general reader rather than for the specialist. This paper is of the tutorial type, treating some of the problems in electron tube voltmeter design and operation, without trying to be all inclusive. The term mid-frequency range is used to indicate that none of the effects which set the upper and lower frequency limits of the instruments are considered.

General Discussion

The electron tube presents a special challenge to those interested in instruments for making measurements of electrical quantities because the electron tube is not, in itself, a precision device. Suitable circuits must be designed to allow the quick response and low input-current characteristics of the tube to be used to advantage without incurring serious limitations on accuracy and permanency of the calibrations.

The most important means of stabilizing electron-tube circuit performance is that of negative feedback. This basic principle has received much attention in recent years not only as applied to all-electric circuits, but also to electromechanical circuits, where it is used in the study of servomechanisms.

Feedback Amplifier Voltmeter

A most useful feedback amplifier circuit is shown in Fig. 1. Here the first stage of amplification is shown, with a cathode resistor R. This resistor carries not only the cathode current of the first tube, but also the output current of the amplifier. This output current I_{out} flows through this resistor on its way to the common cathode-return conductor of the amplifier. Some of this current may also go through the first tube, but for the sake of simplicity we will assume that R is low enough so that this effect is negligible. Also, we will assume that the signal current of the first tube is negligible compared to the output current I_{out}.

In passing through this resistor R, the output current causes a rise in voltage from C to K, which voltage must be combined with the input voltage V_{in} to give the voltage V_{KG} which actuates the amplifier and determines the value of output current I_{out}.

To analyze this situation, three simultaneous equations are written, expressing

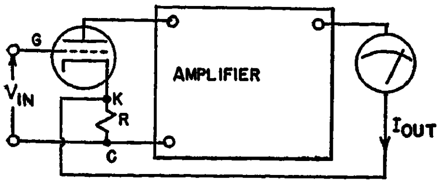

Fig. 1. A common circuit for amplifier stabilization by feedback

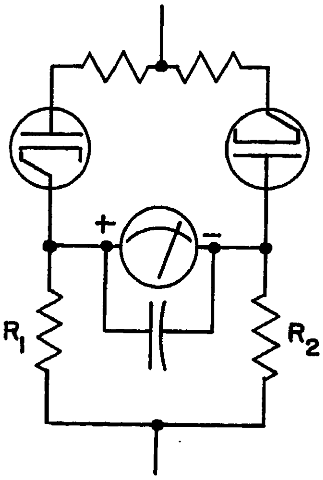

Fig. 2. A full-wave rectifier for an electron-tube voltmeter circuit

in mathematical terms the ideas which have just been described. These equations are

$$V_{CK}=I_{\text{out}}R \tag{1}$$

$$V_{\text{in}}=V_{CK}+V_{KG} \tag{2}$$

$$I_{\text{out}}=gV_{KG} \tag{3}$$

If the second equation is rewritten by factoring V_{CK} out of the right-hand side, there results

$$V_{\text{in}}=V_{CK}\left(1+\frac{V_{KG}}{V_{CK}}\right) \tag{4}$$

Now equations 1 and 3 are solved to find the voltage ratio

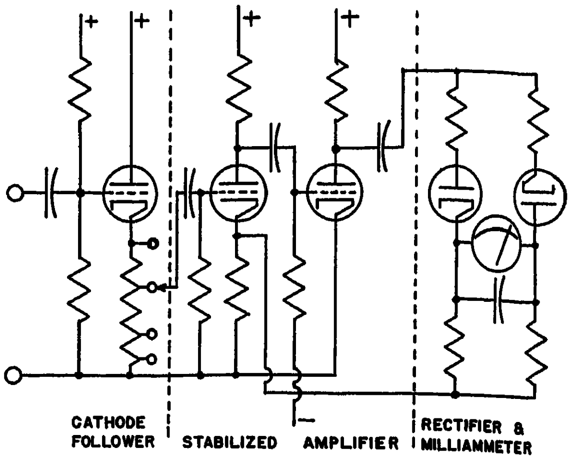
$$\frac{V_{KG}}{V_{CK}}=\frac{1}{gR} \tag{5}$$

Substituting equations 1 and 5 into equation (4) there results

$$V_{\text{in}}=I_{\text{out}}R\left(1+\frac{1}{gR}\right) \tag{6}$$

If gR is made considerably larger than 1, the output current I_{out} multiplied by the resistance R is the input voltage with an error expressed as $100/gR$ per cent. The most important thing about this result is that the characteristic g which is the overall transconductance of the amplifier and is the only term involving the characteristics of the electron tubes, appears only in the error term! All that is required of the amplifier itself is that it amplify enough. Then g will be large enough so that $1/(gR)$ will be negligible.

Fig. 3 (right). An electron-tube voltmeter circuit



In a practical case, R may be 10 ohms. With a 3-stage amplifier comprising two voltage stages each having a gain of 50, and an output stage having a transconductance of 5000 micromhos, the overall transconductance g is $50\times50\times5{,}000\times10^{-6}$ which is 12.5 mhos. The term $1/(gR)$ is then $100/(12.5\times10)=0.8$ per cent. This means that the circuit of Fig. 1 can be made into a voltmeter by using an a-c instrument to measure the output current I_{out} but calibrating it in volts input according to equation 6.

Now, if each tube of the amplifier suffers a 10-per-cent loss in its amplifying abilities, g becomes $45\times45\times4{,}500\times10^{-6}=9.1$ mhos and the term $100/(gR)$ is 1.10 per cent. Therefore, if in the original calibration, a nominal value, such as 0.01 had been used for $1/(gR)$, the resulting overall instrument would be within a tolerance of ±0.2 per cent for a 10-per-cent variation in each stage of the amplifier. This is more than sufficient accuracy for many measurements, so we have a satisfactory electron tube voltmeter, having the high input impedance characteristics of the electron tube, coupled with a freedom from sensitivity to the normal variations in electron-tube characteristics.

In the design of the amplifier itself, there are many problems typical of electronic circuits which must be solved. In particular, the amplifier must be so designed at both its high- and its low-frequency limits that the system will not oscillate. This often requires special attention to the frequency characteristics of the amplifier in these regions, even though they are outside the range of operation of the voltmeter.

The indicator used in the output circuit of Fig. 1 may be any type of alternating-current instrument. For power frequencies, an iron-vane or dynamometer movement could be used, although this is seldom done. For audio work, a dry-rectifier instrument would be applicable, and for higher frequencies a thermocouple instrument could be used. But none of these are as generally satisfactory as the combination of a vacuum-diode rectifier and a d-c milliammeter, because none can match its combination of ruggedness, quickness of response, and large frequency range.

One arrangement for such a combination is shown in Fig. 2, which shows a circuit designed to carry the a-c component of output current. Here a bridge rectifier circuit is used so that current will flow during each half of the cycle. The left-hand diode conducts during one half of the cycle. The current divides between the resistors R_1 and R_2, with the current in R_2 passing through the d-c milliammeter from left to right. During the other half of the cycle, current passes upward through the right-hand diode, again with a division of current between R_1 and R_2, but with the milliammeter again receiving current from left to right. Consequently, the milliammeter receives a unidirectional current, with its variations smoothed out by the shunting capacitor. Thus its reading is propor-

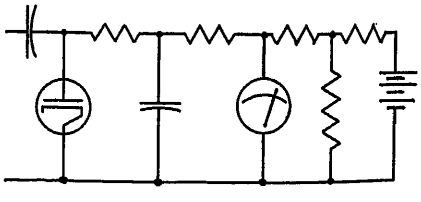


Fig. 4. A half-wave rectifier with zero suppression for a logarithmically scaled instrument

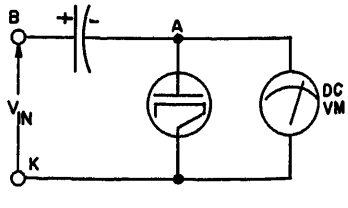

Fig. 5. The basic peak-reading diode circuit

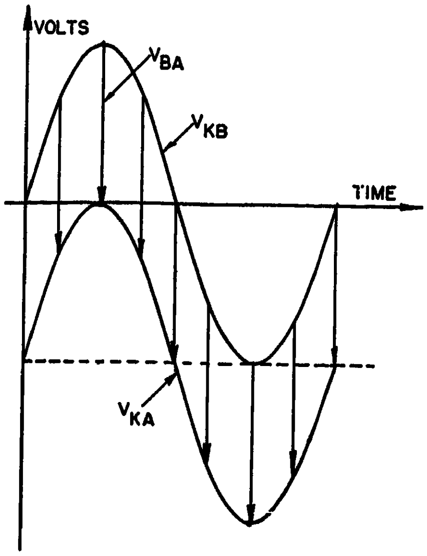

Fig. 6. The suppression of the voltage across the diode of Fig. 5

tional to the average of the rectified input voltage to the overall voltmeter. Usually the milliammeter is calibrated in terms of rms input volts for a sinusoidal input. Then if the input wave contains harmonics the voltmeter reading will not give the rms value, but will give an indication nearly proportional to the average of the rectified wave.

In some circuits, a cathode follower, which will be described later, is placed at the input of the voltmeter. When used with the feed-back amplifier type of voltmeter, a change of range can be accomplished by connecting the input of the feedback amplifier to a tap on the cathode resistor of the cathode follower. This, allows a wide range in input voltages, since the cathode follower can accomodate a large input. A simplified schematic diagram of a voltmeter of this type is shown in Fig. 3.

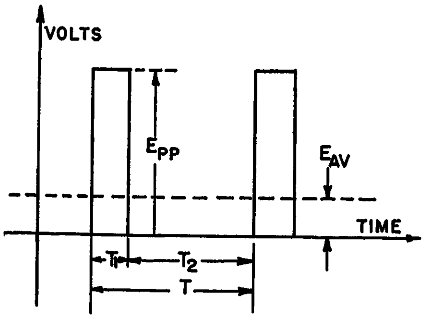

Fig. 7. Voltage pulses used in the analysis of the peak-reading diode operation

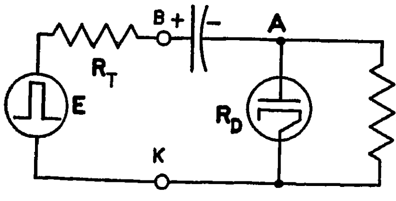

Fig. 8. The equivalent circuit of the peak-reading diode connected to a circuit for measurement of voltage

Another circuit, shown in Fig. 4, employs half-wave rectification and a circuit for injecting a small negative direct current into the milliammeter so that the lowest reading on the scale will be 1/10 of the highest reading instead of zero. This aids in obtaining a logarithmic scale. When this circuit is used in place of the circuit of Fig. 2 as the output indicator in the circuit of Fig. 1, the feedback causes an improvement in the linearity of the rectifier.

Peak Diode Voltmeter

A totally different type of electron tube voltmeter is built around the peak-reading diode circuit, which is shown in its elements in Fig. 5. When this is connected to a circuit for measurement, current flows in the diode whenever the anode is more positive than the cathode. At first, this occurs for each half cycle, but the diode current charges the capacitor, so that diode current can flow only when the input voltage V_{KB} is more positive than the voltage V_{AB} across the capacitor. Consequently, diode current flows during less and less of the cycle of the voltage being measured until in the perfect case, V_{AB} has become equal to the positive peak value of V_{KB}, which is the input voltage. Then the three voltages appear as they are shown in Fig. 6, with the voltage across the diode being the input voltage depressed until it is completely negative, just touching the zero line when the input voltage has positive peaks.

The d-c voltmeter in shunt with the diode will read the average of the voltage across the diode, which will be the difference between the average value and the positive-peak value of the input voltage, and so this ideal circuit reads the positive-peak value of the input.

This analysis neglects the current in the d-c voltmeter, and if the errors are to be studied, this current must be considered. The direct current through the d-c voltmeter must be supplied by the diode, so the diode must conduct during part of each cycle. Consequently, the voltage V_{KA} must become positive at some part of the cycle so the depression of the input voltage is not complete, and some error will result.

In order to analyze this, it is easiest to discard the sinewave input and to use a square topped, pulsed input, such as is

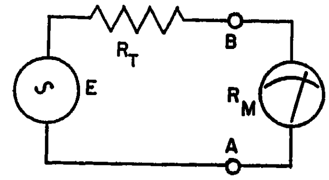

Fig. 9. A voltmeter connected to a circuit with internal resistance

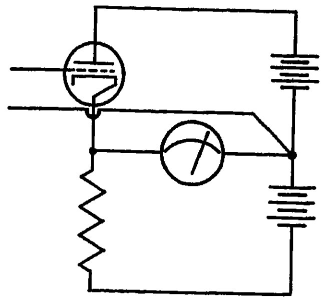

Fig. 10. A simple cathode-follower circuit for use as the d-c voltmeter of Fig. 5

shown in Fig. 7. From this figure, the average value of E is readily calculated to be

$$E_{AV}=E_{pp}\frac{T_1}{T} \tag{7}$$

and the reading of the voltmeter according to the simplified theory would be

$$\text{Theoretical reading}=E_{pp}-E_{AV}=E_{pp}\frac{T_2}{T} \tag{8}$$

The actual reading, however, will be the average current through the voltmeter resistance R_v, multiplied by R_v. Inasmuch as the average current through the capacitor is zero, this will be the same as the average current through the diode, multiplied by R_v.

Analysis of this action will be carried out with reference to Fig. 8, which shows a diode circuit connected to an electromotive force E in series with an equivalent Thevinin resistance R_T. This is done so that the result of the analysis will yield information relative to the loading effect of the voltmeter on the circuit being measured.

By a study of this circuit and Fig. 7, we can express the current in the capacitor for each part of the cycle. The current through the capacitor when the input voltage is positive is

$$I_+=\frac{E_{pp}-V_{AB}}{R_T+\dfrac{R_vR_d}{R_v+R_d}} \tag{9}$$

When the input voltage is zero, the capacitor current is in the reverse direction and is

$$I_-=\frac{-V_{AB}}{R_T+R_V} \tag{10}$$

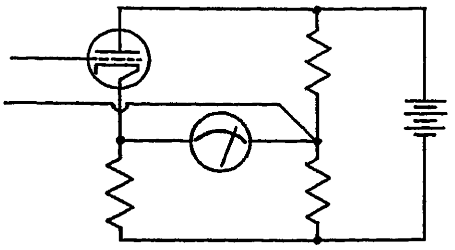

Fig. 11. A variation on the cathode-follower circuit of Fig. 10

Over one complete cycle, the total charge through the capacitor is zero, so

$$I_+T_1+I_-T_2=0 \tag{11}$$

These equations can be easily solved as simultaneous equations if it is assumed that V_{AB}, the voltage across the capacitor, is essentially a constant throughout the cycle. This means that this development is good only if C is large enough so that the time constants are large compared with T_1 and T_2.

By eliminating I_- and V_{AB} from these three equations, there results

$$I_+\left[R_T+\frac{R_vR_d}{R_v+R_d}+\frac{T_1}{T_2}(R_T+R_v)\right]=E_{pp} \tag{12}$$

The diode current is I_+ multiplied by the proper resistance ratio, and the average of this is

$$I_{D_{av}}=I_+\frac{R_v}{R_d+R_v}\,\frac{T_1}{T} \tag{13}$$

so that the actual reading of the instrument is

$$\text{Reading}=I_{D_{av}}R_v=I_+\frac{R_v^2}{R_d+R_v}\,\frac{T_1}{T} \tag{14}$$

When this is combined with equations 12 and 8, there results, after some algebraic manipulation

$$\text{Theoretical Reading}=\text{Actual Reading}\times\left[1+R_T\frac{T}{T_1}\left(\frac{R_d+R_v}{R_v^2}\right)+\frac{R_d}{R_v}\,\frac{T}{T_1}\right] \tag{15}$$

which is the result sought.

The last term in the brackets gives the error resulting from the finite resistance of the d-c voltmeter. If the pulse width, T_1 is only 1 per cent of the period T, then R_v must be 10,000 times R_d for this error to be 1 per cent. If the diode resistance when conducting is 500 ohms, then R_v must be 5 megohms or more, which means that something special must be done with the d-c voltmeter.

The second term in the brackets can best be interpreted in terms of an equivalent resistance of the voltmeter. To do this, consider the simple circuit of Fig. 9. Here a voltmeter is measuring the voltage between terminals A and B, and from its reading there can be calculated the voltage between A and B before the voltmeter was connected. This gives

$$E=\frac{\text{Actual Reading}}{R_M}(R_M+R_T) \tag{16}$$

or

$$E=\text{Actual Reading}\times\left[1+\frac{R_T}{R_M}\right] \tag{17}$$

By comparison with equation 15, the effective input resistance of the diode circuit is the reciprocal of all of the second term in the brackets, except for R_T. This gives

$$R_M=\frac{T_1}{T}\,\frac{R_v^2}{R_d+R_v}=\frac{T_1}{T}\,\frac{R_v}{1+\frac{R_d}{R_v}} \tag{18}$$

Using the values as before, for an example, the input resistance is

$$R_M=0.01\,\frac{5\text{ megohms}}{1.0001}=50{,}000\text{ ohms} \tag{19}$$

This is, of course, an equivalent resistance. During part of the cycle, the resistance is less than this, and during another part of the cycle, it is greater than this, but this value can be used with the simple circuit of Fig. 9 to calculate the effect of the voltmeter on the voltage being measured.

Both of the errors shown in equation 15 depend on the time ratios of the applied electromotive force. Consequently, it would be expected that the equations for a sinusoidal applied voltage would differ somewhat from these. The same basic ideas would be used for the development of the theory, but the mathematics would be more involved, partly because the times at which conduction in the diode started and stopped would not be known, but would have to be found.

The Cathode Follower

The analysis just finished has shown the R_v must be of the order of 5 megohms for satisfactory freedom from errors in the diode circuit. Usually this means that some form of electron tube amplifier must be used to measure the d-c component of the voltage across R_v. Here again the feedback amplifier is of use, but usually only one stage of amplification is employed, with the plate current of the first tube acting as the I_{out} in Fig. 1. Then the resistance R must be much higher than was used before, because g is much lower, so values of R of the order of 10,000 ohms to 50,000 ohms are often used. Such a single-stage feedback amplifier is called a cathode follower.

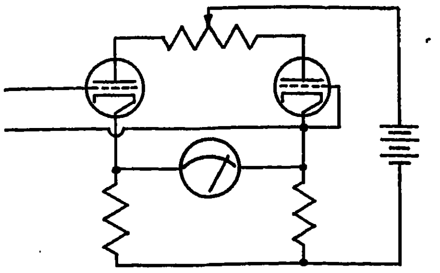

Fig. 12. A balanced, 2-tube cathode-follower circuit for use in an electron-tube voltmeter

In actual use the output from a cathode follower is taken from the cathode or from a tap on the cathode resistor R with a return to the common terminal. Sometimes this return is through an auxiliary circuit designed to eliminate the no-signal d-c component. Thus, in Fig. 10, the return is to a tap on the plate supply of the tube. In Fig. 11, there is shown an alternative in which the return is connected to a tap on a resistive voltage divider placed across the supply. Still another alternative is to use a second cathode-follower circuit, as shown, in Fig. 12. In all of these, various adjustments are provided to allow complete elimination of the no-signal component. The circuit of Fig. 12 relies on similarity between the two halves of the circuit to provide stability of the circuit against variations in ambient conditions.

Usually, the peak-reading diode is connected directly to the circuit being measured, but when very short pulses are to be measured, the input resistance of the diode circuit may become so small, that it is necessary to interpose a cathode follower to increase the input resistance of the voltmeter.

Conclusions

There are many other facets of electron tube voltmeters and their use which have not been touched upon in this paper. Such matters as frequency response, logarithmic scales, and drift compensation could receive attention. In this paper, the author has presented the basic ideas back of the feedback-amplifier voltmeter and the peak-reading diode circuit, with some analytical work to bring out those characteristics which are not particularly related to the frequency of the signal being measured.

L3 Coaxial System—Amplifiers

L. H. MORRIS
NONMEMBER AIEE

G. H. LOVELL
NONMEMBER AIEE

F. R. DICKINSON
NONMEMBER AIEE

Synopsis: The line amplifiers for the *L3* coaxial system are designed to compensate for the loss of the 4 miles of cable which separate the repeaters; the flat amplifiers are used to compensate for equalizer loss and as transmitting amplifiers. The two types are basically similar, consisting of two feedback amplifiers in tandem, separated by an interamplifier network; in the line amplifier, this network is variable, and is automatically adjusted to compensate for variations in cable temperature, and for small deviations from the nominal 4-mile spacing.

Coupling networks, employing high-precision transformers, are used to connect the amplifiers to the coaxial cable through the required power separation filters. The low-impedance windings of the transformers are center-tapped and a balancing network provided to match the cable impedance over the transmitted frequency band. The amplifiers are equipped with plug-in tubes of high figure-of-merit, which were developed for this application. A double-triode output stage is used to obtain improved system signal-to-noise performance. Provision is made for preventive maintenance of vacuum tubes and for a controlled adjustment of gain on an in-service basis.

All important components of the amplifier are subject to quality-control procedures to assure that the average gain of groups of amplifiers will be held within narrow limits and that individual amplifiers will form a normal distribution around the average. This approach is essential in order to meet system equalization and signal-to-noise objectives. Careful mechanical design and rigid control of the mechanical aspects of manufacture are necessary to minimize gain variations which might be caused by variations of parasitic circuit elements and unwanted feedback effects. Special measures were required to keep the temperature rise within the sealed die-cast housing within tolerable values.

IN A TRANSMISSION system such as the *L3* coaxial, the degree to which system objectives are achieved is largely dependent on the quality of the amplifiers which compensate for the cable loss. To a considerable extent, the same statement applies to the similar flat-gain amplifiers used to make up for the loss of the equalizers at various points along the route. The development of an amplifier which would meet the exacting requirements of the *L3* system was, in turn, dependent on new developments in the fields of vacuum tube design and circuitry network-design techniques, element and network fabrication, and statistical quality control. To these new tools were added the lessons learned in years of manufacture and operation of the preceding *L1* system.

The importance of some of these factors can best be illustrated by examining the implications of the amplifier requirements which follow from the material in the companion papers on system design[1] and equalization.[2] Obviously the figure-of-merit, modulation coefficients, and life of the vacuum tubes will be determining factors in setting the amount of feedback that can be obtained, and the signal-to-noise ratio of the system. It is not so immediately apparent that system requirements could not be met with the present 4-mile repeater spacing, if it were not for the use of quality control at every stage of manufacture from elements, and even the raw materials entering into components, to completed amplifiers. As the companion papers[1,2] show, however, the equalization plan of the system is predicted on a degree of reproducibility of amplifier gain and delay characteristics obtainable only by quality control applied at every stage of the manufacturing process.

The present equalization plan is based on the assumptions that the gain of the average line amplifier will match the loss of the preceding line section to within 0.15 decibel (db), and that the average amplifier gain will not vary from one batch of new amplifiers to another by more than about 0.06 db. Under these assumptions, a system equalization plan can be worked out which results in reasonable spacing between equalizers, a tolerable signal-to-noise penalty due to misalignment and equalizer loss, and a practicable procedure for adjusting long systems. Any gross departure from the basic assumptions as to reproducibility of amplifiers would seriously compromise these objectives, which even now are achieved only by using equalization which requires a flat-gain amplifier for every four or five line amplifiers. Now it turns out that with the most precise elements that can be made, the gains of individual amplifiers will vary by about ±0.6 db. We need, therefore, a tool which will permit us to control the gain of the average amplifier to an order of magnitude of greater precision than we can economically control the individual. This is exactly the effect which modern methods of statistical quality control aim at achieving, and since the entire amplifier is merely the sum of its parts, quality control must start at the roots of the manufacturing process. In order to apply quality control intelligently, and to be sure that all important causes of gain variation are understood, it has been necessary to carry out, side by side with empirical laboratory work, a program of computing the insertion gain of the amplifier, starting with fundamental element values. These computations have also proved of value in obtaining satisfactory stability margins in the design of the low- and high-frequency cutoffs of the feedback loops, and in obtaining preliminary information on amplifier-gain deviations for use in equalization planning.

The severe gain and delay reproducibility objectives also have their effect on the mechanical design of the amplifier. At first sight, the unit appears to be a lumped-constant structure rather than one in which distributed effects would be of paramount importance. Usually the circuit designer in such a case is interested in the mechanical design only for reasons of neatness and economy, but when we look deeper we find that in the amplifier structure as a whole, as well as in the case of certain components, the effects of distributed capacitance and inductance could easily defeat our objectives if the mechanical design were not such as to assure precise control of element placement and wiring lengths.

For these reasons, an order of mechanical accuracy is specified beyond that which can be justified by the accuracy of transmission measurements on individual amplifiers. This striving for mechanical accuracy is carried all the way through, from element piece parts, through subassemblies to the assembly on the final amplifier framework. The logical expectation is that by reproducing the amplifiers as exactly as possible, we will control not only the known elements but also the many parasitic effects, and thereby minimize the appearance of

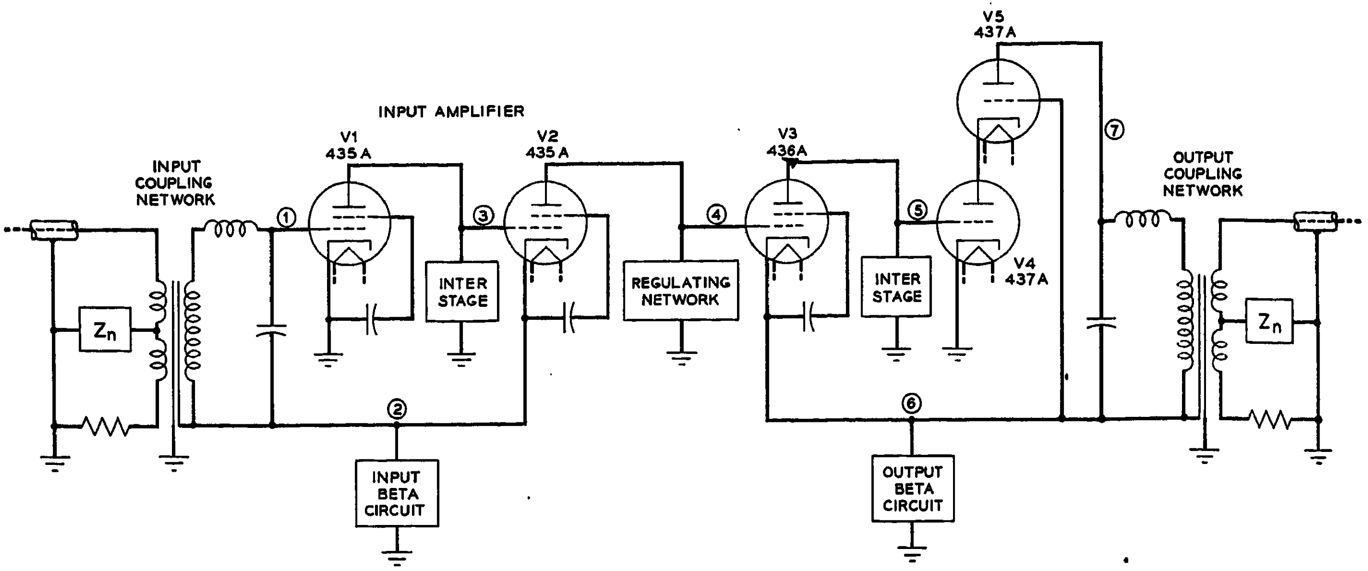
Paper 53-222, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 18, 1953; made available for printing April 27, 1953.

L. H. Morris, G. H. Lovell, and F. R. Dickinson are with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

Many members of the Bell Laboratories have made important contributions to the *L3* amplifier design. Particular mention should be made of the work of S. E. Miller on fundamental amplifier design, S. Darlington and T. R. Finch on network design, C. W. Thulin on the precision transformer, B. J. Kinsburg on quality control problems, E. Ley on mechanical design, and E. F. O'Neill on the flat-gain amplifier and on high-frequency stability problems in both amplifiers.

Fig. 1. Block schematic of line amplifier



shifts in amplifier gain and delay, which would be substantial in the system, even though difficult to detect in the measurement of individual amplifiers.

Another design feature of the amplifier, based on the system equalization point of view, is the omission of all adjustable elements, or trimmers, to control the transmission. By eliminating gain adjustments, the possibility of adjusting one element to compensate for the shortcomings of another, and the possibility of systematic errors of setting due to faulty or inaccurate adjustment techniques, are both eliminated. Either of these possibilities would tend to convert relatively large random effects into smaller but systematic effects, a conversion which would penalize the system equalization. Obviously, however, the elimination of gain-adjusting elements puts a higher premium than ever on the requirement that all elements, including tube capacitances, show only small random variations about tightly controlled nominal values.

In addition to the gain requirements discussed above, the following line-amplifier objectives are to be met:

1. The gain of the amplifier must be continuously variable, under the control of a regulator circuit, to compensate for differences in lengths of cable sections, and for variations of cable loss caused by temperature changes. The shape of the gain change should match the square root of frequency shape of the line-loss change over the transmitted band to within a few hundredths of a decibel. This accuracy of shape, which, of course, is based on equalization considerations, should hold over the entire regulation range, which is about ±6 db at the top transmitted frequency.

2. The input and output impedances of the amplifier should match the cable impedance in order to minimize the effects on television transmission of echoes caused by line irregularities, such as splices. Tolerable values of reflection coefficient at amplifier input and output are about 5 per cent at the television carrier and 10 to 15 per cent at the upper-band edge.

3. Feedback consistent with system-modulation requirements, shaped across the transmitted band to minimize low-frequency intermodulation products and to give a smooth, easily equalized shape of gain change as tubes age, must be obtained, while maintaining adequate margins against singing.

4. Other requirements include design and selection of elements to assure as small a change of gain versus ambient temperature as possible, mechanical design provisions for keeping the temperature rise within the unit to a minimum, both in order to keep the temperature-gain effect small and to obtain long element life, a sealed housing to avoid damage by humidity in exposed locations, and provision of facilities for testing tubes in service.

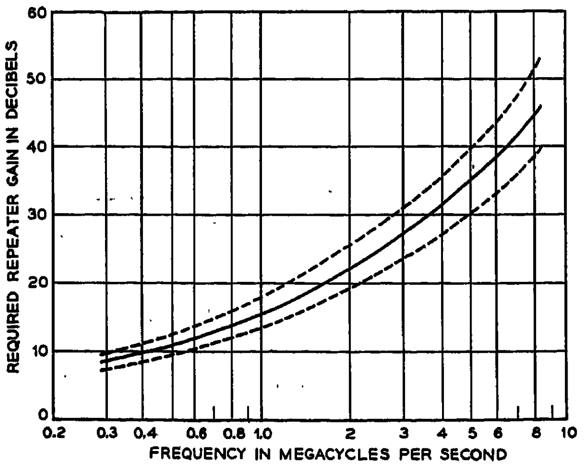


Fig. 2. Required line repeater gain

Configuration

The circuit configuration of the line amplifier is shown in Fig. 1. It consists of two independent feedback amplifiers, with a regulating network between them acting like a 2-terminal interstage. Each of the amplifiers is essentially a 2-stage circuit—the input amplifier, literally so and the output amplifier essentially so, since the double-triode output circuit acts like a single stage. Each amplifier is connected to the coaxial through a coupling network, which consists of a transformer plus gain-shaping and impedance-adjusting elements. Since there is no feedback around the coupling networks, they directly affect the insertion gain of the amplifier, as do the two beta circuits and the regulating network. The required shaping of insertion gain across the transmitted band is obtained and controlled by the design of these five networks. Fig. 2 shows the required amplifier gain for nominal and extreme thermistor settings; these required gains differ from the line loss by the small losses of the associated repeater components. At a midrange thermistor setting, about 37 db of gain shaping is needed. The manner in which this shaping is distributed among the five networks has important effects on the feedback which can be obtained, and the sensi-

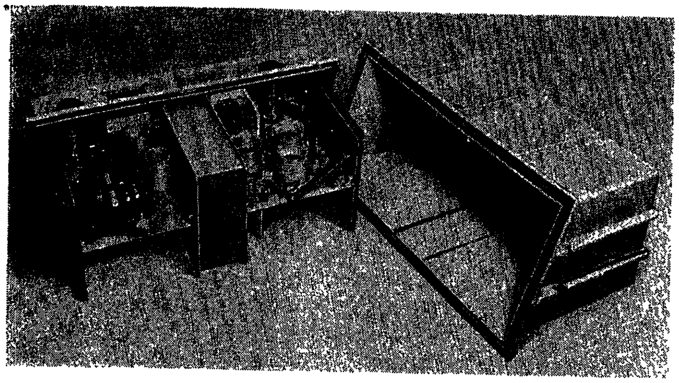

Fig. 3. Line amplifier and sealed housing

tivity of amplifier gain to element variations.

This configuration offers several advantages, one of the most important of which is that the regulating network is between the amplifiers. In most other configurations, the only gain-determining network available for the regulating function is the beta circuit. When the feedback is not infinite, this introduces errors for which it is difficult to compensate, and limits the available feedback by complicating the design. In this configuration, the impedances which the amplifiers effectively present as shunts across the regulating network are high, and can be allowed for in the design, so that the regulation error can be made much smaller than the error associated with beta-circuit regulation in an amplifier having relatively little feedback. Other major advantages are the superior signal-to-noise performance, and the relative simplicity of the feedback loops of this amplifier, as compared to alternative designs.

Mechanical Design

The mechanical assembly of the amplifier, like the configuration, is divided into three main sections. The input and output amplifiers are mounted on separate chassis, which are designed for ready removal from the main base casting. The regulating network is mounted in an enclosed, shielded compartment, which also serves to shield the component amplifiers from each other. Figs. 3 and 4 show the assembled amplifier.

Because of the wide frequency range and close control of parasitic capacity and lead inductance required, the *L3* amplifier was designed as an integrated whole, and all networks were designed with, and as part of, the amplifier. In each case circuit elements were placed in space in the best possible position for optimum electrical performance, and supporting structures were then designed to maintain the desired space relationships. These supporting structures are made as separate units which mount on the amplifier chassis, so that the networks can be individually tested before final assembly into the amplifiers, and can be removed for repair or replacement if necessary.

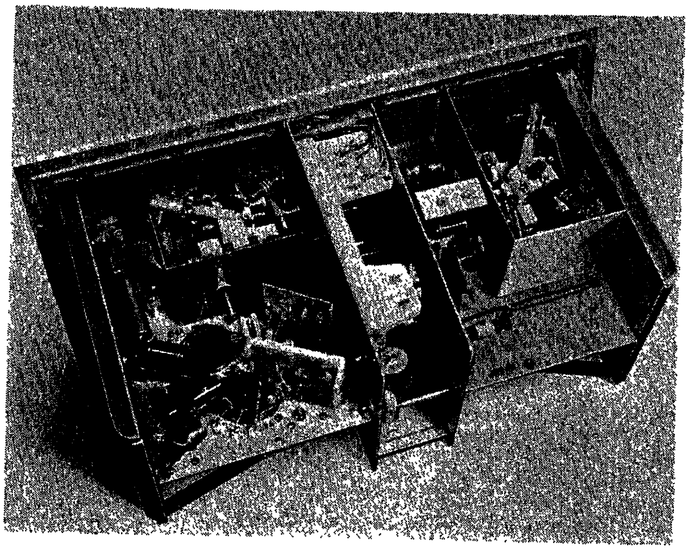

Fig. 4 (right). Another view of amplifier, showing networks

Heretofore, this method of design has been impracticable because it results in very complicated supporting structures. It was feasible in this case because of the availability of a new type of material, which removes many of the mechanical-design constraints. This is a cold-casting resin, and parts are produced in a cheap phenolic mold. Since the process is practically equivalent to the sand-casting of metals, complex parts can be economically manufactured even in the relatively small quantities required for *L3* production. Where necessary to assure accurate location or orientation of parts, the cast resin frameworks are milled or spot-faced. The structure used in the input interstage, shown in Fig. 5, is an example. Circuit elements are wired to pins driven into the casting or, in some cases, to wires imbedded in the material. All wiring can thus be made direct with a minimum of bending and no doubling back, resulting in a reproducible and uniform product.

The entire ampifier is housed in a sealed die-cast container to protect the components from humidity damage. Dessicant is enclosed in each amplifier. It would have been desirable to make this housing of aluminum, but the high melting point of this metal makes it impractical for such a large casting to meet the air-tightness requirement. A zinc-base die casting alloy was therefore used. Sealing is accomplished by rubber gaskets at all openings for connections, and at the joint between the two parts of the housing. The removable part of the casting which serves as a cover is made as large a part of the total housing as possible, in order to provide maximum accessibility for maintenance of the units mounted on the base. The entire housed unit is arranged to mount on a relay-rack mounted panel by means of slides which are self-locking. Signal and power connections are made by means of flexible cords which are available on the panel to plug into the unit after it is in place on the slides.

Vacuum Tubes

The tubes have been fully described in an earlier paper[3]; their characteristics are summarized in Table I. They are plugged into conventional sockets, and single rather than parallel tubes are used in each stage. These are departures from the practice of the *L1* coaxial system, in which two tubes in parallel were soldered in each stage. The use of sockets increases the parasitic capacities and reduces the obtainable feedback by 1 or 2 db, but it was felt that the resulting maintenance economy was worth this sacrifice. With single tubes, the failure of one tube results in a line failure and a

switch to the protection line. At first sight, it would appear that using parallel tubes in each stage should greatly decrease the probability of line failure. A study of *L1* experience, however, showed that most tube failures could either be forestalled by preventive maintenance, or else were of such a nature (for example, shorts within the tube) that the parallel tube would not afford protection against line failure. The reliability advantage of parallel tubes, then, turns out to be small; their use, on the other hand, increases the wiring complexity greatly when sockets are used. The small gain in reliability would not compensate for the degradation in performance caused by the complication of wiring and the resulting capacity penalties. The applied voltages and current drains are shown in Table II.

Heat Dissipation

In common with many modern designs with high-gain vacuum tubes, the problem of heat dissipation was acute in the *L3* amplifier. The amplifier is enclosed in a sealed housing of sufficient size to dissipate readily the heat generated. However, with the usual types of chassis and tube-shield construction, vacuum-tube envelope temperatures were so high that long tube life could not be assured. Consequently a new type of tube shield was developed. This shield is of heavy copper tubing equipped with internal helical springs mounted in such a manner that each turn of the spring makes contact with both the glass tube envelope and with the copper tube, as shown in Fig. 6. Thus, each turn of the spring provides two metallic heat conducting paths to carry away the heat from the tube envelope. A total of 480 conducting paths are provided for each of the large tubes used in the output amplifier by the use of these springs. Good contact is made between the copper tubes and the chassis, so that heat generated within the vacuum tube is efficiently conducted through metallic paths to the copper chassis of the amplifier. In order not to raise the temperature of the chassis and consequently the temperature of the circuit components, large ribs are provided in the housing, with which the chassis makes intimate contact. A continuous metallic conducting path is thus provided from vacuum tube envelope to amplifier housing. This design resulted in a temperature drop in the output amplifier tubes of about 70 degrees centigrade without any temperature rise in the chassis or circuit elements over that produced when ordinary types of shields were used. The smaller vacuum tubes in the input amplifier do not ordinarily run as hot as those in the output amplifier, and a temperature drop of only about 55 degrees centigrade was attained by these methods.

Coupling Networks

The input and output coupling networks are essentially identical. The low side of each transformer is a balanced center-tapped winding which, together with the balancing network, acts as a hybrid, to produce a good 75-ohm impedance facing the cable. The use of this type of connection gives a signal-to-noise advantage over the use of a brute-force high-side terminating network. The advantage is theoretically 3 db in the case of the output coupling network, and would approach the same figure in the case of the input network if tube noise were dominant over the resistance noise of the cable.[4] Aside from the fact that the design of a high-side shunt termination network for an off-ground peaked transformer is well-nigh impossible, the use of a balancing network in a hybrid connection has the important additional advantage that the adjustment of this network to obtain a good reflection coefficient has negligible effect on the insertion gain of the circuit.

A relatively modest share of the total shaping required has been allocated to the coupling networks: 5.5 db each, or 11 db total. One reason for this is that although these networks are outside the feedback loops in the usual sense, nevertheless the impedances which they present to the amplifiers are important factors in the feedback design, and the effects which they produce must not be allowed to become so severe as to limit the feedback to too low a value. It is obvious from inspection of Fig. 1 that only a part of the voltage developed across the input beta circuit by the plate current of the second tube will appear as a grid-cathode voltage to drive the first stage. The proportion of the beta circuit voltage which will be thus effective in producing feedback around the loop will be dependent on the potentiometer division between the impedance of the coupling network and the grid-cathode impedance of the first tube. The greater the peaking of the input coupling network, the greater its impedance at high frequencies, where the grid-cathode capacitive impedance is already decreasing, and hence the greater the potentiometer term loss. A similar loss occurs in the output amplifier. The plate current of the output stage divides between the output coupling network and the parasitic admittances to ground. The portion of the plate current which returns directly to cathode (ground) through the latter path, without passing through the beta circuit, is not effective in producing loop feedback.

A second, and even more important, limitation is that the sensitivity of the insertion gain to variations in the cou-

Table II. Power Requirements of Amplifier Unit

+315 volts	41 milliamperes

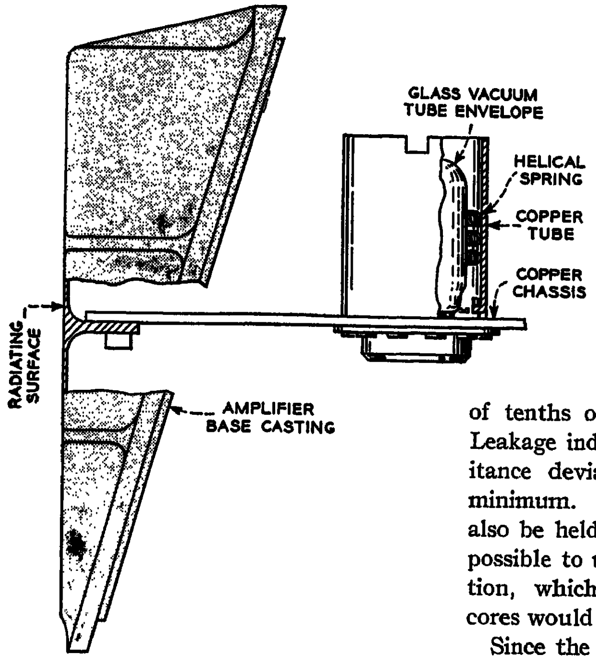

Fig. 6. Tube shield, for heat conduction

pling-network elements is increased as the slope is increased. The same considerations lead us to keep not only the slope but also the gain level or efficiency of these networks relatively low. The maximum-possible coupling network gain which can be obtained over the entire frequency spectrum is limited by the capacity across the circuit, as shown by Bode's resistance integral theorem. This capacitance cannot be reduced without incurring a more severe potentiometer term penalty and thus limiting feedback, so the total gain area cannot be profitably increased. The in-band gain can be made greater or less, as we concentrate more or less of the total gain area in the transmitted band, but it is found that attempting to get high values of in-band gain area leads to networks which are increasingly sensitive to element deviations. A resistance area efficiency of about 50 per cent turns out to be the most acceptable compromise.

In spite of these steps, the coupling networks are the most important source of manufacturing deviations, but by improved mechanical design and the use of quality control, these effects have been reduced by an order of magnitude as compared to previous designs. For example, the end capacitance of each coupling network is a quartz-disc capacitor, and the peaking or splitting coils are tension-wound on ceramic forms to give inductances of 1 per cent tolerance with distribution requirements within this range. The windings of the transformers, shown in Fig. 7, are made by plating the turns on threaded forms machined from optical-grade quartz or Vycor glass, to tolerances of tenths of a thousandth of an inch. Leakage inductance and parasitic capacitance deviations are thus held to a minimum. Split ferrite cores, which must also be held to close tolerances, make it possible to use these methods of fabrication, which previously available tape cores would not have permitted.

Since the amplifier configuration gives series feedback on the tubes adjacent to the cable, and cathode feedback on the tubes adjacent to the regulating network, the high-impedance winding of each coupling network is necessarily off-ground. This leads to considerable difficulty in specifying the equivalent circuit. For an on-ground coupling network, the equivalent circuit of Fig. 8(B) would be adequate for gain and feedback computations—essentially a reactive equalizer plus an ideal transformer. Even then, the capacities and inductances associated with the transformer itself would have to be given as functions of frequency because of the distributed nature of the device. When, however, the high-impedance winding is raised above ground potential by the voltage developed across the beta circuit, which is nearly the same magnitude as the voltage across the coupling network, the effects of distributed parasitic capacitances to ground, and the lumped capacitance from the junction of transformer and peaking coil, become of prime importance. The coupling network, therefore, cannot be adequately represented by merely lifting the circuit of Fig. 8(B) off-ground.

In order correctly to understand and compute the amplifier gain, it was necessary to develop a complex mathematical analysis of the distributed structure of the transformer, in conjunction with an extended program of precise measurement of the transformer constants. Even then, one must be content with an accuracy of a few tenths of a decibel and a few degrees of phase, as compared with the order-of-magnitude better accuracy which can be obtained for a 2-terminal lumped-constant network. The agreement between measurement and computation of amplifier gain and reflection coefficient is sufficiently good, however, to assure that all the important effects are sufficiently understood to make intelligent control possible.

Using the results of this analysis, the off-ground coupling network can be represented by the equivalent circuit of Fig. 8(C), where the values of the pi of admittances are obtained in terms of the fundamental parameters of the transformer and associated elements. This representation is convenient for insertion gain and feedback computations. The most important difference between the equivalent circuits of Figs. 8(B) and 8(C), from a practical standpoint, is the presence in the latter of the admittance Y_{1CN}, which is a manifestation of the capacitance to ground from the high impedance winding and the junction of transformer and peaking coil. I_2 and the contributions to Y_{2CN} not directly attributable to the obvious shield-to-shield capacity of the transformer can be set equal to zero with little error, but Y_{1CN} affects the insertion gain and feedback by about 2 db.

It will be observed that the transformer is shown with two shields, one connected to the bottom of the high-impedance winding, which is the top of the beta circuit; the other connected to ground. The first of these, which is physically adjacent to the high-impedance winding, acts to collect, and carry to the beta circuit, the distributed capacitance of the high winding, thus avoiding intolerably large capacitance from this winding to ground. The second shield prevents capacitative coupling of the large beta-circuit signal voltage to the low-impedance winding, which would lead to a very poor reflection-coefficient performance. Typical curves of the reflection coefficient are shown in Fig. 9. Since the amplifier is an active device, the reflection coefficient is to some extent a function of the vacuum-tube transconductances, and tends to be degraded as tubes age.

Amplifier Equations

Using the equivalent circuit of the coupling network shown in Fig. 8(C), the circuit of the input amplifier can be represented as in Fig. 10, and the equations shown can be derived from straight forward nodal analysis of the circuit. Similar equations can be derived for the more complicated output amplifier. From these, using Thevenin's theorem, the gain of the tandem combination can be computed, as well as the feedbacks on the various tubes.

Similarly the input amplifier can be replaced, for convenience in reflection-coefficient calculations, by the pi of admittances and the driving current of Fig. 10(B). The equations of Fig. 10(B) expressed in terms of the cofactors of the circuit determinant are of general application for the reduction of a multinode circuit to simpler form.

Regulating Network

Like the coupling networks, the regulating network between the amplifiers is outside the feedback loops, and the gain of the amplifier is very nearly a direct function of the impedance seen looking into the network. This impedance is controlled by a single variable resistance—the thermistor—which is directly heated by the d-c output current of the regulator. The output of the regulator, in turn, is a function of the magnitude of main pilot level at the output of the amplifier. The whole forms an automatic-volume-control circuit, which acts to keep the level of the main pilot constant at amplifier output, under the assumption that any changes in this pilot level are caused by line temperature or length deviations. The invariant arms of the regulating network are designed to give the accurate shaping of network impedance versus frequency required so that the amplifier gain change will have the wanted square-root of frequency shape. The design of the network is fundamentally based on the variable-equalizer theory developed by H. W. Bode,[5] but the process of finding physical networks which will give the desired performance to a very high order of accuracy makes use of newer methods developed by S. Darlington.[6,7] Since these methods were also used in the design of several other amplifier networks, and because the precision thus made possible is essential to the system, a brief recapitulation of the steps involved is of interest.

Fig. 11 shows the basic configuration of the regulating network. It was selected because it is one of the simplest that gives symmetrical gain changes controlled by a single resistor. It is also capable of absorbing the parasitic interamplifier capacitance, and gives some advantageous gain shaping at normal setting, although this shaping is not under design control.

We need to find the impedance of the two arms Z_1 and Z_2 that will give the required square-root of frequency shape of gain change (with a value of 6 db at 8 megacycles) as the thermistor is varied by a factor of three. For this circuit, the change in gain may be expressed as a ratio of two impedances

$$\epsilon^{\alpha+j\beta}=\frac{Z_H}{Z_N}=\frac{\dfrac{1}{Z_1}+\dfrac{1}{Z_2+R}}{\dfrac{1}{Z_1}+\dfrac{1}{Z_2+kR}}=F(p)\qquad(1)$$

$$\epsilon^{-\alpha-j\beta}=\frac{Z_L}{Z_N}=\frac{\dfrac{1}{Z_1}+\dfrac{1}{Z_2+R}}{\dfrac{1}{Z_1}+\dfrac{1}{Z_2+\dfrac{R}{k}}}=\frac{1}{F(p)}\qquad(2)$$

where

Z_N = the imepdance looking into the network with a thermistor value R
Z_H = the impedance looking into the network with a thermistor value kR
Z_L = the impedance looking into the network with a thermistor value R/k
For this design, R = 500 ohms and k = 3

We may solve equations 1 and 2 and obtain expressions for Z_1 and Z_2. However, for synthesis Z_1 and Z_2 should be expressed in terms of singularities in the p-plane. This may be accomplished by approximating the wanted gain change with a Tchebycheff series, as developed by

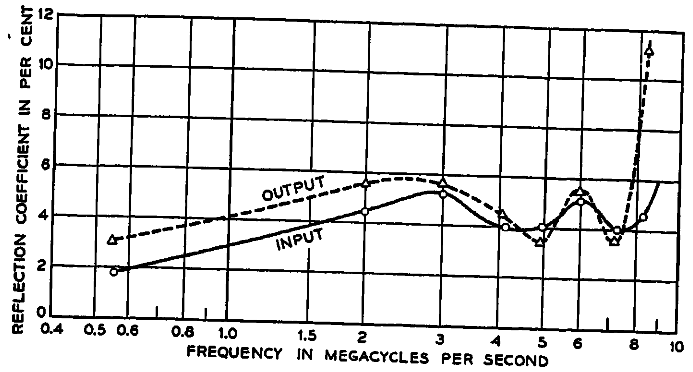

Fig. 9. Reflection coefficient performance

S. Darlington.[7] The steps in the process are:

1. The coefficients of a Tchebycheff series that matches the desired gain change over the frequency band of interest are found

$$\alpha = C_0 + C_2\cos 2\phi + C_4\cos 4\phi \ldots C_{2n}\cos 2n\phi \quad (3)$$

where the relation between ω and ϕ is given by the band-pass transformation

$$\omega^2 = K\frac{k_1+\sin^2\phi}{k_2-\sin^2\phi}$$

$$K = \omega_{c1}\omega_{c2}$$

$\omega_{c1} = K\frac{k_1}{k_2}$ = lower cutoff frequency, 0.2 megacycle

$\omega_{c2} = K\frac{k_1+1}{k_2-1}$ = upper cutoff frequency, 8.35 megacycles

and

$$C_{2k} = \frac{2}{n+1}\sum_{r=1}^{r=n+1} \alpha_r \cos 2k\phi_r \qquad \begin{array}{l} k=1,2\ldots n \\ r=1,2\ldots n+1 \\ \text{(Match points)} \end{array}$$

$$\phi_r = \frac{(2r-1)}{(2r+1)}\frac{\pi}{2}, \quad \alpha_r = \text{gain at } \phi_r$$

2. The coefficients of a related power series are determined

$$\epsilon^{2\alpha} = 1 + A_2Z^2 + A_4Z^4 + \ldots A_{2n}Z^{2n} \equiv F(Z^2) \quad (4)$$

where

$$A_2 + S_2 = 0 \quad \text{and} \quad S_{2k} = kC_{2k}$$
$$2A_4 + A_2S_2 + S_4 = 0$$
$$nA_{2n} + A_{2n-2} + \ldots = 0$$

3. $F(Z^2)$ is expressed as a rational fraction containing both natural modes and infinite loss points

$$F(Z^2) = \frac{N(Z^2)}{D(Z^2)} \quad (5)$$

where the coefficients of N and D may be found from the continued fraction expansion of $F(Z^2)$. The degree of N and D fixed by the allowable approximation error and the complexity of the network.

4. The roots of N and D (in terms of Z^2) are found and then transformed to the p-plane using the transformation

$$E_4 = E_{0c}\left[\theta i\frac{Y_2}{Y_4}\frac{B-D\frac{\sigma_4}{Y_2}-E\frac{\sigma_1}{Y_2}-\frac{\sigma_1}{Y_2}\frac{\sigma_4}{Y_2'}}{1+B+D+E} + KiY_{c1}\frac{1}{Y_4}\frac{B+E+\frac{\sigma_4}{Y_2'}}{1+B+D+E}\right]$$

B. Equivalent circuit of input amplifier as seen by coupling network

$$Y_g = \frac{\Delta_{22}-\Delta_{21}}{\Delta_{12-12}} = Y_1 \qquad Y_{\beta 1} = \frac{\Delta_{11}-\Delta_{21}}{\Delta_{12-12}} = Y_2 + \sigma_3 + \sigma_4 + P_3S_2P_4$$

$$Y_{g\beta} = \frac{\Delta_{21}}{\Delta_{12-12}} = Y_{12} \qquad Y_y = \frac{\Delta_{12}-\Delta_{2i}}{\Delta_{12-12}} = -\left[P_{32}S_1 + \frac{S_1S_2}{Y_{33}}P_4\right]$$

where the cofactor Δ_{12-12} is found by striking out the first and second row and first and second column of the circuit determinant, the sign following the usual rules for the sign of a cofactor

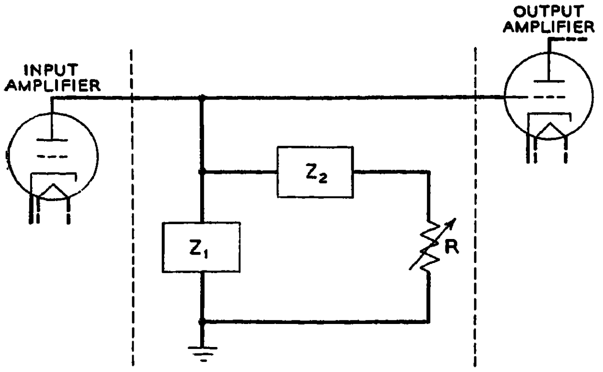

Fig. 11. Regulating-network block schematic

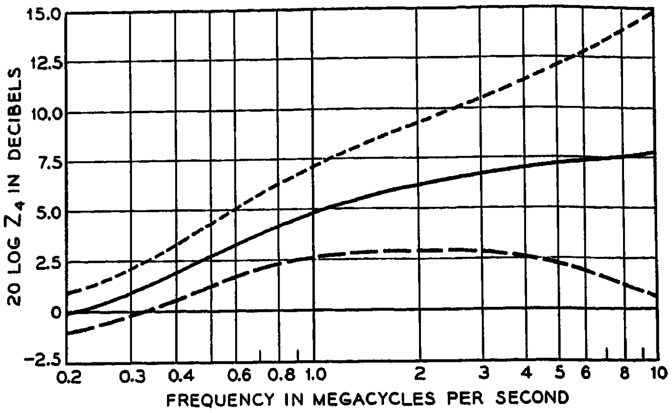

Fig. 12. Regulating-network gain versus frequency—for extreme and mid-range thermal settings

$$p^2\sigma = K - \frac{2K(k_1+k_2)}{\psi + 2k_2 - 1}$$

where

$$\psi = \frac{1+Z^4}{2Z^2} \tag{6}$$

These four steps result in a polynomial $F(p)$ satisfying the requirements on the change in gain. In this specific case

$$F(p) = \frac{1.06(p+0.0960)(p+0.0280)\,(p+0.9890)(p+0.2890)}{(p+0.1058)(p+1.803)\,(p+0.0300)(p+0.3492)} \cong \epsilon^{\alpha+j\beta} \tag{7}$$

Solving equations 1 and 2 obtain

$$Z_2 = \frac{k-F}{kF-1}R, \qquad Z_1 = \frac{(k^2-1)(F^2-1)}{(kF-1)(k-F)} \tag{8}$$

where

$$F(p) \equiv F$$

Since the design must absorb the interstage capacitances (and also the stray capacitances of some of the elements in the physical network), Z_1 must include a shunt capacitor. It can be shown that the desired result is obtained when

$$F \rightarrow 1 + g\frac{1}{p} \text{ as } p \rightarrow \infty \tag{9}$$

Since the derived transmission function F, equation 7, does not satisfy the condition expressed by equation 9, the function must be modified in order to provide a shunt capacitor in Z_1. To accomplish this we use equation 5 expressed as a bilinear form of the nth term of the continued fraction expansion.

$$F(Z^2) = \frac{N_1(Z^2) + K_n N_2(Z^2)}{D_1(Z^2) + K_n D_2(N^2)} \tag{10}$$

The coefficient K_n is modified so that the new $F(p)$ satisfies equation 9. The modification of K_n does not substantially alter the required in-band transmission and also does not produce nonphysical singularities. The new F obtained is

$$F(p) = \frac{(p+0.0289)(p+0.1018)(p+0.3431)\,(p+1.017 \pm j1.628)}{(p+0.0310)(p+0.1132)(p+0.4426)\,(p+0.6158 \pm j1.368)} \tag{11}$$

By using this result in equation 8 expressions for Z_1 and Z_2 were obtained from which the configuration shown in Fig. 11 was synthesized.

Fig. 12 shows the voltage which would be developed across the regulating network versus frequency in response to a constant current driving force, for the midrange and extreme values of thermistor resistance. The slope across the band for the midrange value is 7.5 db; this is the regulating network contribution to the total slope of 37 db required of the complete amplifier.

To the extent that the differences between the curves of Fig. 12 fail to exactly match the desired square-root of frequency characteristic, the action of the regulating network will introduce an equalization error. This regulation error is shown in Fig. 13. It amounts to a few hundredths of a decibel for a 6-db gain change, caused in part by network design imperfections and in part by the fact that very small second-order effects result in the amplifier gain not exactly following the regulating-network impedance.

Beta Circuits

Starting from our basic requirement that a slope of 37 db across the transmitted band must be obtained, and noting that the total of the contributions from the coupling networks and regulating network is 16 db, we are left with about 20 db of shaping to be supplied by the beta circuits. The input beta circuit has been designed to supply most of this remainder, the contributions of the output beta circuit and the $\mu\beta/1-\mu\beta$ effects in amplifiers being only 3 db. The original design procedure for this network was basically the same as for the regulating network, but the final values of the elements represent a long process of incorporating secondary corrections as our knowledge of the amplifier grew. Original constraints included the necessity of including as part of the beta circuit not only the relatively large parasitic capacitance of the amplifier and the coupling network shield to shield capacitance, but also the screen resistor and by-pass capacitor of the second tube, which, as usual, is by-passed not to ground but to cathode, so that modulation product components of the screen current will not be introduced into the signal path via the beta circuit. It is also required that the beta circuit have the correct d-c resistance to serve as the cathode-bias resistor of the second tube, and that it incorporate provision for metering this bias through suitable decoupling elements, which are among the gain-determining elements of the network. Finally, this network was used as the mop-up equalization network of the amplifier, and its element values were readjusted to give the correct amplifier gain after the performance of a representative group of amplifiers with average coupling networks and tubes had been determined. In doing this tailoring, it is necessary to precorrect for the effects of noninfinite feedback, since the gain of the amplifier is not exactly a direct function of the beta-circuit admittance. The configuration of the input beta circuit is shown by Fig. 14; it is a simple 2-terminal network. Its in-band impedance varies from about 1,000 ohms at 300 kc to 110 ohms at 8.35 mc.

The output beta circuit is relatively flat, which in this case is the optimum condition for signal-to-noise and feedback-loop stability considerations. Because of this simplicity, it is possible to incorporate in this network provision for adjusting the gain of the amplifier, to reduce the misalignment of the system.

Misalignment Adjustment

We can distinguish three major effects which will contribute to misalignment

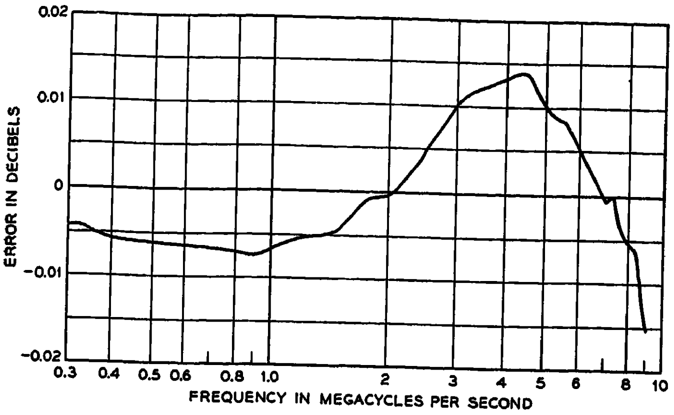

Fig. 13. Regulation error per 1-db regulation

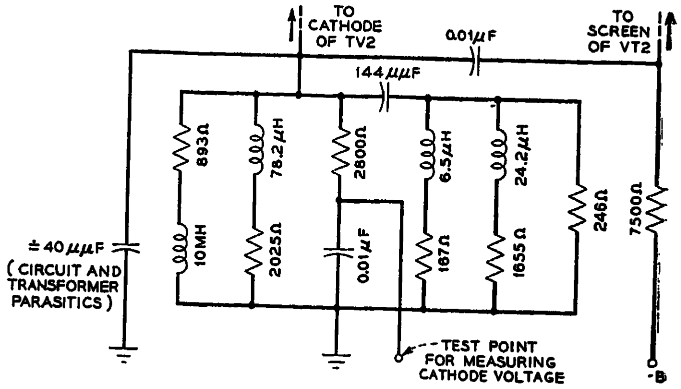

Fig. 14. Input beta circuit

and consequent degradation of system signal-to-noise ratio:

1. Design error—the degree to which the design gain of the amplifier, because of the finite number of elements and other limitations, fails to match the line loss.
2. The cumulative effect in the individual amplifier of manufacturing deviations of the elements.
3. The aging of the components of the amplifier, of which the tube aging will, of course, be the dominant short-term effect.

The signal-to-noise performance of the system can be improved by reducing the misalignment, if this is done without resorting to measures which would introduce systematic instead of random gain deviations.

If we study the shapes of gain change introduced by the more important deviation contributors, particularly the element variations, we find, as might be expected, that in general the effects are small at low frequencies and increase sharply near the upper edge of the band, if the thermistor is held constant. In the system, the regulation around the main pilot will automatically act to reduce the deviation at 7 megacycles to zero, adding a square root of frequency curve that results in a bow-shaped deviation, as illustrated by Fig. 15. Examining the signal-to-noise effects of the degradation caused by misalignment, we conclude that it is most desirable to reduce as much as possible the misalignment at 4 megacycles, the television carrier frequency in the combined system. The output beta circuit has, therefore, been designed to give varying amounts of this shape, the total range being ±0.6 db at 4 megacycles, in 0.2-db steps. The successive steps of this gain adjustment are simple multiples of each other, symmetrical in the two directions of adjustment, so that we put into the system a single systematic shape, which will be small in magnitude at the equalizing points because the different settings of this control in successive line repeaters will tend to cancel out. This setting of output beta circuit gain is controlled by a *GAIN ADJ* switch, accessible from outside the amplifier housing. The adjustment will be made on an in-service basis as part of normal maintenance procedures, using the level at each repeater of one of the system pilot frequencies, 3,096 kc, as the index of proper setting.

Manufacturing Testing

As mentioned above, the mechanical design of the amplifier has been planned to permit the separate testing of the five gain-determining networks, the tuned interstage of the input amplifier, and the separate input and output amplifiers, before their assembly with the regulating network to form complete amplifiers. Variations in environment are minimized by the use of jigs which also make it unnecessary, in general, to solder to the network under test. Visual gain sets which cover the transmitted band and are accurate to 0.02 or 0.03 db are used. The component network or component amplifier under test is connected in series with a complementary or equalizing network, to obtain a flat transmission characteristic which can be accurately compared to the transmission of standard attenuators. The completely assembled amplifiers are similarly tested. Quality-control charts of the resulting measurements on all components are useful in detecting shifts in transmission which might be caused by loss of control in element manufacture or by shifts of element values caused by subsequent damage in handling.

D-C Feedback

In addition to the loop feedback at signal frequencies, local d-c feedback is used on each stage. The grid of each tube is returned to a +9-volt potential rather than to ground, and about +10 volts is developed across each cathode resistor. The usual stabilizing effects of self-bias are thus obtained in exaggerated degree, each tube having about 20 db of local d-c feedback. Care must then be taken to select the cathode by-pass and interstage coupling condensers so that the transition from low-frequency local feedback to in-band loop feedback is accomplished smoothly, without the instability which might be caused by a balancing out of these two feedbacks in the transition region.

For maintenance measurements, the 9-volt bias potential and the d-c cathode voltage of each tube are brought out to a multipin amplifier test jack through appropriate decoupling filters. Thus, the bias on each stage can be measured on an in-service basis. Filament-voltage dropping resistors which can be switched in or out of circuit are provided on the repeater panel, so that bias can also be observed for a filament supply voltage 10 per cent below normal. The activity or change in plate current with filament voltage thus measured, or the history of the bias at normal filament voltage, will be used to

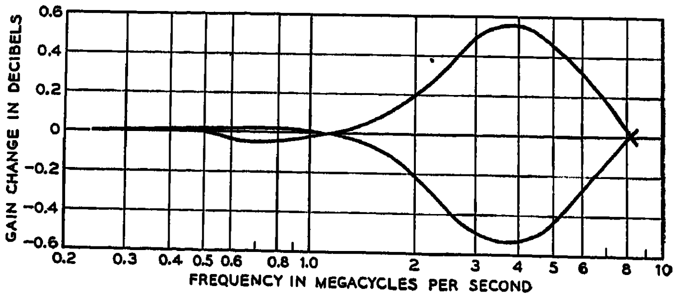

Fig. 15. Misalignment adjustment

determine when amplifiers should be taken out of service for tube replacement.

The upper triode is, of course, a special case: since it is the plate-supply path for the lower triode, its cathode is about 160 volts above ground and its grid is returned to a similarly high potential. About 35 db of d-c feedback is obtained on this stage; the same provisions for measurement of bias and activity are made. To avoid excessive filament to cathode voltage, a separate filament winding, which floats at the +190-volt supply potential, is used for this tube.

Loop Feedback

The design of the feedback loops of the input amplifier follows conventional practice. The constraints which operate to limit the amount of feedback which can be obtained in the transmitted band are well known.[8] Broadly speaking, the figure-of-merit of the vacuum tubes and the circuit capacitances determine the asymptotic cutoff, which in any feedback amplifier limits the magnitude of the feedback which can be built up in the band. In multiloop structures, there are additional limitations. Consider, for example the formula given in Fig. 10(A) for the feedback on the second tube. If we increase without limit the magnitude of the first tube transconductance, we find that the feedback on the second tube approaches the value $S_1P_4Z_{32}$. This is a limit, common to multiloop structures, over and above the usual limit imposed by the Nyquist stability criterion. A similar *SPZ* limit can be derived for the feedback on each stage. The same multiloop mechanisms which operate to limit the feedback also result in making the feedback on any given stage relatively insensitive to variations in other transconductances or impedances. In a single-loop circuit, a 1-db change in beta-circuit impedance or first-stage transconductance causes a 1-db change in the feedback on every tube. In the multiloop case, the feedback on, say, the second stage would generally change only 1/2 db at most frequencies. While this is an advantage, in the sense that transconductance decay does not decrease feedback as rapidly as it would in a single-loop amplifier, it is a disadvantage in that it militates against improving stability margins by shaping the out-band impedance of the beta circuit.

The capacitance distributions within the input and output amplifiers are such that while the *SPZ* limitations on feedback are closely approached, the most stringent limitation on the feedback obtained is the Nyquist criterion. The use of the Nyquist criterion, particularly with respect to defining the margins against singing, is likewise complicated by the multiloop nature of the circuit. Ignoring some very recent work, the implications of which have not been fully explored at this writing, it can be said of a multiloop structure that the apparent margins against singing shown by any plot of feedback give no certain information as to how safe from singing the circuit is. The phase, as well as the magnitude, of the feedback on each stage is a function of the magnitude of the other transconductances and either decay or increase of these transconductances might destroy the phase margin. In these circumstances, it is theoretically necessary to examine for stability every conceivable combination of transconductances. A more practical expedient, of course, is to rely on judgment, backed by computation and laboratory experiment on the circuit for a wide, but far from infinite,. number of circuit conditions.

Another difficulty arises from the fact that the feedback on each tube is different, so that gain and phase margins obtained for one return ratio do not imply equal gain and phase margins for the return ratio on some other tube of the same amplifier. It does not follow, however, that it is necessary to investigate separately the margins on each stage versus circuit element variations. The point to be stressed here is that we are using the behaviour of the return ratio merely as an index of our real concern: the position on the p-plane of zeros of the determinant of the circuit, and the determinant is the same for both stages. Rather than asking how many decibels of gain margin and how many degrees of phase margin any particular return ratio displays, we ought instead to inquire how quickly the apparent margins disappear as we change transconductances and network impedances. The margins on all the return ratios will vanish simultaneously, regardless of the apparent difference in original margin magnitudes. It is therefore satisfactory to examine the behaviour of whichever return ratio is most easily observed.

The choices made in the course of designing the coupling network also affect the magnitude and shape of the feedback which can be obtained: as mentioned above, the relative magnitude of the impedance seen looking into the coupling network and the impedance from first tube grid to ground determines how much of the voltage developed across the beta circuit will reach the first stage as a driving force.

Study of the modulation products which will arise in system operation, both for the all-telephone case and for the combined telephone-television signal, led to the conclusion that optimum shaping of the feedback for the *L3* system would be to maximize the feedback at low frequencies, in order to suppress intermodulation products falling in that part of the spectrum in the combined telephone-television case. Shaped feedback, falling off at the higher frequencies, is also consistent with obtaining a smooth and simple shape of gain-change as tubes age (known as "mu-beta effect"), which is desirable from the equalization standpoint. With these considerations in mind, the interstage of the input amplifier has been peaked well above the transmitted band (at 11 megacycles) to partially compensate for the input potentiometer term, and to help in achieving this smooth shape of mu-beta effect. If flat feedback over the band were the objective, it would also be necessary to design the grid-cathode admittance of the second tube so that the parasitic grid-cathode capacity would be absorbed in a flat impedance versus frequency, but in this case the desired shaping of the second-tube feedback is attained by taking advantage of the way in which the grid-cathode capacitance naturally limits the high-frequency feedback on this stage.

The loop feedback in the output amplifier is similarly shaped, for the same modulation and equalization reasons. The use of the double-triode circuit in this amplifier is an unusual feature. This connection of two triodes, sometimes referred to as the "cascode circuit," has appeared in many contexts in recent years, usually to serve some other purpose than here. It serves as a superior output stage in the *L3* amplifier largely because the effective transconductance which can be obtained is about 3-db higher than that of a pentode of the same grid-cathode spacing. The effective transconductance, ignoring for the moment the division of output current between the load impedance and the internal plate impedance of the upper triode, is very nearly the transconductance of the lower triode. Since no current is lost to a screen, this is higher than that of a pentode of the same spacing. The output impedance of the upper triode is multiplied by the local feedback consequent on its cathode being off ground by the plate impedance of the lower triode. Since the load presented to the lower triode is a low impedance, approaching the reciprocal of the transconductance of the upper triode, the grid-plate capacitance of the lower triode is not enhanced by feedback. The higher value of transconductance means less grid drive for the same output current, and more obtainable feedback; both contributing to superior modulation performance.

The modulation of the upper triode, and the changes in transconductance of this tube, are suppressed by approximately the sum, in decibels, of the local and loop feedback. In consequence, the modulation and mu-beta effect contributions of this tube to the complete amplifier are negligibly small.

It will be observed that the grid of the upper triode is not connected to ground, but to the top of the beta circuit. In consequence, the grid-plate capacitance of the upper triode appears as part of the end capacitance of the coupling network, rather than as a parasitic capacity to ground. This results in a gentle potentiometer term in the output amplifier. This connection, however, also has the effect of vitiating to some extent the desirable qualities of the circuit, particularly at the higher frequencies, where the grid-cathode capacitance of the upper triode becomes important.

Because of this gentle output-potentiometer term, it is not necessary to tune the interstage of the output amplifier, which consists simply of the circuit capacitance plus a network which has the characteristics of a 10-micromicrofarad capacitance in the transmitted band. Above the band, this network shapes the gain and phase characteristics of the feedback loop to obtain the desired stability margins. The incorporation of this network reduces the in-band feedback by about 3 db, a sacrifice which unfortunately is necessary to assure stability when the thermistor in the regulating network is at its minimum value. For this value of thermistor, the phase and magnitude relations of the regulating-network impedance and the grid to cathode capacitance of *VT3* produce a potentiometer term in the feedback loop which appreciably reduces the margins around 30 megacycles. The stability margins for the midrange value of thermistor would be satisfactory without this sacrifice of in-band feedback. When the thermistor is at maximum resistance, some degradation of phase margin at 10 megacycles occurs, again because of the potentiometer term effect mentioned in the foregoing, but in this case the remaining margin is sufficient, since the circuit elements are still under good control at this frequency. Because the plate-cathode impedance of *VT2* is very high, the similar potentiometer term at the output of the input amplifier causes only negligible changes in input amplifier stability margins as the thermistor changes.

In the 70-megacycle region, there are two almost equally important feedback loops in the output amplifier—one through the transconductance of the lower triode; the other through the grid-plate capacitance of this tube. Balances between these feedback paths are observed in the 70 to 100-megacycle region in the course of measuring the feedback, sometimes accompanied by 180-degree shifts in the phase of the loop transmission at frequencies above the balance point, an effect which theoretically depends on just how the two vectors go through the balance point. The occurrence of these balances is accompanied by a few degrees loss of phase margin in the 30-megacycle cutoff region, which must also be allowed for in setting the 30-megacycle stability margins, since sufficient control of parasitics to prevent these 70-megacycle effects is out of the question.

Parasitic resonances between the lead inductances and the capacitances of the circuit, which tend to cause instabilities in the very-high-frequency region about 200 megacycles are damped by small resistors in the leads, and the lead inductances are kept small by careful mechanical design. In this frequency region, neither measurement nor computation of stability margins can be trusted as anything but a rough guide. On the other hand, adding damping resistors in grid leads and other critical points to prevent 200-megacycle sings causes a phase margin penalty in the 30-megacycle region, so a nice judgment of how much damping to add is called for. Final values of damping were chosen so that typical amplifiers could not be made to sing by increasing critical lead lengths, or by substantial increases in parasitic capacity, thus assuring that manufacturing variations of elements and wiring will not cause high-frequency sings. The return ratio of *VT4* is shown on Fig. 16, the mu-beta effects of both amplifiers on Fig. 17.

Signal Levels, Modulation, and Noise

Fig. 18 shows the signal levels within the amplifier in decibels relative to one volt from grid to cathode of *VT4*, which is a convenient point to use as a reference for system signal-to-noise studies. It will be noted that as a result of using the input beta circuit to give so much of the shaping of amplifier gain, the input ampli-

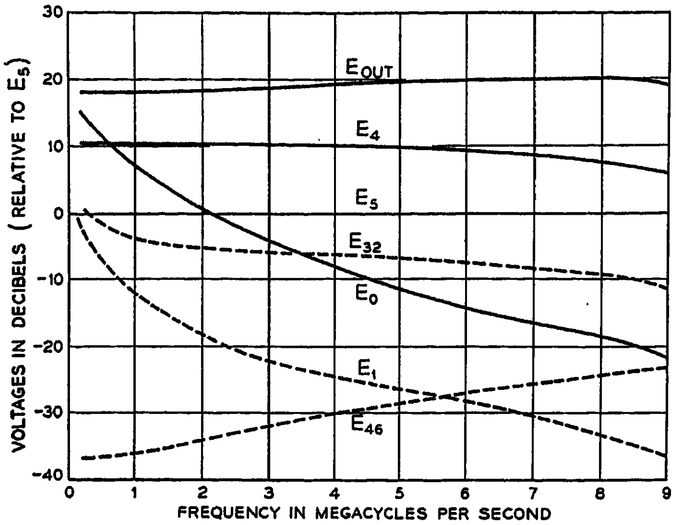

Fig. 18. Signal levels within amplifier

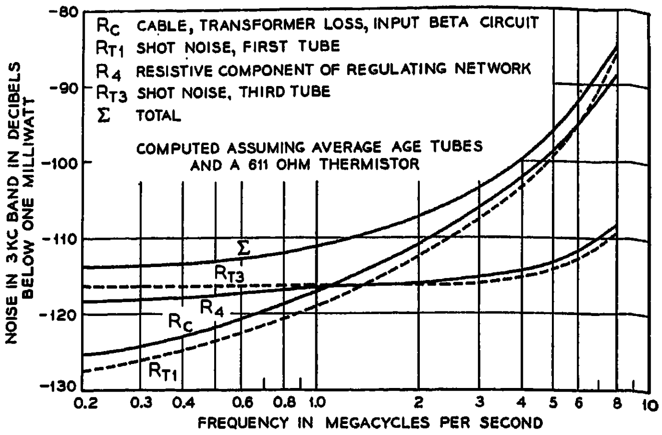

Fig. 19. Thermal noise at line amplifier output

fier has little gain at low frequencies. In consequence, the input tube of the output amplifier and the regulating network are important thermal-noise sources at low frequencies. The relative magnitudes of the noise sources are shown on Fig. 19, which gives the noise at amplifier output as a function of frequency.

Comparison of the grid to cathode voltages of *VT2* and *VT4* shows that the former will be an important modulation contributor, since the driving force on these tubes is nearly equal, particularly at low frequencies. Typical amplifier modulation values are given in Table III. Computations using the measured feedback and the performance of single tubes without feedback check the measured values of amplifier modulation to within a couple of decibels if the third-order coefficient of the tube is corrected to take account of the fact that some third-order modulation is generated by the interaction of the fundamentals and the feedback second-order products. In general, the effective third-order coefficient of the tubes is approximately equal to the voltage sum of the tube's uncorrected third-order coefficient and a coefficient 6-db worse than the square of the tube's second-order coefficient. If this interaction correction is not taken into account, the correlation of tube modulation, feedback and amplifier modulation is unsatisfactory. The analysis leading to this result, which is due to F. B. Llewellyn, S. E. Miller, and R. W. Ketchledge, is too long to give here.

Load-Carrying Capacity

The load-carrying capacity of an amplifier is difficult to define with exactness. One possible definition is the load at which the modulation coefficients of the amplifier have departed appreciably from the small-signal power-series values because of loss of feedback, as the transconductance is cut off during part of the cycle. The signal carried without serious overload, in terms of a single frequency, is practically constant in the transmitted band, as a consequence of the fact that the output voltage and the lower-triode grid voltage have nearly the same shape versus frequency characteristic, as shown in Fig. 18. The output coupling-network shaping approximately compensates for the potentiometer term division of current between the load impedance and parasitic paths to ground. Departure from the small-signal power-series behaviour just begins to be appreciable at +14 decibels referred to 1 milliwatt (dbm) of any single frequency. At +18 dbm, the d-c effects of overload show up as slight changes in the transmission of the pilot frequencies. At +26 dbm, the second-order modulation is 3 db, and the third-order modulation is 6 db, higher per line amplifier than would be predicted from small-signal behaviour.

Table III. Modulation Products, in Decibels Below 1 Milliwatt at Amplifier Output, for Fundamentals 5 Decibels Above 1 Milliwatt at Amplifier Output

Type	Fundamental, Megacycles	Product, Megacycles	Product, Decibels Below 1 Milliwatt
2F	0.5	1.0	72
	1.0	2.0	65
	3.0	6.0	55
	4.0	8.0	51.5
3F	0.25	0.75	95
	0.667	2.0	97
	2.0	6.0	87.5
	2.66	8.0	81.5

Flat Amplifier

The flat-gain amplifier, which is used as a transmitting amplifier, and to make up for equalizer loss at various points in the system, is basically the same as the line amplifier, with only the obviously necessary modifications. The input beta circuit is nearly flat, the regulating network has been replaced by a fixed-gain network (which contains a single variable element whose adjustment at the factory compensates to some extent for variations in the coupling networks), and the input coupling network has been modified so that the peaking used in the line amplifier is replaced by a drop in the high-frequency gain of this network. The output beta circuit has been modified to give flat gain control of ±1.0 db in 0.2-db steps. The interstage designs are changed to readjust the feedback so that the modulation suppression and the change in gain as tubes age will be nearly the same as in the line amplifier. Somewhat more feedback is obtained in the output amplifier, since no network is necessary in the output-amplifier interstage to adjust the 30-megacycle phase for an unfavorable regulating network setting.

The nominal gain of the flat gain amplifier has been set at 34 db, and is flat to within ±0.2 db over the transmitted band. The amplifier circuit capacities are low enough so that the interamplifier network could be built to give considerably more gain than this; the limit has been set so that flat-gain amplifier noise contributions to the complete system noise will not exceed about 1.0 db at the television carrier.

Co-ordination of M1 and N1 Telephone Carrier Systems

Synopsis: The Bell System's new *N1* carrier system is a low-energy cable carrier system and is subject to interference from existing carriers with overlapping frequencies and higher energy levels. This paper is concerned with the development of a suppression device to prevent energy from the *M1* open-wire carrier system disturbing the channels of the *N1* system. The problem is complicated by the requirement that other types of open-wire carrier systems, notably the *01* system, must work through the suppression unit. Field tests of the suppression unit developed, consisting of a low-pass filter with mid-point grounded, indicate satisfactory transverse and longitudinal loss to the unwanted *M1* frequencies without degrading the performance of the line at frequencies below the *M1* band.

Newly developed methods of telephone transmission are not always completely different from existing techniques. This means that some engineering effort must be applied to co-ordinating the new methods with the old. In the case of the Bell System's new *N1* cable carrier system the co-ordination problems are considerable. The *N1* system frequency band overlaps those of the existing *K* cable carrier system, and the *J*, *M*, and *O* open-wire carrier systems. In addition to the frequency overlap, the systems operate at different levels, the *N1* having the lowest levels. Fig. 1 shows the frequency assignments of the various systems and indicates their relative transmitting levels.

Each of the conflicts among these systems presents its own peculiar problem. On some of the conflicts considerable work has been done, and much information is available. This paper treats only the problem of interference in *N1* systems caused by *M1* systems and the interrelated problem of operating *01* carrier on lines used for *M1* systems.

The M1 and N1 Conflict

The *M1* and *N1* systems are similar in that they are both double-side-band carrier-transmitted systems using different bands of frequencies for the two directions of transmission. The *N1* system frogs or interchanges the two frequency bands at each repeater. That is, if the high group of frequencies, as illustrated by Fig. 1, are received by the *N1* repeater, they are modulated by a group modulator with a frequency of 304 kc and transmitted to the next repeater as the low group. The high and low groups are kept separate at a repeater or terminal by a high low-pass filter which acts as a roofing filter for the low group. There is a pass-band filter at the input to the high-group repeater designed to suppress radio-frequency interference. However, the band-pass filter has little loss in the *M1* frequency range, being most effective above 500 kc. Under this arrangement, at the input to a high-group-to-low-group repeater, not only is there direct interference from the *M1* low-group frequencies, but in addition the *M1* high-group frequencies may be modulated by the 304 kc *N1* modulator and translated to frequencies within the *N1* band. Table I shows the *M1* carrier frequencies and the type of interference they produce in the *N1* channels.

Ordinarily at any one location there will be only one or two *M1* systems, but there may be 50 or more *N1* systems. Since each *M* channel can interfere with a channel in each *N* system, the interference must be controlled or there will be serious interference in many telephone facilities. The interference may be controlled by suppression, or the *M1* systems may be replaced with a new noninterfering type of system at appreciable economic penalty.

Suppression Required

As mentioned earlier, the *N1* system is a cable system and the *M1* an open-wire system. Where *M1* and *N1* high-group receive equipments were in the same office, experience indicated that even by maintaining good physical separation between the equipments, by using shielded wire for the carrier leads, and by providing separate cables for the *M1* and *N1* systems, there would still be excessive interference in the *N1* channels. The problem could be avoided by arranging the *N1* systems so that only low-group receive repeaters were located in offices containing *M1* equipments. However, the economics of additional *N1* repeaters, the problem of co-ordinating the direction of transmission of all the *N1* systems in an area, and the desirability of locating *N1* equipment in existing telephone buildings normally precludes the shifting of an *N1* repeater just to avoid conflict with a few *M1* channels. Where *N1* system layouts place *N1* high-group receive repeaters or terminals in the same location as existing *M1* equipment, approximately 125 decibels of loss is required between the *M1* carriers and the input to the *N1* equipment. The 125-decibel loss is based on the requirement that, to prevent excessive interference in an *N* channel, the level of an interfering tone should be 45 decibels below the level of the *N* channel carrier. Since the level of the *N* channel carrier at the input to a high-group repeater or terminal may be as low as 50 to 60 decibels below one milliwatt while the output level of the *M1* carrier is 25 decibels above one milliwatt, the required loss is 45+55+25, or about 125 decibels.

Paper 53-225, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 18, 1953; made available for printing May 1, 1953.

Nature and Estimated Loss of M to N Coupling Path

At these frequencies most of the coupling is on a longitudinal basis. The longitudinal component of the *M* energy couples through the telephone office wiring and onto the non-*N* pairs in the *N* cable where it crosstalks to the *N* pairs. On the *N* pairs the longitudinal *M* energy is converted to metallic *N* interference by the unbalances of the pairs. The longitudinal loss of the telephone office wiring is between 10 and 30 decibels. This, with a typical 10-decibel crosstalk coupling loss in the cable, and a longitudinal-to-metallic conversion loss of approximately 30 decibels, gives a total loss in the *M*-to-*N* coupling path of about 50 to 70 decibels. The loss in the coupling path is far short of the desired 125 decibels, as discussed. Additional loss may be obtained by moving the *M* terminals from the office to pole-mounted equipment cabinets on the open-wire line. With the *M* equipment pole-mounted, the loss in the coupling path is increased by the longitudinal loss of the open-wire entrance cable and the crosstalk coupling loss in the open wire. The longitudinal loss of cable at *M* frequencies is about 20 decibels per mile but, unfortunately, most entrance cables are relatively short, so that after moving the *M* terminals and allowing for 10 to 20 decibels crosstalk loss in the open wire there is usually some 20 to 40 decibels of loss still required. Fig. 2 shows a typical plant layout of the type just discussed.

The M1 and 01 Conflict

In past years, *M* carrier suppression devices have been developed for use on open-wire lines where it is desired to operate the same *M* channel at two different locations along the line. The two principal devices used by the Bell System are the type-*A* and type-*C* suppression units. Both type-*A* and type-*C* suppression units are half-section filters. Type *C* uses a different coil from that of type *A*, and has about 5 decibels more loss to *M1* frequencies. When inserted in an open-wire line both type-*A* and type-*C* suppression present an impedance mismatch to the open wire at frequencies above 30 kc. The resultant reflection coefficient is about 35 per cent at 70 kc to 70 per cent at 120 kc. Where it is desired to operate *01* carrier on a line equipped with type-*A* or type-*C* suppression, the high reflection contributes substantial reflected near-end crosstalk which will make some of the *01* carrier channels useless for commercial service. In addition, type-*A* suppression introduces a transmission impairment to *01* carrier frequencies which will reduce the allowable length of the *01* repeater section. Type-*C* suppression, which was designed for voice frequency lines, has a greater loss at carrier frequencies above 10 kc than does type-*A* suppression, with the result that neither *C* carrier nor *01* carrier can be used on a line equipped with type-*C* suppression units.

The F1100 Filter

The problem resolves itself to developing a device that, when placed in an open-wire carrier line, will suppress, both longitudinally and metallically, *M* carrier energy by 30 decibels or more, and at the same time will not increase the transmission loss or the crosstalk of the line at fre-

quencies below the *M* range. In addition the installed cost of the device must be appreciably less than the cost of replacing the *M1* systems or adding an *N1* repeater point.

It was felt that a low-pass filter with the mid-points of certain shunt elements grounded would meet these requirements. The problem was discussed with representatives of an outside manufacturer who designed and built the *F1100* filter to the required specifications. The filter has a cutoff frequency of 175 kilocycles, and a longitudinal loss (on the bench with a zero-ohm ground) in the low-pass section of 50 or more decibels to frequencies above 180 kc. The transmission loss of the low-pass section was less than 0.3 decibel through the *01* carrier frequency range with a reflection coefficient when inserted in a 600-ohm line of less than 5 per cent in the passband. Two *F1100* filters are mounted with their associated protector strips in one type-*B61* filter assembly box for crossarm mounting. Fig. 3 shows a schematic of the filter and its wiring in the filter box.

The field trials involved only the suppression of *M* energy. Therefore, the *F1100* filters were ordered with the high-pass section replaced by a high-pass-section simulating network. This saved approximately $50 per filter. It is felt that when it is desired to operate *01* systems on the same pairs as the *M1* systems, the *M* coupling units may be replaced by the complete *F1100* filter, and the high-pass side of the filter used to couple the *M*'s to the line.

Results of Field Trials

Field trials were conducted at two locations, and longitudinal losses in excess of 30 decibels were obtained, see Table II. The arrangements necessary to obtain this loss are summarized:

1. A good local ground is required. The ground used for field trials had a d-c resistance of less than 2 ohms.
2. The shunt elements of the filter (Fig. 3) are terminated on separate lugs. This arrangement is provided so that separate ground leads can be used for each shunt element where maximum suppression is desired. Physically separated grounds for the shunt elements will reduce the amount of *M* energy that by-passes the series elements of the filter via the ground path. To obtain the results shown in Table II, terminals 5 and 7 were connected to a driven ground rod while terminal 9 was connected to the sheath of the entrance cable.
3. For the tests, all bridling and ground wires from the hot or line side of the filter were kept physically separated from the quiet or drop side leads. For greater suppression, it might be helpful to shield all leads to the filter.
4. The disturbing *M1* equipment was located far enough from the telephone office so that the effect of the run-around paths, near-by power lines, telephone exchange plant, fire alarm circuits, etc., was minimized. Where the possibility of the *M1* energy's by-passing the suppression unit via some adjacent wire structure is remote, the ideal location for the filter is on the terminal pole of the open-wire line between the open-wire line and the open-wire entrance cable. However, where the terminal pole supports one or more exchange cables as well as the toll entrance cable, it is not very satisfactory for a suppression point. Field trials indicated that where exchange cables were on the toll open-wire pole line, the best location for the suppression unit was at the end of the exchange cable. When the filter is placed in the open wire at the end of a cable, the cable sheath should be used for the shunt element ground with additional grounds provided by driven ground rods as required. The d-c resistance of the cable sheath and parallel ground rod to ground should not exceed 10 ohms.
5. The voice-frequency leads from the drop side of the *M1* equipment are suppressed with capacitors from each wire to ground. It was found that the *M1* equipment should be located one pole further from the office than the filters, and that the voice pairs to the *M1* should be shielded from the open wire, as well as suppressed.

Table II. Typical Suppression Given by F1100 Filter

Frequency, Kc	Suppression, Decibels
185	37
200	32
215	30
230	41
280	44
340	21
400	31

In addition to the suppression measurements, transmission and crosstalk tests were made in 2-kc steps from 40 kc to 156 kc on the open-wire line before and after the filters were cut in. There was no appreciable difference in the before and after tests of transmission and crosstalk indicating that the filters could be used without adverse effect on lines carrying *01* carrier.

Conclusions

The tests showed that the *F1100* filter would produce 30 or more decibels of longitudinal loss to *M* carrier frequencies without upsetting the characteristics of the open-wire line below 156 kc. However, the field trials indicated that each location where *M*-to-*N* interference could be expected should be treated as an individual case, and a complete engineering investigation made. Where the required suppression is not too great, or the run-around paths too many, the *F1100* filter will provide an economical method of retaining existing *M1* channels which would otherwise have to be replaced.

In addition, where existing *M* suppression is used to separate *M1* systems on the same line, and it is desired to operate *01* systems along the line, the *F1100* filters can be used to replace the *M* suppression units.

The Electric Strength of Air in Nonuniform Fields at Radio Frequencies

J. B. WHITEHEAD
FELLOW AIEE

D. L. BIRX
ASSOCIATE MEMBER AIEE

C. F. MILLER
MEMBER AIEE

Synopsis: The purpose of this study is to investigate the electric strength of air in the frequency range of 2.0 to 16.0 megacycles per second, using a central wire and cylinder as electrodes. Work has previously been done with a similar electrode arrangement up to 1.5 megacycles per second.[1] A reduction in breakdown voltage up to 6.0 per cent was noted in this instance. The present investigation shows that above 2.0 megacycles per second, the breakdown voltages are an average of 32.0 per cent under the corona starting voltages, at 60 cycles per second.

Theory of Breakdown

THE ORIGINAL theory of breakdown as proposed by Townsend[2] is still basically accepted today, but with some modifications.[3] This theory is based on the premise that a free electron within the gap will be accelerated by the field, and if the field is strong enough this electron may acquire sufficient energy to ionize a molecule upon collision. The newly formed electron travels on with the original and in this way an avalanche of electrons is formed.

Behind the avalanche is left a trail of positive ions. In the case of d-c fields or at low power frequencies, when the field due to the concentration of these ions reaches a certain fraction of the applied field, a positive space-charge streamer will be formed, which is capable of self propagation towards the cathode.[4] The conditions in such an avalanche in an undistorted field may be expressed in terms of the distance, x, of the electron from its starting point and Townsend's first coefficient α which is the number of ion pairs created by one electron per unit length of its path in the field direction. For one electron starting, n electrons appear x centimeters nearer the anode, where, for a uniform field

$$n=\epsilon^{\alpha x}$$

and for a nonuniform field

$$n=\epsilon^{\int \alpha dx}$$

With cylindrical electrodes, it would seem reasonable that the electron must attain its critical velocity when moving toward the wire, because the intensity of the field increases in that direction. Thus it has been observed that corona starts first when the wire is positive.[5] At the critical voltage, the wire breaks out into a glow known as visual corona.

If the voltage is raised above this point, the boundary of the glow extends out in space towards the outer cylinder, and eventually a voltage is reached when a highly ionized column of air extends completely across the gap, and a spark breakdown occurs. The ionic charge formed around a corona wire during any half-wave is all of the same sign as the potential of the wire and may be referred to as a space charge. The boundary of this space charge varies with the frequency, size of wire, and rise of voltage above the corona voltage.[5]

At power frequencies, the space charge formed on any half-wave returns to the wire on the next succeeding half-wave. The velocity of the ions varies with the strength of the field. Values of mobility are reported for positive ions ranging from 1.5 to 10.0 centimeters per second per volts per centimeter.[5–7] It is seen then that as the frequency of the applied voltage rises, depending upon the size of the gap, a point is reached where these ions are not able to get out of the gap each cycle.[8] They remain and cause an ever increasing space charge to grow about the wire. This space charge will eventually be limited by the diffusion of the ions towards both electrodes, where recombination can readily take place. A reduction in the total voltage across the electrodes at which breakdown occurs is therefore possible, not only because the concentration of positive ions that has to be produced by the electron avalanche initiating breakdown will be less, but also because the initial space charge is sufficient to distort the electric field within the gap and so produce enhanced values of α.

Experimental work has shown that at still higher frequencies, another reduction in the breakdown voltage does occur,[9] and this is attributed to the fact that the electrons find it impossible to get out of the gap at this stage.

The peculiarities of radio-frequency discharges support this theory quite well. It is observed that over the frequency range herein investigated, corona as it is known at 60 cycles per second does not exist. No visible effect is noticed until the voltage is reached which causes complete breakdown of the gap between the wire and cylinder. The discharges occur

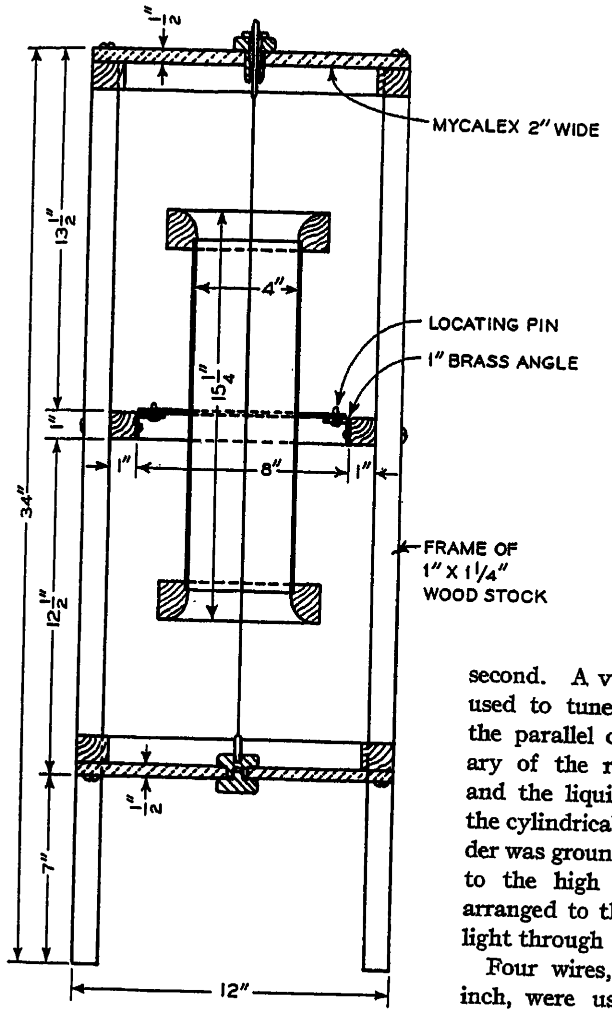

Fig. 1. Test setup showing mount for wire and cylinder

at one or several points along the wire, and take the form of brushes extending radially out from the wire. The breakdown is complete, extending all the way across the gap for the wire sizes and cylinders used. This effect has been observed before.[10]

If breakdown occurs initially on the part of the wave when the wire is positive, the accumulated positive space charge will have the effect of extending the inner conductor out toward the surrounding cylinder, causing most of the voltage to be applied between the cylinder and some point intermediate between the cylinder and the wire. When a discharge occurs, its tendency then is to completely bridge the gap.

Experimental Procedure

A Navy type-*TDH-4* transmitter with power capability of 3 to 5 kilowatts over the frequency range of 2 to 18 megacycles per second was used to provide the breakdown voltages. Four radio-frequency transformers provided voltage step-up, and these were tuned at frequencies of 2.0, 4.8, 9.81, and 16 megacycles per second. A variable liquid capacitor was used to tune the secondaries.[11] Across the parallel combination of the secondary of the radio-frequency transformer and the liquid capacitor was connected the cylindrical electrode gap. The cylinder was grounded, and the wire connected to the high voltage. A sunlamp was arranged to throw a beam of ultraviolet light through the gap.

Four wires, nos. 23, 16, 12, and 1/8 inch, were used for the investigation. These were suspended in turn within the cylinders, nos. 1, 2, 3, and 4, of radii 1.15, 2.44, 3.30, and 4.9 centimeters respectively. The length of the cylinders was in every case at least four times the diameter, to assure uniform field at the center. Grading flares were provided at the ends. The electrodes were mounted in a sturdy wooden frame with glass bonded mica insulation at the ends to support the wire. The cylinders were designed to mount each on the same support whereon they were located by means of aligning pins. This arrangement permitted rapid change of electrodes while at the same time assuring perfect alignment. The entire assembly was aligned very carefully at the time of building by inserting a rigid steel rod through the holes in the end insulators and the cylinders.

Two combination capacitor-divider vacuum-tube voltmeters were used to obtain the voltage measurements. One was fixed permanently in the system, and the other was used as a standard. The fixed meter was of necessity located at a finite distance from the spark gap. The meter combination used as a standard was accurately calibrated at the factory. During calibration of the fixed meter, the capacitor divider of the standard was mounted in the same position normally occupied by the electrodes. Measurements showed that the electrodes and the capacitor divider each presented about the same loading on the circuit. Calibration runs were made for each frequency used.

The high-Q resonant circuits used to generate the breakdown voltages provided a means of detecting the start of any discharge. The voltage was applied by slowly reducing the bias on the final stage of the transmitter, and breakdown was indicated by a sudden fall in the applied voltage, as the circuits were extremely sensitive to any loss.

The breakdown voltage was found to be especially affected by the surface condition of the wire. Before each measurement the wires were polished with jeweler's rouge, wiped with a rag dipped in alcohol and then washed with distilled water. The inside surfaces of the cylinders were polished, but dust or slight

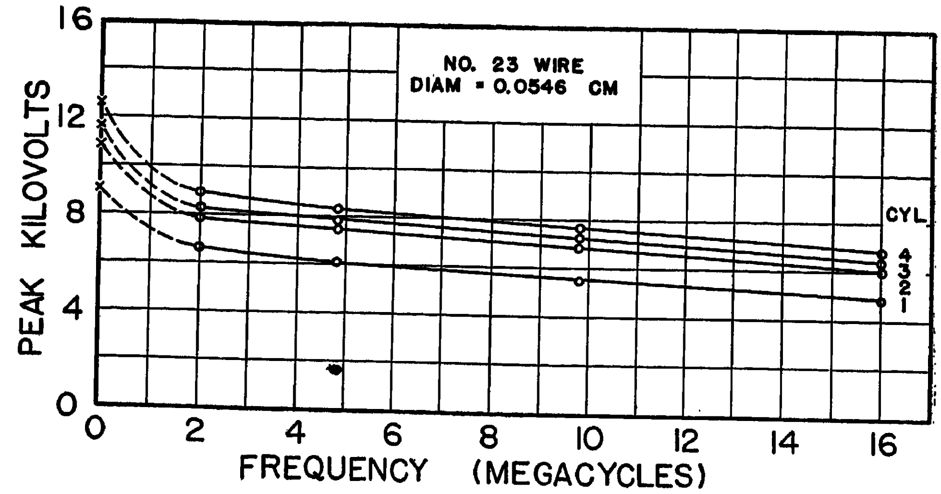

Fig. 2. Gap breakdown voltage using no. 23 wire as central electrode. 60-cycle point is voltage for visual corona

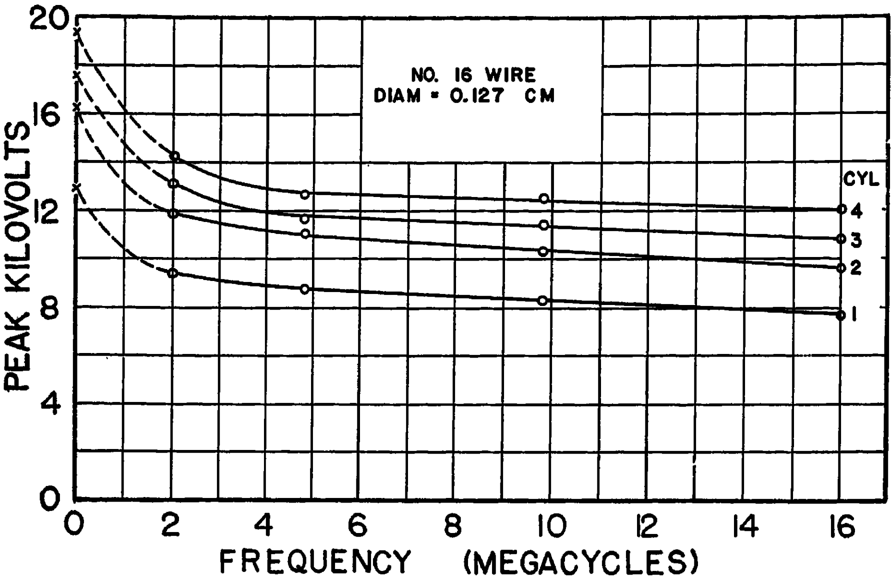

Fig. 3. Gap breakdown voltage using no. 16 wire as central electrode. 60-cycle point is voltage for visual corona

irregularities here were found to have little effect on the voltage.

Results

The results of the investigation are shown in Figs. 2 to 5. The breakdown voltage versus frequency curves are for the most part straight lines, all having a slight negative slope. This slope has a tendency to be greater at the lower frequencies. The experimental curves are connected with dotted lines to the 60-cycle voltage corresponding to the appearance of visual corona. The exact shape of the curve between 60 cycles and 2.0 megacycles per second is not known, but it probably does not differ much from the form shown.

Whitehead and Gorton[12] found that corona voltage at 2.0 kc is lower by 3 to 4 per cent than it is at 60 cycles per second. Misere[1] reported in experiments on fine wires and cylinders that at 500 cycles per second a drop of 1.4 to 2.0 per cent was noticed while at frequencies up to 1.4 megacycles per second, a 6.0 per cent decrease was observed. These results indicate that the slope of the breakdown curve may increase more than that shown between 1.0 and 2.0 megacycles per second, and then approach the 60-cycle value more nearly parallel to the horizontal axis.

Githens[13] covered this frequency range and showed a similar reduction in voltage at pressures up to about 1/2 atmosphere. Lassen[14] and Oler[15] who worked with spheres and small gaps in the frequency range in question reported a 10 to 15 per cent lowering of the radio frequency breakdown voltage from the 60-cycle value. This drop is accounted for by the accumulation of a positive-ion space charge in the gap. Pim[9] reports drops of approximately 44 per cent at higher frequencies, where electrons are not removed from the gap and remain to increase the ionization efficiency. In the present investigation, where drops of the order of 30 to 35 per cent are encountered, it would appear that both of these phenomena are active.

In Appendix I, the frequencies at which the ions and the electrons are left in the gap are computed. Two ion mobilities are used to cover the range of those reported, and the calculations show that at frequencies as low as several hundred cycles, with the largest cylinder, it is possible for ions to remain in the gap to distort the field. Such things as diffusion and recombination are not taken into account and these would have the effect of raising the frequency at which the accumulation of space charge becomes effective.

The mobility of the electron is not too well defined, but the drift velocity may be expressed as

$$v=k\frac{X}{P}$$

where

k = constant
X = field strength, volts per centimeter
P = pressure, millimeters of mercury

Assuming a straight-line extrapolation of the curve, see Fig. 2,[16] one finds $k=3.9\times10^5$ millimeters of mercury = centimeters per second per volts per centimeter. At 760 millimeters pressure, then, the electron mobility would be 513 centimeters per second per volts per centimeter. Using this value, it is found that with the largest cylinder, the electrons will not be removed at frequencies as low as 60,000 cycles per second.

These figures affirm the belief that with the frequencies and gap widths used, both ion and electron accumulations are contributing to the lowering of the voltage. The downward slope of the curves out to 16 megacycles per second would indicate that the point has not been

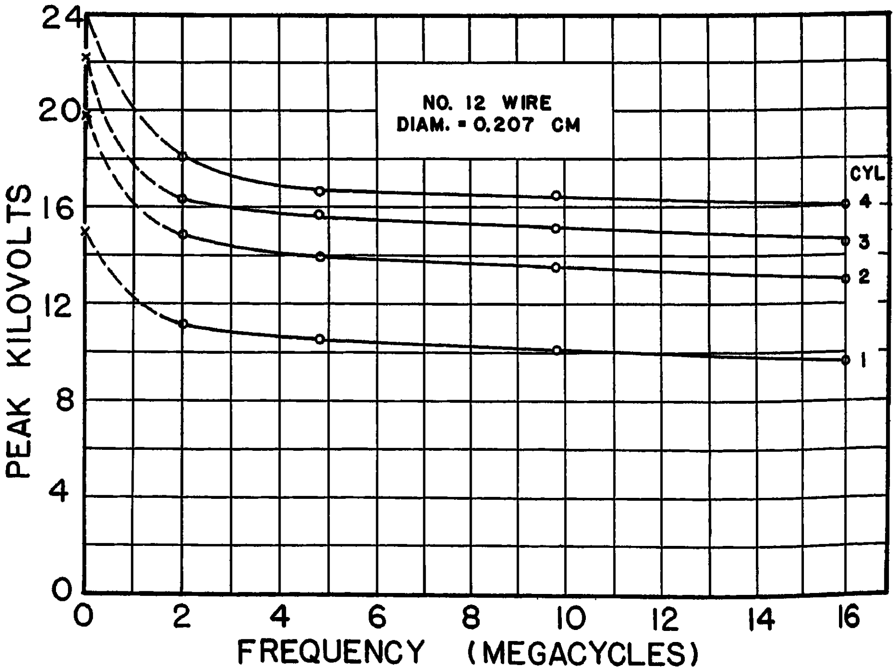

Fig. 4. Gap breakdown voltage using no. 12 wire as central electrode. 60-cycle point is voltage for visual corona

reached where the electrons have their maximum effect and the breakdown voltage levels off.

As a check on the accuracy of the theory of breakdown it was desired to determine, if possible, on what part of the radio-frequency cycle discharge actually occurred. To accomplish this, a source of steady d-c voltage was connected between the outer cylinder and ground. The cylinder was placed first at +430 volts and then at −430 volts with respect to ground. The radio-frequency breakdown voltage to ground was measured in each case, and this value was compared to that obtained with the cylinder grounded. Raising the cylinder to a positive potential with respect to ground caused an increase in the radio-frequency voltage to break down the gap. Placing the cylinder at a negative potential with respect to ground caused the gap to break down at a voltage lower than that required with the cylinder grounded. Thus, it is reasonably well established that the discharge occurs on that half of the radio-frequency voltage cycle for which the wire is positive. The difference in the peak voltage required for breakdown when the cylinder was grounded and when it was placed at a d-c potential either above or below ground, was of the same order of magnitude as the d-c voltage.

The absolute accuracy of the voltage measurements in this investigation is limited by the accuracy of the radio-frequency voltmeter used as a standard. This meter was carefully calibrated at the factory, and corrections, where necessary, were supplied by the manufacturer. Each point on the breakdown curves was determined by the average of at least five readings. Except for the smallest wire, the average deviation of these readings was less than ±2.0 per cent. Measurements on different days showed that the results are repeatable within a limit of ±2.0 per cent.

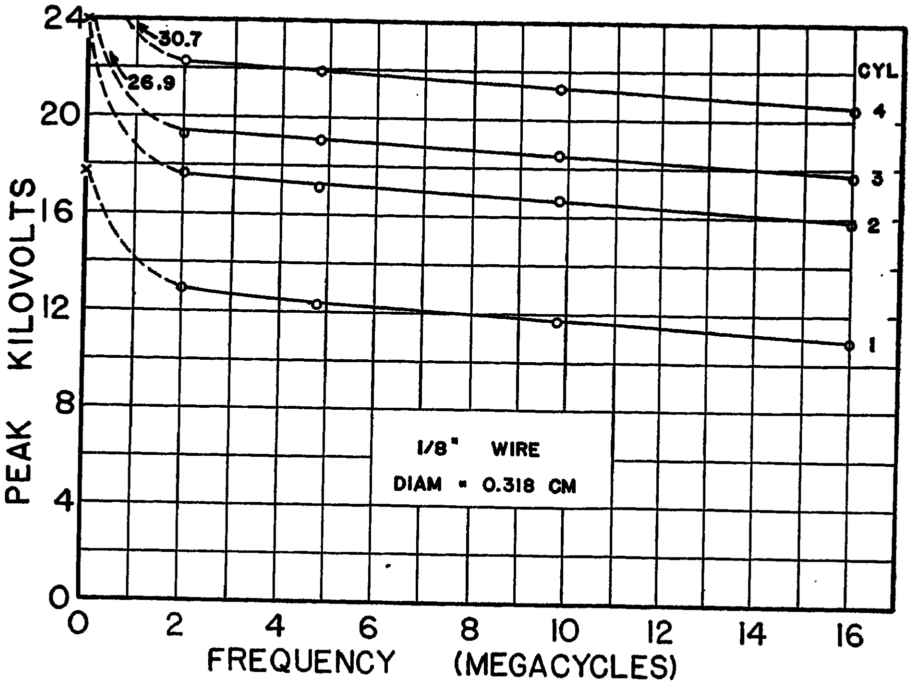

Fig. 5. Gap breakdown voltage using 1/8-inch wire as central electrode. 60-cycle point is voltage for visual corona

Conclusions

1. Accurate measurements of the breakdown potential of atmospheric air at radio frequencies between central wire and cylinder electrodes have been made. A frequency range of 2.0 to 16.0 megacycles per second was investigated, disclosing that the apparent strength of air at 2.0 megacycles per second is approximately 30 per cent below the 60-cycle value, and that the breakdown voltages decline at an average linear rate of 120 volts per megacycle as the frequency is raised above this point.

Table I. Critical Frequencies

Wire Size	Cylinder Radius R, Centimeters	Critical Frequency, Kc Ions $K_i=1.5$	 $K_i=8.0$	 Electrons $K_e=513$
1/8 inch	1.15	6.58	35.1	2250.0
No. 16	1.15	3.23	17.2	1100.0
1/8 inch	4.90	0.35	1.9	121.0
No. 16	4.90	0.18	0.9	60.6

2. A modified Townsend theory of breakdown can be used to explain the results obtained. It has been demonstrated that due to the finite mobilities of the electrons and ions, these particles will not be cleared from the gap, but will remain to cause field distortion which results in lower breakdown voltages and discharges of a different nature from those obtained at 60 cycles per second.

3. The discharge was found to occur on that part of the cycle when the wire is positive with respect to the cylinder. This agrees with results obtained at 60 cycles per second, and supports the theory presented.

Appendix I. Influence of Frequency on Space-Charge Distortion

The gradient in the gap at any distance x from the axis of the wire and at any time t is

$$X_x=\frac{E}{x\log_e\frac{R}{r}}$$

where

$E=E_0\sin\omega t$ = applied voltage
R = cylinder radius
r = wire radius

The velocity v of an ion at point x is then given by

$$v=\frac{kE_0\sin\omega t}{x\log_e\frac{R}{r}}$$

where

k = mobility constant of ion

The distance dx traversed in time dt is then

$$dx=\frac{kE_0\sin\omega t}{x\log_e\frac{R}{r}}dt$$

Integrating

$$\frac{x^2}{2}=-\frac{kE_0\cos\omega t}{\omega\log_e\frac{R}{r}}+C$$

Now assume ions to be formed at the surface of the wire and have zero initial velocity at the point in the voltage cycle when $E=0$ and $\omega t=0$, $v=0$.

Then

$$C=\frac{r^2}{2}+\frac{kE_0}{\omega\log_e\frac{R}{r}}$$

The ion will have moved a maximum distance x when $\omega t=\pi$. Here

$$x^2=\frac{4kE_0}{2\pi f\log_e\frac{R}{r}}+r^2$$

Now placing $x=R$, the cylinder radius, and solving for the frequency

$$f_c=\frac{2kE_0}{\pi(R^2-r^2)\log_e\frac{R}{r}}$$

This is the critical frequency, above which not all of the ions will be removed from the gap. Charge will accumulate, resulting in space-charge distortion of the field, with subsequent lowering of the breakdown voltage. The last equation may also be used to find the critical frequency for electrons if the electron mobility is substituted for the ion mobility.

1. For ions, $K_i = 1.5$ to 10.0 centimeters per second per volts per centimeter.
2. For electrons, $K_e = 513$ centimeters per second per volts per centimter

On the basis of this equation, the critical frequencies for a number of wire and cylinder sizes have been calculated and are listed in Table I.

Preliminary Development of a Magnettor Current Standard

E. P. FELCH
MEMBER AIEE

J. L. POTTER
MEMBER AIEE

Synopsis: In the wartime development of the air-borne magnetometer, a method of detecting extremely small changes in magnitudes of magnetic fields was developed. The principle involved was the use of a second-harmonic type of magnetic modulator now known as a magnettor. This instrument can detect changes in magnetic fields in the order of 10^{-5} oersted. A study was made at Rutgers University under the sponsorship of Bell Telephone Laboratories to determine the feasibility of obtaining a standard of current using the magnettor principle. In this case, the magnettor was placed in a stable permanent-magnet field of a few oersteds and the field nulled by means of a solenoid carrying the current to be stabilized. This current was supplied by an electronic self-balancing system, which maintained a null condition. If a field of 1 oersted is used, an ultimate accuracy of one part in 10^6, or 0.001 per cent, might be expected.

In the experimental tests, when the temperature was varied over a range from 20 to 50 degrees centigrade, an accuracy of better than 0.1 per cent was maintained, and if the magnettor was held at a constant temperature the accuracy was better than 0.01 per cent.

The device can be used to develop a standard of current and voltage. It can also be used as a power level reference standard or as a voltage reference source in regulated power supplies where high accuracy and stability are demanded. It is believed that with further development work the instrument can be made to approach the accuracy of the standard cell.

IN THE development of electric equipment and in electrical measurements, it is desirable to have standards of voltage and current for use as power reference standards, in communications systems, in calibration of indicating instruments, as standard reference voltages for regulated power supplies, and as potentiometer standardizing references.

The panel type of indicating instrument has an accuracy of ±2 per cent of full-scale value, the portable laboratory instrument has an accuracy of 0.25 to 1 per cent, and the best laboratory standard indicating instrument has an accuracy of 0.1 per cent of full-scale value. These laboratory standards are not considered portable as they require leveling and special handling.

The standard cell used with a suitable measuring potentiometer is the ultimate in accuracy in measuring electric voltage or current. The accuracy is about 0.001 per cent if extreme care is taken. The normal accuracy is better than 0.01 per cent.

The gas discharge tube is commonly used as a reference voltage source in regulated power supplies. These tubes will maintain a voltage within 1 or 2 per cent, and special tubes may be better than 0.25 per cent for a relatively short period of time.

Rutgers University entered into a contract with the Bell Telephone Laboratories to study the feasibility of using the second-harmonic type of magnetic modulator, known as a magnettor, in conjunction with a standard magnetic field to produce a current or voltage standard for reference purposes that would be a portable, rugged, and reliable device.

The theory of the operation of the magnettor is described in the literature[1–6] and will not be treated in this paper. The application of such techniques to a current standard was suggested several years ago.[7]

Fig. 1. Block diagram of magnettor standard

cillator has its wave form purified by a 1,000-cycle band-pass filter which excites the magnettor standard assembly located inside a magnetic shield case. This cavity contains the permanent magnets and d-c solenoid which produce opposing fields on the magnettor core. If a d-c residual flux is produced in the magnettor core, a second harmonic is produced across the magnettor coil and is accepted by a 2,000-cycle filter. This signal is amplified by a 2,000-cycle tuned amplifier. The 2,000-cycle output from the amplifier will reverse in phase 180 degrees when the d-c flux in the magnettor core reverses direction.

To detect this phase change in voltage, the 1,000-cycle voltage from the oscillator is doubled in frequency in the frequency doubler and then, by a phase-shifter circuit, can be brought in phase or 180 degrees out of phase with the 2,000-cycle error voltage of the amplifier.[2,3,9] These two signals are combined in a balanced detector circuit and rectified so that a direct voltage output is produced that is positive for one phase of the 2,000-cycle error voltage and negative for the opposite phase. The output of the d-c amplifier, which is a cathode-follower in this case, feeds the direct current into the d-c solenoid which opposes and nulls the field of the permanent magnets. If a complete nulling of the two fields were produced, the 2,000-cycle error voltage would be zero. The current flowing in the standard resistance is checked by means of a conventional precision potentiometer-measuring circuit (not shown in diagram).

The circuit diagram of the amplifier and phase detector as used for these tests on the magnettor and cavity is shown in Fig. 2. The amount of development work done on the circuit was limited, and it could undoubtedly be simplified and improved. The voltage gain of the a-c amplifier was about 82 decibels, which was adequate for these tests.

The experimental laboratory setup for testing the magnettor standard is shown in Fig. 3 with a portion of the auxiliary test equipment. The magnet magnetizing equipment and wave analyzer are not shown in this setup. Preliminary work was done using a wave analyzer in place of the amplifier, and current was supplied to the solenoid by using a battery and variable resistance.

Experimental Work and Results

Considerable initial thought was given to possible structures that could be used to produce and maintain a standard magnetic field for the magnettor unit. It was decided to try relatively long rod magnets mounted in a retaining magnetic case or cavity. The long magnets were considered advantageous because they would not be demagnetized easily.[8]

A number of the experimental cavities which were constructed during the course of the work are shown in Fig. 4. The first of these cavities was constructed using Alnico magnets and is shown as the second from the top in Fig. 4. When this cavity was tested and the magnet field was nulled by a direct current from a battery, it was found that the smallest output voltage that could be obtained was about 1,200 microvolts output from the 2,000-cycle filter. When the magnettor was nulled in the earth's field, the residual second-harmonic output was about 10 microvolts. Hence it was realized that the shape of the flux field produced by the magnets and the cavity must have a major effect upon the residual second-harmonic voltage.

When the phase of the second-harmonic voltage is compared to the 1,000-cycle driving signal, the second-harmonic phase remains unchanged at high signal outputs, but as the null condition is approached the phase position changes from 0 degrees to 180 degrees without the magnitude of the error voltage going through zero. This residual second-harmonic voltage can then be considered as a quadrature component of second-harmonic voltage. The quadrature component of second-harmonic voltage may be due to:

1. a second harmonic from the oscillator;
2. stresses in the magnettor core;
3. the two magnetic fields (that from the magnet and that from the solenoid) having flux lines of dissimilar shape.

The reason why item 3 produces the quadrature component has not been definitely determined. When a solenoid longer than the core nulls the earth's field, the lines of flux of both fields are essentially parallel along the axis of the magnettor core, and do not produce an appreciable quadrature component in this case.

Since difficulty was experienced with the quadrature component in the initial cavity constructed, a study was made with an experimental setup in a large magnetic shield case. This model was made of plastic material with magnets held in place by tape on a plastic tube. This unit is shown as the bottom unit in Fig. 4. Numerous tests were conducted with the plastic model to determine the cause of the quadrature component, such as:

1. nulling one solenoid field against another;
2. changing the number of magnets;
3. changing the length of the magnets;
4. changing the strength of the magnets.

The nulled field of the two solenoids made no noticeable difference as long as they were concentric and symmetrical with respect to the magnettor core. When one solenoid was moved up or down with respect to the axis, the residual second-harmonic voltage increased.

The most significant point was the effect that the change in magnet length had on the residual voltage. This is shown for a typical case in Fig. 5. It is

noted that there is an optimum length of magnet for this particular construction.

A rather extensive secondary effect was the change in residual voltage with the strength of the magnets. A typical curve is shown in Fig. 6. This was not expected but was observed in the previous tests. This change was attributed to the fact that the kernels of the magnetic poles shifted up and down along the rod magnets as the strength of the magnets was varied. Drill-rod magnets were used in all of these tests.

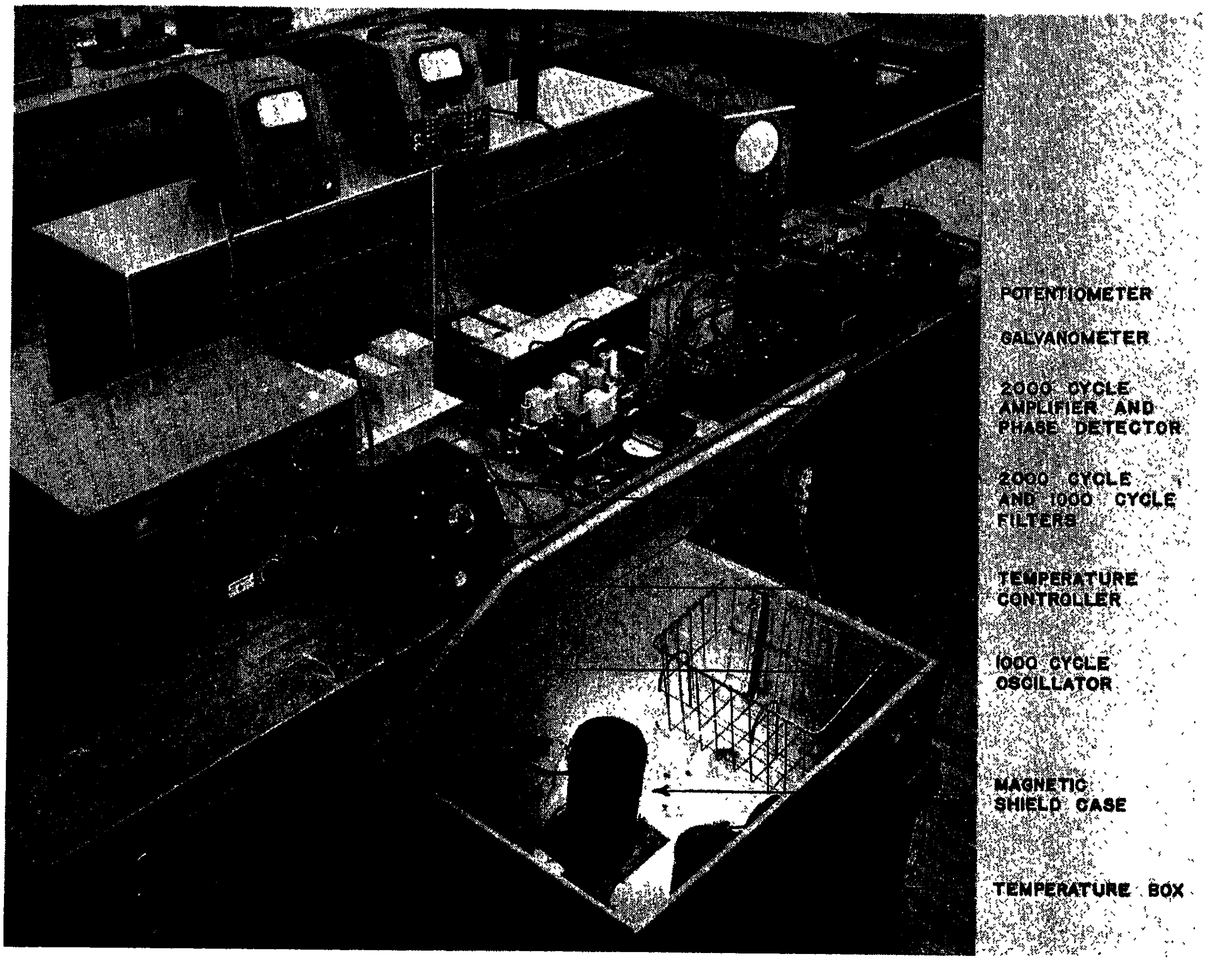
Factors affecting choice of magnet length are listed in Appendix I.

A second cavity was constructed and is shown in Fig. 4, second from the bottom. This cavity was constructed so that magnets of different lengths could be used. Tests were made with two magnets and four magnets with identical results. It was found that the residual second-harmonic voltage could be reduced to a satisfactory level using this assembly. Little change was required in magnet length in going from the plastic model to the cavity to keep the residual second-harmonic voltage at a low value. When a shift was made from the steel drill-rod magnets to Vicalloy magnets, a small change in magnet length had to be made in order to obtain a satisfactory nulling level. This again was attributed to shifting of pole kernels.

It might be stated at this point that two lengths of magnettor cores were tried. The lengths were 3/4 inch and 1½ inches. No significant difference in results was observed except that the short core had considerably less output. Hence most tests were conducted with the 1½-inch cores.

After eliminating the quadrature component of second-harmonic voltage to a satisfactory degree, attention was turned to stability of the field with respect to time and temperature; especially to determine any hysteresis effect as a function of temperature. Several tests were conducted with this cavity using drill-rod and Vicalloy magnets, which were supported on the same brass frame as the d-c solenoid and magnettor. The Vicalloy magnets were, of course, superior in stability, but the results showed a temperature coefficient that was negative. This cavity was then modified to the extent

Fig. 3. Experimental equipment for testing magnettor standard assemblies



of mounting the magnets in two brass holders fastened to the cavity wall. This construction showed an improvement in temperature coefficient because the brass holders and the steel cavity expanded in the opposite directions. This resulted in a decrease in the negative temperature coefficient.

It was reasoned from the results of the previous tests that a larger diameter cavity would further decrease the temperature coefficient. A new cavity was designed and constructed with a larger diameter. It is shown in Fig. 4 as the top cavity. It was also decided to shorten the length of this cavity. It was found in testing the cavity that the residual second-harmonic voltage could not be reduced to a satisfactory value regardless of the length of the magnets used. This result was attributed to the shorter length of the cavity. However, several tests were made with the cavity and it was found to have a positive temperature coefficient.

The results of these tests led to the design and construction of another cavity, shown in Fig. 4 as the middle assembly. This cavity was longer than the preceding one and of a smaller diameter. Tests made with it indicated that it had a negative temperature coefficient that was lower than any obtained with previous cavities. The greater length also made possible low values of residual second-harmonic voltage. In all these cavities, little change in the length of the magnets was required to give satisfactory results.

Considerable difficulty was experienced in early tests with the current drifting in value with respect to time. This condition was found to be caused by residual magnetism in the cavity which was being demagnetized in the presence of the earth's field. When the final demagnetization was made inside a

Reference current = 1.00440 milliamperes

magnetic shield this difficulty was overcome.

A temperature-compensating nickel alloy was tried as a means for further reduction of the temperature coefficient. The permeability of this material decreases as the temperature increases. This may be used as a magnetic shunt to compensate a magnet in which the flux decreases with increase in temperature. A strip of the compensating alloy is shown attached to the magnet holders in Fig. 7. This strip is 0.02 inch by 1/8 inch by 5/8 inch, which yields a temperature coefficient close to zero. A strip 2 inches long causes the current to increase about 2 per cent for a 20-degree-centigrade temperature change. The compensating alloy supplies a convenient method of adjustment of temperature compensation.

If the mounting screws are tightened on the magnet ends, then, as the temperature changes, the pressure on the ends of the magnets will vary, causing a change in flux by magnetostrictive effect. To avoid this, the screws are backed by small nonmagnetic compresion springs.

Significant points in connection with cavity design and compensation are summarized in Appendix II.

In Fig. 8 is shown a plot of per-cent

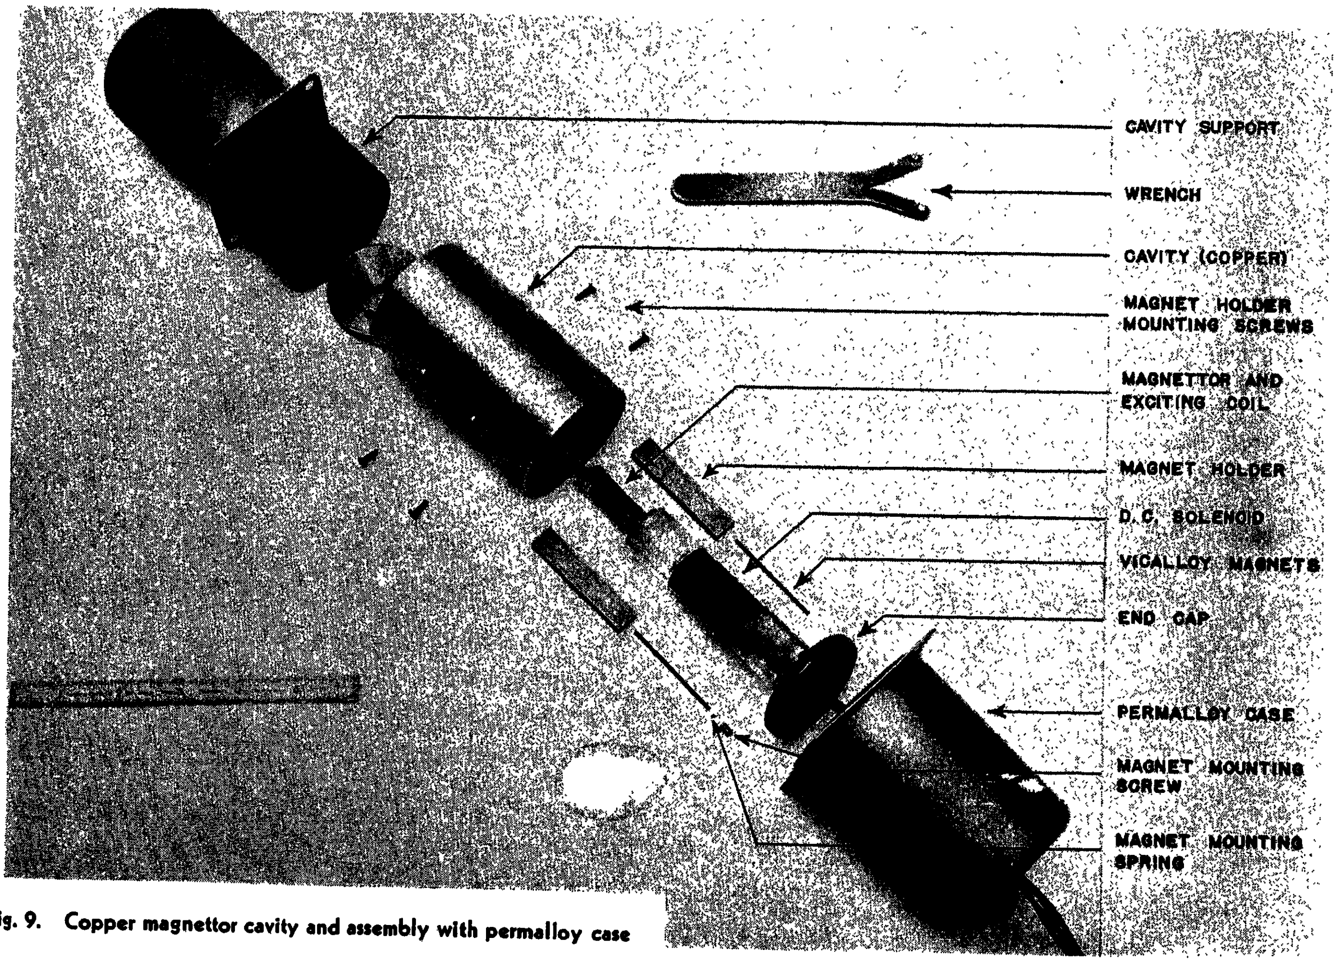

Fig. 9. Copper magnettor cavity and assembly with permalloy case

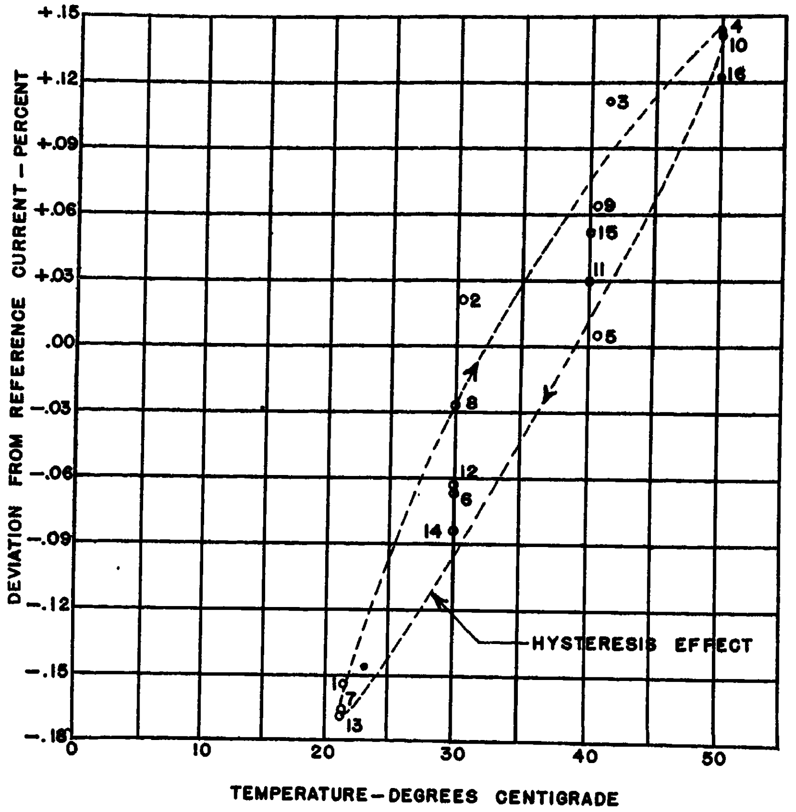

Fig. 10. Per-cent current deviation versus temperature (copper cavity with permalloy shield)
Reference current=1.00380 milliamperes

change in current with respect to temperature. Time is included indirectly, as this curve was a continuous run taken over a period of 2 weeks. Points are numbered in the order taken. After the initial temperature cycle, the current stayed well within ±0.05 per cent for a 30-degree-centigrade change in temperature. If the temperature was held constant, the current change was less than 0.01 per cent for a period of several days at least.

It is noted, of course, that a definite hysteresis effect is present in the temperature cycle, and it is believed that this is due to the cold-rolled steel cavity. A change to silicon steel, Armco iron, or other more suitable magnetic material should improve this effect. If the hysteresis effect can be eliminated to a large extent, and proper temperature compensation used, it is possible that the accuracy might be improved to ±0.01 per cent to a 30-degree-centigrade change.

To check the hysteresis effect, a new cavity was constructed of copper and a permalloy shield case was used. The exploded view of this magnettor assembly is shown in Fig. 9. No attempt was made to provide temperature compensation in this structure. The results of the tests on this cavity are shown in Fig. 10. The points are numbered in the order taken. In spite of the fact that no auxiliary temperature compensation was used, the current was held to within ±0.18 per cent for a 30-degree-centigrade change in temperature. Since the temperature coefficient is positive in this case, the compensating alloy cannot be used.

The copper cavity in the permalloy shield case exhibited less hysteresis effect than the cold-rolled steel case. The hysteresis effect should be still further reduced if the temperature compensation is improved by the techniques described earlier.

The cavity structures during tests were placed inside a larger special permalloy shield which was effective enough so that changing its position in the earth's field produced no effect on the magnettor current.

In Fig. 11 is shown the drive voltage of the oscillator and its effect on the standardized current. The effect of the drive voltage, however, is small enough not to limit the precision of the magnettor standard. If the oscillator frequency remained within 0.1 per cent, the change in current was not observable. These are reasonable tolerances for a well-designed oscillator.

Conclusions

There are many factors, but only one of major importance, that affect the accuracy to which the current can be maintained in the magnettor standard.

1. The reference magnetic field is affected by temperature change which is, no doubt, the main source of error. All other effects are really secondary in nature.
2. The effect of temperature can be overcome to a satisfactory degree by proper temperature compensation by either changes in cavity design or by temperature-compensating nickel alloy.
3. The hysteresis effect needs to be studied with a view toward reducing its magnitude.
4. The magnettor core is unaffected in its operation by normal temperature changes.
5. While the accuracy depends on oscillator drive voltage and frequency, these offer no problem at present.
6. As far as could be observed, the strength

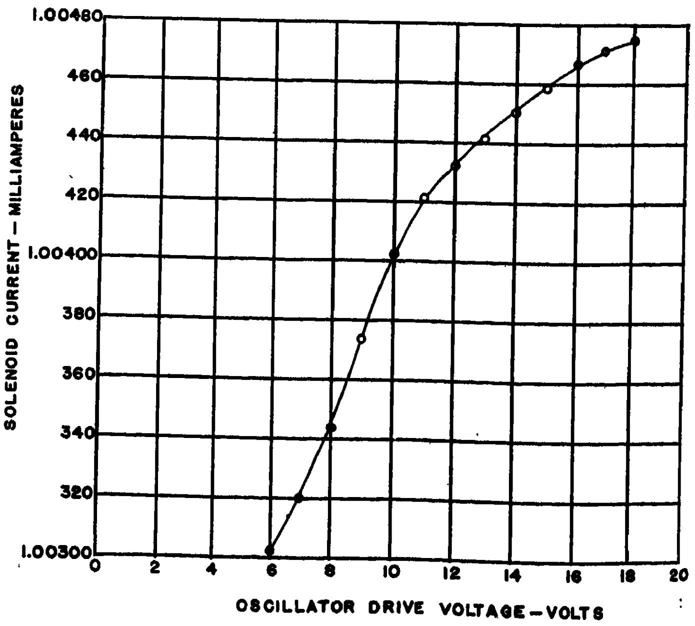

Fig. 11. Effect of oscillator drive voltage on solenoid current

of magnets with respect to time was very stable, and it is not anticipated that this will be a problem since they are used at a low flux density in the cavity.

7. These tests have shown that a current can be standardized to within ±0.05 per cent for a 30-degree-centigrade temperature change with the possibility of reducing it to ±0.01 per cent for the same change in temperature. When the temperature is held constant the present accuracy is better than ±0.01 per cent for a few days. It is conceivable that with temperature regulation and by careful design accuracies of ±0.01 per cent or better could be obtained.

Appendix I. Factors Affecting Choice of Magnet Length

The length of magnets for minimum quadrature voltage depends upon the following:

1. Length of d-c solenoid.
2. Diameter of d-c solenoid.
3. Distance magnets are placed from the solenoid.
4. Strength to which magnets are magnetized and demagnetized.
5. Composition of magnets.
6. Type of field in which magnets are magnetized and demagnetized. The pole kernels are shifted according to the type of field used. Considerable difference is noted, for example, when the magnets are demagnetized in a solenoid field or in the field between poles of an electromagnet.

Other considerations with respect to the magnets are:

1. The two magnets must be identical as to diameter, length, heat treatment, and composition (matched pairs).
2. When magnets are being demagnetized they must be kept symmetrical to one another and thereafter kept away from other magnetic materials and strong fields.

Appendix II. Cavity Design and Compensation

Significant points in connection with the design of the cavity and its treatment:

1. The length of cylindrical cavity is of considerable importance. If the cavity is too short, a poor residual nulling level will be obtained regardless of the length of the magnets used.
2. The diameter of the cavity apparently does not affect the residual level.
3. The steel cavity must be demagnetized in the absence of a d-c field.
4. The effect of the cavity on the length of the magnets required appears to be only secondary in nature.
5. The temperature coefficient can be changed from negative to positive as the diameter of the cavity is increased.
6. The temperature coefficient of the cavity must be negative to use the compensating alloy.
7. The amount of compensating alloy to use depends on placement of strip; strength to which a given set of magnets is magnetized; and heat treatment of magnets.

Synopsis: A study has been made of the effect of stress on the magnetic properties of ferrites. Rectangular hysteresis loops were obtained by encasing toroidal specimens in plastics which shrink during polymerization. Ferrites having this type of hysteresis loop are useful in magnetic switching and magnetic memory devices.

FERRITES HAVING rectangular hysteresis loops are important for use in magnetic switching, magnetic amplifiers, and magnetic memory devices.[1–3] Hysteresis loops of this nature have been obtained with toroidal cores of polycrystalline ferrites, having negative magnetostriction, by applying pressure on the outer curved surface of the toroid. This pressure produces an internal compressive stress which acts circumferentially around the toroid causing this direction to become a direction of easy magnetization. The magnetic domains line up in this direction giving a rectangular hysteresis loop. If the magnetostriction is positive, the domains align themselves transversely and the hysteresis loop flattens out. Hysteresis loops have been traced while the cores were subjected to pressures ranging up to 1,200 pounds per square inch. Rectangular hysteresis loops on ferrite cores subjected to stress have also been obtained by W. N. Papian.[4]

A practicable method used for stressing the cores was to encase the wound cores in a plastic which shrinks when it polymerizes. Hysteresis loops were taken before and after encasing the cores in plastic and changes in the hysteresis loops of an encased core were observed as the temperature was varied from 0 to 66 degrees centigrade. The switching time of a core having a coercive force of 0.1 oersted was measured as a function of the applied field. Most of the ferrites have negative magnetostriction, so that this technique is applicable to a great variety

of compositions having a wide range in values of coercive force.

The stressing of ferrites may be found useful for other applications, since a compressive stress tends to establish an axis of easy magnetization parallel to the stress when the magnetostriction is negative, thus making a polycrystalline material assume the magnetic characteristics of a single crystal having one axis of easy magnetization. A tensile stress would have a similar effect for a material with positive magnetostriction. The effective anisotropy is a function of the stress and the magnetostriction.

Experimental Procedure

Toroidal specimens having an outside diameter of approximately 0.7 inch, an inside diameter of 0.4 inch, and an axial height of 0.15 inch were used. The upper and lower surfaces of the toroidal specimen were ground flat and parallel on a surface grinder, using a diamond wheel; then the specimen, Fig. 1, *E*, was placed inside the hollow toroidal brass casing *D*, and the threaded plug *B* screwed into place. Hydraulic pressure was applied to the outer curved surface of the toroid by forcing oil into the chamber *C*.

The complete assembly for applying hydraulic pressure is shown in Fig. 2. Pressure was applied by means of the hydraulic jack *B*, and the value of the pressure determined by a pressure gauge *C* mounted on the jack. Primary and secondary windings were wound through the toroidal assembly *A*, and hysteresis loops traced on a Cioffi recording fluxmeter as the pressure on the outer curved surface of the toroid was varied from 0 to 1,200 pounds per square inch.

The pressure *P* applied in this manner produces a compressive stress[5] in the core, which has a tangential component σ_θ and a radial component σ_r. σ_θ is a maximum at the inside diameter of the toroid, and has its minimum at the outside diameter; while σ_r is zero at the inside diameter, and has its maximum value at the outside diameter. However, σ_θ is always larger than σ_r, and it is the former component which determines the direction of easy magnetization. The average value of σ_θ is given by the equation

$$\sigma_\theta = bP/(b-a)$$

where b and a are the outside and inside diameters, respectively.

Magnetic Results With Pressure Device

Tests were made on a series of Ni—Zn ferrites. Specimen *1785-11* has the stoichiometric ratio, $Ni_{0.3}Zn_{0.7}Fe_2O_4$; the others have the same Ni to Zn ratio of 3 to 7, but with varying amounts of iron. The chemical compositions of the specimens in this series are given in Table I.

The effect on the hysteresis loop of applying a pressure of 1,000 pounds per square inch on specimen *1579-36*, in which 67.1 atomic per cent of the metal content is iron, is shown in Fig. 3. The remanence increased from 750 to 1,500 gausses, while the coercive force remained the same. Fig. 4 shows some of the magnetic properties of the above specimen:

1. B_m, the value of the magnetization for a field H of 0.7 oersted;
2. B_R, the remanence;
3. The ratio B_R/B_m;
4. The coercive force H_c, plotted as a function of the pressure.

The ratio B_R/B_m increases from a value of 0.46, for no pressure, to 0.85 for a pressure of 1,200 pounds per square inch. There is no appreciable change in the coercive force up to a pressure of 900 pounds per square inch, while from there on there is a slight upward trend. In order to determine the effect of higher stresses on the coercive force of a sample, the inside diameter of specimen *1614-17* was increased so that a given value of P would produce a value of σ_0 approximately three times as great as that obtained with the previously mentioned specimen. When subjected to a pressure of 1300 pounds per square inch, the coercive force of this specimen increased from 0.09 to 0.18 oersted.

Curves are shown in Fig. 5 for specimen *1785-11*, which has the stoichiometric ratio previously mentioned. Specimen *1796-5*, with 68.6 atomic per cent of its metal content iron, has the highest iron content of the series. This specimen showed a decrease in remanence and an increase in coercive force when pressure was applied, as seen in Table I. Harvey, Hegyi, and Leverenz[6] show that the magnetostriction changes from a negative to a positive value near this composition. The exact composition where this occurs, however, it not given. The compositions with higher iron content have positive and those of lower content have negative magnetostriction. It is quite likely that the composition of specimen *1796-5* lies on the positive side, which would explain why the remanence decreased with pressure. It should be mentioned here that, in general, the magnetic properties returned to their original values after the release of pressure.

Curves showing the permeability μ as a function of the flux density B, obtained with and without pressure, are given in Fig. 6 for specimen *1785-2*. The maximum permeability increased with pressure from 12,600 to 36,800. This is

the highest maximum permeability thus far reported for a polycrystalline ferrite.

Table II gives data showing the effect of pressure on a number of different ferrites. Specimens of Ferramic *G* and *H* with B_R/B_m ratios 0.63 and 0.69 without pressure show increases to 0.90 and 0.88, respectively, with pressure. A Mn—Zn ferrite (specimen *1116-56*) showed a decrease in remanence with pressure. This indicates that the material has a positive magnetostriction. However, for a material with positive magnetostriction, tension should cause the remanence to increase. Further tests are being made along this line.

Cores Cast in Plastic

Another method used to stress a specimen in order to obtain a rectangular hysteresis loop was to encase a core, with its primary and secondary windings, in a rigid grade of casting resin. For this purpose, a hard type of styrene polyester resin was employed, namely Selectron *5003*. During polymerization, this resin shrinks about eight per cent by volume, thus exerting a considerable stress on the specimen. Fig. 7 shows a wound core cast in a Selectron disk having a thickness only slightly greater than the thickness of the core. With this method a whole array of cores could be cast in resin at one time. Fig. 8 shows hysteresis loops for specimen *1785-10*, before and after casting in a Selectron disk; see Fig. 7. The ratio B_RB_m increased from 0.34 to 0.83, and the coercive force from 0.017 to 0.05 oersted. As the maximum field strength was gradually decreased, loops were traced on the above mentioned specimen; see Fig. 9.

To check the effect of thickness of the plastic encasement on the magnetic properties a core of similar composition, specimen *1785-19* was cast in the center of a cylinder of plastic as shown in Fig. 10. None of the cast disks of Selectron showed any signs of cracking, but a large cylinder of Selectron developed cracks. To avoid this condition a silica and glass fiber-filled Selectron was used in the casting of this cylinder. The filled compound shrinks only about 6 per cent by volume, but this is apparently enough to impart an appreciable stress on the ferrite core.

Fig. 11 shows the hysteresis loops obtained on the specimen shown in Fig. 10, before and after casting. In this case, the coercive force increased from 0.02 to 0.13 oersted, which is a much greater increase than is observed when a core is cast in a disk. This can be seen by comparing these values with those in Fig. 8, where B_R/B_m increases from 0.43 to 0.88 and the coercive force increases from

0.017 to 0.05 oersted. In Fig. 12, the rectangular nature of the inner hysteresis loops is seen.

Two other resins which have been tried for encasing ferrite cores are Bakelite epoxide and Araldite. These materials shrink less than Selectron during polymerization, and consequently they subject the encased cores to somewhat smaller stresses.

Effect of Temperature

Since the plastic and the ferrite have different coefficients of thermal expansion, and the magnetostriction becomes zero before the Curie temperature is reached, variations in temperature such as might be encountered in the use of one of these units might be sufficient to relieve the stress on the core. To check this, hysteresis loops were traced at temperatures ranging from 0 to 66 degrees centigrade. Specimen *1615-12* was selected for these tests.

Fig. 13 shows the hysteresis loops taken both before and after casting the core in a Selectron disk and Fig. 14, the series of loops for the previously mentioned range of temperatures. The values of B_m, B_R/B_m, and H_c taken from this series of loops are plotted as a function of temperature in Fig. 15. The permitted operating temperature range will depend on the magnetic requirements and can be determined from these curves.

The time required to switch the magnetization from remanence, after magnetization in one direction, to saturation in the opposite direction, was measured as a function of the applied magnetic field; the results for one of the specimens are plotted in Fig. 16. A switching time of one microsecond was obtained for a field

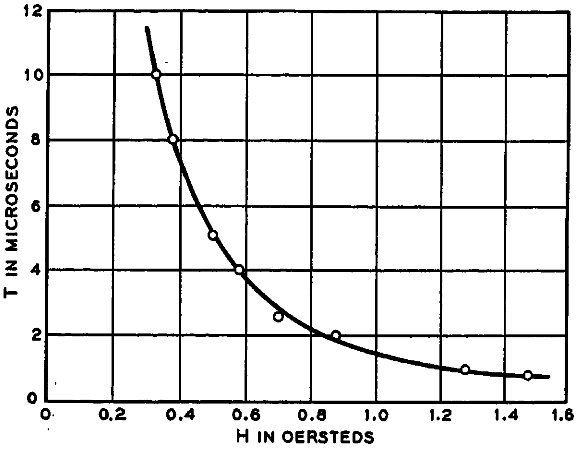

Fig. 16. Switching time as a function of the applied field for a specimen having a composition approximately $Ni_{0.3}Zn_{0.7}Fe_2O_4$

of approximately 1.3 oersteds. The core had a coercive force of 0.1 oersted after being encased in a plastic disk. The outside diameter of the core was 0.175 inch, the inside diameter 0.092 inch, and the thickness 0.040 inch.

Summary

Pressure applied on the external curved surface of a toroidal core of ferrite having a negative magnetostriction tends to establish a direction of easy magnetization which extends circumferentially around the core. The pressure increases the maximum permeability and the remanence, thus causing the hysteresis loop to become more nearly rectangular. Quantitative measurements of this effect were made on a series of specially prepared ferrites having various compositions, one of which had the stoichiometric ratio $Ni_{0.3}Zn_{0.7}Fe_2O_4$ and the others, the same Ni-to-Zn ratio, but with either slightly less or slightly more iron. Rectangular hysteresis loops with very low values of coercive force were obtained. This combination of magnetic properties should make the material very desirable for use in magnetic memory devices.

It has been shown that a simple and practicable means of stressing the cores to obtain rectangular hysteresis loops is to cast the wound cores in a resin which shrinks during polymerization. Although with this technique it is not yet certain that the stress will remain constant with time, one core cast in a Selectron disk has shown no change in magnetic properties after a period of 6 months, and others have shown no change for the shorter periods of time for which they have been observed. Further work on this aspect of the problem has been planned, which will involve testing at periodic intervals, cores cast in different plastics and then held at various temperatures.

A Level Compensator for Telephotograph Systems

T. A. JONES
NONMEMBER AIEE

W. A. PHELPS
NONMEMBER AIEE

SINCE 1936, a number of different telephotograph systems[1] have been operated over the lines of the Bell System on a leased-wire basis. The requirements which a line facility must meet for such service are in several respects more severe than the requirements for voice-message service. Telephotograph - transmission requirements have usually specified that abrupt variations in line net loss should be limited to ±0.2 decibel, single frequency noise power should be at least 50 decibels below maximum signal power, and throughout the useful frequency band (1,200 to 2,600 cycles per second), the envelope delay should be equalized within ±300 microseconds. Such requirements were originally satisfied by using 4-wire *H-44-25* side circuits in cable, where available, and elsewhere by using 2-wire open-wire side circuits. These facilities were delay-equalized over the necessary frequency range, and precautions were taken to minimize various transmission disturbances.

However, the long voice-frequency loaded cable circuits, such as those which formerly connected New York and Chicago, have been largely supplanted by multichannel (so-called broad-band) type-*K* carrier telephone systems[2,3] operating on nonloaded cable pairs, or by type-*L* carrier telephone systems[4] working over coaxial cables. Special services such as carrier telegraph, program, and telephotograph transmission must now use channels of these broad-band carrier systems for long-haul applications, and this requirement has brought new problems.

For speech transmission, the complex pilot regulating equipment of the broad-band systems accomplishes substantially perfect control of the line net loss, but it produces frequent variations of a few tenths of a decibel, which are often sufficient to cause marked deterioration in the quality of transmitted pictures. Also, signals passing through type-*K2* carrier systems are slightly affected by 60- and 120-cycle-per-second modulation caused by the a-c filament supply used for some of the amplifier tubes. This effect also is negligible for speech transmission, but is sometimes quite apparent in transmitted pictures.

The possible severity of these types of interference is illustrated in Fig. 1, which is a section of a picture transmitted over a New York-Chicago-Atlanta-New York loop composed of a number of type-*K* carrier channels in tandem. For comparison, the same picture before transmission is shown in Fig. 2. In the transmitted picture of Fig. 1, which is built up of vertical lines, it may be noted that in some areas which should have a constant shade almost every line has a different density, and on each side of the picture there is a group of very dark lines caused by larger level changes. The whole picture is covered by slanting striations due to power frequency interference. It should be realized, however, that these defects are normally less pronounced than in Fig. 1, which was chosen to illustrate the problem clearly.

Instead of modifying the carrier equipment to eliminate the interference at its several sources, it was deemed more practical to cancel the interference from the signal delivered by the carrier facility. This function is performed by the recently developed telephotograph level compensator, which consists of a pilot channel arrangement designed for insertion in the telephotograph connecting circuits. This arrangement utilizes a single-frequency pilot current, which is transmitted over the line facility along with the picture current, and is modulated during transmission by the same interference which modulates the picture signal. After transmission the modulated pilot current is separated from the picture current and is rectified in order to recover the low-frequency interference. The interference is then used to remodulate the picture current in phase opposition to the existing modulation. The use of the level compensator results in a substantial reduction of interfering low-frequency amplitude modulation resulting from level changes or power-frequency interference.

Description of the Level-Compensator Terminal Circuits

The level-compensator sending circuit is shown in Fig. 3. In this circuit a 3,145-cycle-per-second pilot current, obtained from the standard carrier supply equipment used in carrier telegraph systems, is combined with the 1,200- to 2,600-cycle-per-second picture signal from the sending subscriber. From this circuit the picture and pilot currents pass to the carrier telephone sending equipment.

The pilot frequency has been chosen above rather than below the picture-signal band, so that the full frequency range of the carrier telephone channel below 2,700 cycles per second is available to the subscribers for alternate speech transmission, when desired. Filter *F1* provides substantial attenuation to picture or speech-frequency components lying in the pilot-channel band between 2,945 cycles per second and the 3,500-cycle-per-second upper limit of the carrier telephone channel. Such components are thereby prevented from actuating the receiving compensator equipment. Equalizer *E1* equalizes the delay of this filter over the picture signal frequency band. Filter *F2* attenuates certain extraneous frequency components which are present in the 3,145-cycle-per-second carrier supply. The level of the pilot current delivered by the sending circuit is adjusted 13 decibels below that of the maximum picture current. This adjustment permits the pilot current to be transmitted well above line noise, without causing appreciable intermodulation with the picture current.

The level compensator receiving circuit, shown in Fig. 4, is connected between the output terminals of the broadband carrier telephone channel and the receiving subscriber. In this circuit, the picture and pilot currents, together with any modulated interference picked up during transmission, are separated by low-pass and high-pass filters. The picture current from low-pass filter *F3* flows through delay-equalizer *E3*, which corrects the delay distortion of the filter, into a variolosser network consisting of a special type of balanced modulator. This network contains fixed resistors as series elements and a varistor bridge as a shunt element. The picture current flows through the variolosser at levels low enough to result in negligible signal distortion. The pilot current, after passing through high-pass filter *F4* and its delay equalizer *E4*, is amplified, rectified, and passed through low-pass filter *F5* in order to recover any low-frequency modulation to which the pilot current may have been subjected during transmission. This low-frequency current, in series with an adjustable d-c bias current, is used to control the resistance of the varistor bridge network in the variolosser, and thus to control the transmission loss introduced by the variolosser in the picture branch.

For effective operation of the level compensator the transmission loss of the variolosser, as controlled by the modulation envelope superimposed on the pilot current, must vary in magnitude and phase so as to cancel the interference envelope superimposed on the picture current. The magnitude requirement is met by proper adjustment of the pilot amplifier gain and d-c bias current. The phase requirement is met by designing the picture and pilot branches so that modulation frequencies up to about 200 cycles per second suffer substantially the same delay in the two branches.

Delay Equalization of the Carrier-Telephone Channel

As previously mentioned, for satisfactory operation of the types of telephotograph system under consideration, the maximum deviation of the envelope delay of the transmission circuit from end to end should not much exceed ±300 microseconds over the picture-signal frequency band from 1,200 to 2,600 cycles per second. When the picture signals are transmitted over a broad band carrier facility, the principal sources of delay distortion are the channel band-pass filters of the carrier-telephone terminals. This distortion must be corrected by delay equalizers to meet the requirement just stated.

When a level compensator is added to a carrier-telephone channel, in order to reduce the effect of amplitude modulation interference at frequencies up to 200 cycles per second, the problem of equalizing envelope delay of the carrier facility becomes somewhat greater. Such interference may be introduced by the terminal amplifiers or line repeaters of the carrier facility. At the points of introduction, simultaneous modulation of the picture and pilot carriers occurs. In order that the pilot-carrier modulation may be used effectively to cancel the picture-carrier modulation in the level-compensator receiving circuit, both must reach the variolosser in this circuit simultaneously. To accomplish this, the envelope delay effective over a frequency band, extending 200 cycles per second above and below the pilot frequency, must be adjusted to the same value as that effective over a band 200 cycles per second above and below the picture-carrier frequency. For this reason, the delay equalization of each carrier-channel filter carrying the picture and pilot currents must be effective over the pilot band as well as the picture band; that is, from 1,200 to 3,345 cycles per second. In a multisection carrier facility, consisting of channels of two or more carrier-telephone systems connected in tandem, the channel filters at each connecting point must be delay equalized at that point, so that interference introduced in any or all sections can be compensated at the receiving terminal.

The delay equalizers provided for the carrier-telephone channel filters and for the receiving-level compensator circuit are sufficiently accurate so that the level compensator may be expected to reduce level changes and 60- and 120-cycle-per-second modulation interference by at least 20 decibels if the number of carrier sections in the line facility is not too great. This degree of interference reduction has been found adequate to render broad-band carrier facilities suitable for telephotograph transmission.

Performance Characteristics

A typical characteristic showing the variation of the output level with the input level of a properly adjusted level compensator receiving circuit is shown in Fig. 5. This curve indicates that, in the absence of power frequency modulation, level changes in the line facility as large as ±5 decibels can be tolerated without exceeding the usual limit of ±0.2 decibel in the receiving subscriber's loop. The adjustments necessary to obtain this performance are easily made with the aid of simple testing equipment, and are stable over a period of several weeks.

After the circuit has been adjusted for level compensation, its typical performance with respect to modulation interference over the frequency range from zero to 300 cycles per second is as shown in Fig. 6. This curve applies to the level compensator sending and receiving circuits connected together by an artificial resistance line containing a source of modulation interference. The reduction of such interference due to the use of the compensator is plotted as a function of the modulation frequency, and amounts to nearly 40 decibels for 60 and 120-cycle-per-second interference. Of course, the interference compensation obtained during transmission over an actual carrier facility would be considerably lower due to imperfections in the delay equalization of the facility.

The performance of the level compensator equipment when simultaneous level changes and 50- or 130-cycle-per-second modulation are introduced in the connecting resistance line is given by the curves of Fig. 7. These curves show that the protection against modulation in the power-frequency range falls off as the line loss departs from its normal value. However, it is expected that a substantial compensation for such interference will be obtained in actual practice since the variations in line net loss normally encountered in broad-band carrier channels are small.

A sample picture, locally transmitted, containing line-level changes from 0.5 decibel to 7 decibels, with no level compensator in circuit, is shown in Fig. 8.

The effect of a level change of 0.5 decibel may be clearly seen in the picture. The same test picture transmitted with the level compensator in circuit is shown in Fig. 9. In this picture no change smaller than 6 decibels produces a noticeable effect.

Sample pictures were also locally transmitted to illustrate the performance of the level compensator in reducing the effect of 120-cycle-per-second modulation interference on the line. The picture of Fig. 10 was transmitted without the level compensator, and that of Fig. 11 was transmitted after the compensator had been added. No interference pattern is visible in Fig. 11, even for modulation levels only 15 decibels below the maximum picture level.

The tests which have so far been made over actual broad-band carrier facilities indicate that the level compensator should greatly extend their usefulness for telephotograph transmission.

L3 Coaxial System—Television Terminals

JOHN W. RIEKE
ASSOCIATE MEMBER AIEE

R. S. GRAHAM
ASSOCIATE MEMBER AIEE

Synopsis: Television terminals are required at circuit ends of the *L3* coaxial system, at the transmitting end to condition video signals for carrier transmission, and at the receiving end to detect the transmitted signals. Special signal characteristics, that is, a degree of modulation which exceeds the value commonly referred to as 100 per cent modulation, require departures from standard modulating and detecting processes. The high degree of modulation requires both careful control of transmitted wave form and, at the receiver product, demodulation with phase-synchronous carrier (homodyne detection).

Carrier regeneration requirements result in the choice of 1-step frequency translation from the video frequency spectrum to the allocated vestigial side-band carrier spectrum. The 1-step process using a single modulator results in unusual balance requirements for the modulator itself and an unusual circuit configuration.

Transmission quality objectives for the terminals are such as to permit six pairs of television (TV) terminals to operate in tandem in a transcontinental circuit. This permits a degree of interconnecting flexibility in operation with other systems, that is, *L1* coaxial or microwave systems. These objectives place severe requirements upon the transmission stability of various filters and other circuits within the terminals. New network techniques both in design and fabrication are brought to bear in the effort to achieve required performance. The transmitting and receiving terminals are described, illustrating the functional operation and mechanical and electrical arrangements of the equipment.

THE MAIN features of the *L3* coaxial cable transmission system, including its TV transmitting and receiving terminal equipment have been described.[1] The transmitting terminal conditions a TV signal for carrier transmission over the system simultaneously with a group of 600 telephone messages. The receiving terminal reconverts the carrier signal at each receiving point along the cable route. Primarily, the transmitting terminal is a modulator which translates the composite video picture spectrum of frequencies up to the carrier band of frequencies, and the receiving terminal is a detector which retranslates the carrier spectrum back to its original band of frequencies.

Particular characteristics of the transmitted TV signal, which are intended to aid in achieving optimum transmission quality, have necessitated the departures from past techniques in modulation and demodulation processes that are described in the following. Described also are the methods employed to achieve transmitted picture quality adequate for tandem operation of as many as six pairs of transmitting and receiving terminal equipments in a 4,000-mile TV transmission circuit. Operation with several pairs of terminals in tandem occurs when *L3* coaxial systems are interconnected with *L1* coaxial systems or microwave radio systems.

L3 TV terminal development has been in progress since early in 1948. Two transmitting and two receiving terminals have been built on a preproduction basis, and are currently being tested under field conditions as part of the *L3* system field trial. Development effort is continuing on the terminals with emphasis on equipment reliability, including means for maintaining and improving transmission quality.

Frequency Allocations

The *L3* coaxial system was designed to have as broad a transmission band as the economics of repeater spacing, together with presently realizable feedback amplifier performance, permit.[2] The band extends from 300 kc to 8.5 megacycles. In comparison with this band, a broadcast TV signal occupies the frequency spectrum from zero frequency up to 4.5 megacycles.

From the foregoing it is evident that the TV spectrum will not occupy fully the available system transmission band. It is feasible and attractive to allocate part of the transmission band for TV transmission, and the remainder for transmission of message channels. Detailed allocations then result from a compromise among transmission performance, cost, and the number of message channels made available.

From these considerations vestigial side-band transmission of the TV signal, rather than double side-band transmission is called for. The smaller the vestigial band of transmitted frequencies, the smaller will be the total TV band required. However, both the cost of band-shaping filters and the difficulty of maintaining satisfactorily low values of vestigial side-band quadrature distortion in-

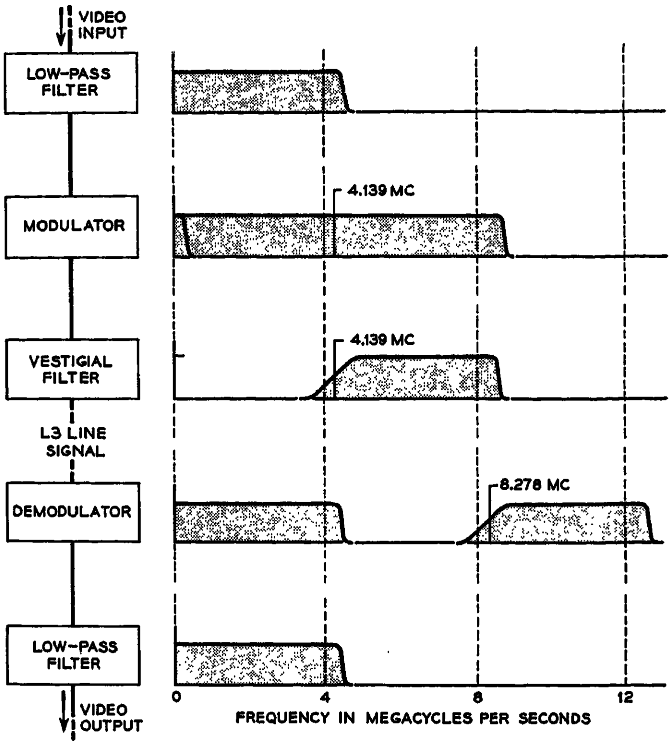

Fig. 2 (right). Television terminal modulation processes

crease as the vestigial bandwidth is reduced. The compromise of these factors resulted in the choice of a 500-kc vestigial side band.

Another choice made was to transmit the TV signal in the upper part of the *L3* band, and the message channels in the lower part. This allocation was determined by considering the noise distribution in the transmission band, together with the modulation distortion, (harmonic distortion), produced by the repeaters. By transmitting TV in the upper part of the band, a minimum modulation distortion is achieved since the harmonics of the TV signal largely fall outside the transmitted band, or at high frequencies where their effects in the picture are relatively less visible than low-frequency distortion. This factor outweighs the higher noise level in the upper part of the band.

As to the TV carrier location, it is placed at the bottom of the TV band at 4.139 megacycles, with the vestigial side band extending down to 3.64 megacycles and the main side band extending upward to 8.50 megacycles. Alternatively, the carrier could have been located at the top of the *L3* band with a main lower side band and vestigial upper side band, but this choice would be disadvantageous because of higher noise levels and poorer repeater gain stability near the top edge of the transmitted band.

The final allocation of frequencies is shown in Fig. 1. Just below the TV band from about 3 to 3.5 megacycles is a dead space. This frequency space is needed for the filters which are employed to separate the telephone signals from the TV signals at TV and telephone dropping points. A very high value of loss is required of these filters in their attenuating bands, and if this is built up over too small a frequency band the resulting delay distortion introduced into the TV band becomes very difficult and expensive to equalize. Below this guard band is the master group of 600 telephone channels, which is transmitted simultaneously with the TV signal.

The detailed allocation of specific frequencies, that is, TV carrier and the pilot frequencies, results from consideration of effects produced by these frequencies in telephone channels as a consequence of modulation distortion in repeaters. These considerations have been described in detail.[1]

Modulation Process

In the *L1* coaxial cable system[3] frequency translation by the TV terminals is accomplished in two stages. The 2-step process employs a first modulator supplied with a very-high-frequency carrier to translate all video frequencies to a band far outside the final transmitted band of frequencies where the upper side band is suppressed. A second modulation then translates the vestigial side-band signal back down in frequency to the final band. In contrast, the *L3* terminals employ only a single step of modulation to convert the signal directly to the assigned band as shown in Fig. 2. In general, this can be accomplished if the carrier frequency is at least half the sum of input and vestigial bandwidths. Then the lower modulation side band does not fold over the zero frequency axis to produce frequencies which fall back into the vestigial or upper side bands. Some fold-over is evident in the *L3* case shown in Fig. 2 at low frequencies of the modulator output. Single-step modulation is advantageous in that the very high frequencies encountered in the multistep process are avoided. The disadvantage of the 1-step process is that many extraneous products of modulation, which in the 2-step process can be suppressed with filters, must be reduced to tolerable levels by balances in the modulator.

The modulator, Fig. 3, is a combination of two double-balanced modulators of a form often employed for modulation of telephone signals.[4] The effect of a double-balanced varistor modulator of the type represented by either of the two in Fig. 3 is to multiply the input signal by a square-wave function having the period of the particular carrier frequency. Since the square wave contains all odd harmonic multiples of the carrier frequency, its multiplication by the input signal generates a series of double side-band output spectra, each centered about one of the harmonics of the carrier. It happens in this case that the lower side band of the third harmonic spectrum of the carrier modulator contains frequencies low enough to overlap the high frequencies of the carrier spectrum upper side band, and this overlap results in quite visible picture distortion.

It is possible, by employing a second modulator paralleling the first but driven with a frequency three times the carrier frequency, to generate a signal spectrum centered at carrier third harmonic which will cancel the corresponding output of the carrier modulator. Successful translation of the video spectrum to the *L3* carrier band in a single modulation step depends upon the maintenance of this and other modulator balances to unusually stringent requirements.

The carrier supply oscillators for the modulators and demodulators are of the Meacham bridge type[5] with quartz crystal frequency control and thermistor amplitude control. Frequency stability of two parts per 1,000,000 is required for successful carrier regeneration at the receiver. A constant temperature oven for the quartz plus the inherent stability of the bridge-type circuit is expected to provide the required frequency stability between monthly maintenance periods.

A feature of the signal transmitted over the *L3* system is a degree of modulation which exceeds the value commonly referred to as 100 per cent modulation. The resulting wave form contains a maximum ratio of information to peak carrier, important from the standpoint of optimum signal to noise performance. Fig. 4 shows progressively the reduction in peak carrier amplitude, which may be effected by subtraction of carrier component from a modulated signal. Figs. 4(B), 4(C) and 4(D) each contain the same amplitude of video modulation. Fig. 4(B) represents a video-modulated carrier signal with maximum carrier occurring at tips of synchronizing pulses, and a minimum carrier, equal to 20 per cent of maximum carrier, corresponding to picture white. Fig. 4(C) represents the same signal as Fig. 4(B) except that the 20-per-cent excess carrier has been subtracted. This is the 100-per-cent modulation case. Fig. 4(D) shows the effect of further carrier subtraction, or addition of negative carrier, to reduce to a minimum the peak amplitude of the modulated signal. The wave form of Fig. 4(D) employed for *L3* transmission requires $7^1/_2$ decibels less maximum carrier power than that of Fig. 4(B) for the same transmitted information. The term excess carrier ratio has been devised to describe degrees of modulation which exceed 100 per cent. It is the ratio of peak carrier amplitude to the peak-to-peak modulation amplitude. Excess carrier ratio (ECR) for the wave forms of Figs. 4(B), 4(C) and 4(D) respectively are 1.2, 1.0 and 0.5.

Modulated signals of the forms of Fig. 4(B) or 4(C) may be detected by rectification, that is, envelope detection. However, rectification of the wave form, Fig. 4(D) produces a spurious envelope wherein video signals which exceed a particular value are inverted. It is necessary to employ homodyne detection, that is, a demodulator driven by a locally generated carrier which is synchronous in phase angle and frequency with the carrier component of the signal wave. As described later, homodyne detection also makes possible the necessary suppression of the quadrature distortion associated with vestigial side-band transmission. Quadrature distortion associated with envelope detection is tolerated in the *L1* coaxial system, but with tandem operation of terminals required in the *L3* system it would accumulate to intolerable values.

Vestigial Side-Band Considerations

A vestigial side-band signal is produced by a band-shaping filter following the modulator. In this filter the lower side band is suppressed completely except for those frequencies which are within 500 kc of TV carrier. Lower side-band frequencies within 500 kc of carrier are suppressed only partly, as also are upper side-band frequencies within 500 kc of carrier, to achieve a symmetrical response function in the vestigial side-band region.

It is convenient in a discussion of vestigial side-band transmission to consider the transmission as made up of two components, each symmetrical about carrier frequency, a real or in-phase component, and a quadrature component which is a distortion term.[6] The process is illustrated in Fig. 5. Here the response function shown in Fig. 5(A) represents idealized conditions for vestigial side-band transmission. The main side band is shown extending from carrier frequency F_c to the upper cutoff F_u. A vestige of the lower side band extends from carrier frequency to the lower cut-off F_v. Constant envelope delay is required in the entire band from F_v to F_u. In the frequency region $F_c \pm F_v$ the response characteristic is so shaped that the sum of responses at corresponding frequencies above and below carrier add to a constant value. The summing of signal components in the vestigial bands above and below carrier is accomplished by the receiver demodulator.

The response function of Fig. 5(A) may be considered to be the sum of the two response functions 5(B) and 5(C) which have even and odd symmetry respectively about the carrier F_c. Both 5(B) and 5(C) are double side-band functions. The component in Fig. 5(B) represents the normal double side-band output of the modulator supplied with video and carrier signals. The other component, Fig. 5(C), represents the output of a modulator supplied with carrier and signal

voltages each shifted in phase by 90 degrees and with the amplitude attenuated as shown in the vestigial region $F_c \pm F_v$. The modulation transmitted by a circuit with the response function of Fig. 5(C) is called the quadrature component and is related to the normal modulation, depending upon the shape and extent of the vestigial side band. Fig. 6 illustrates the real and quadrature components of an idealized rectangular wave form demodulated after transmission over circuits having the response functions of Fig. 5 respectively.

The 90-degree shift of carrier frequency in the quadrature component of the vestigial side-band signal makes possible the suppression of this component. The transmitted vestigial side-band signal may be written

$$V(t) = P(t)\cos ct + Q(t)\sin ct \qquad (1)$$

where

$c = 2\pi$ times carrier frequency

$P(t)$ and $Q(t)$ = real and quadrature modulating functions[6] typically as represented in Fig. 6

The demodulator may be regarded as an ideal multiplier of signal and carrier supply. Let the carrier supply be denoted

$$C(t) = \cos(ct - \phi) \qquad (2)$$

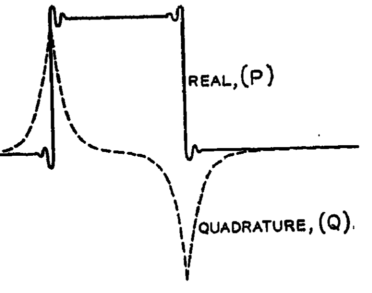

Fig. 6. Real and quadrature components of a rectangular pulse after vestigial side-band transmission

where ϕ = the phase of the receiver-carrier supply relative to the carrier factor of the real component of the signal. The demodulator output is the product $V(t)$ $C(t)$. A low-pass filter rejects the output components in the band of frequencies about twice carrier frequency so that the demodulated video signal output is the lower frequency component. Thus, neglecting a factor of 1/2

$$V_0(t) = P(t)\cos\phi + Q(t)\sin\phi \qquad (3)$$

It is seen that real and quadrature video components in the demodulator output exist in the same proportion as the components of the demodulator carrier supply in phase and in quadrature respectively with the real carrier component of the vestigial signal. By providing carrier exactly in phase with the real component of the signal, the quadrature component in the output may be completely suppressed. It has been determined that to suppress the quadrature component resulting from the *L3* vestigial band shape to barely perceptible (threshold) values, the phase angle of the carrier regenerated at the receiver must be maintained to an accuracy of ±2.5 degrees. A requirement for one demodulator, when six pairs of terminals contribute to produce quadrature distortion at threshold value, becomes 2.5 degrees divided by the square root of 6, or about 1 degree.

The regeneration of carrier at the receiver is one of the principal *L3* terminal features. Here a 4.139-megacycle carrier must be provided to demodulate the overmodulated *L3* signal. The required carrier must be reconstituted from information carrier in the signal itself. It would be possible of course to transmit separately a signal from which carrier frequency could be derived, but carrier frequency is really the smallest part of the required information. It is the phase angle of the carrier of the received signal which must be duplicated closely at the demodulator and separate transmission of carrier phase angle does not seem feasible. A phase-controlled oscillator is employed for the carrier supply at the receiver, with phase control obtained from information residing in the signal itself, and frequency synchronization an additional burden upon the phase control system.

The basis for synchronizing the receiver oscillator to the carrier of the received signal lies in the phase angle of the carrier frequency component of the vestigial side-band signal average over a period of time of the order of one frame-scanning period. Referring again to Figs. 5(B) and 5(C), it may be noticed that the quadrature response function is zero at carrier frequency. This means that the quadrature component of the transmitted signal contains no carrier frequency component and will not affect the determination of the real carrier component phase angle based upon averaging over a sufficient period of time. Another signal characteristic presents more serious problems. The degree of modulation employed in *L3*, shown in Fig. 4(D), makes the average carrier polarity indeterminate. That is, the carrier polarity for a video amplitude corresponding to picture white is opposite to that corresponding to picture black or sync pulses. The polarity reverses as the composite signal changes through its half peak-to-peak value. The average polarity determined from a predominantly white picture is thus opposite to that determined from a predominantly black picture. A carrier oscillator, phase-synchronized to the average carrier phase of the signal would execute 180-degree phase reversals as picture content change from average white to average black, producing sudden video polarity reversals at the demodulator output.

This signal carrier polarity ambiguity which is momentary in character can be exchanged for one which is not time-variable by a multiplication operation. The modulated signal is squared, that is, multiplied by itself on an instantaneous basis, in a square-law circuit. Such an operation squares carrier amplitude and doubles carrier frequency and phase angle, the latter effect converting 180-degree phase reversals into 360-degree changes which are indeterminable in the average phase detector. Under these conditions the phase-synchronized demodulator carrier supply, stably locked to the average phase of the squared signal, experiences no phase reversals with change in picture content. The ambiguity now is in the determination of incoming signal polarity. The squaring operation eliminates any basis for determining polarity so that the demodulator carrier may with equal likelihood lock to either polarity relative to the signal and thereby, at the demodulator output, produce video signal wave forms of either polarity.

The method used to secure phase synchronization of the local receiver oscillator to the received signal is described next with reference to Fig. 7. Signal from the line, together with the output from the carrier oscillator, is brought to the demodulator where the desired video output signal is obtained as the lower side band of the modulation product. This process has already been described in equations 1 to 3. In the carrier regeneration process, signal and carrier phase shifted by 45 degrees, equations 4 and 5, are each squared in square-law circuits

$$V(t) = P \cos ct + Q \sin ct \qquad (4)$$

$$C(t)\underline{/45 \text{ degrees}} = \pm \cos(ct - \phi - \pi/4) \qquad (5)$$

Band-pass filters select from the squaring circuit output signal frequencies in the neighborhood of twice carrier frequency. From the signal squarer

$$1/2(P^2 - Q^2) \cos 2\,ct + PQ \sin 2\,ct \qquad (6)$$

and from the carrier squarer

$$1/2 \sin(2\,ct - 2\phi) \qquad (7)$$

The two squared signals at twice carrier frequency are multiplied together in a product modulator. This product contains signals in two bands of frequencies, one band in the region of four times carrier frequency and the other in the video frequency band starting at zero frequency. The lower frequency component of this product is selected by a low-pass filter following the product modulator yielding

$$\frac{(P^2 - Q^2)}{2} \sin 2\phi + PQ \cos 2\phi \qquad (8)$$

The d-c component of the low-pass filter output is a suitable control voltage for synchronization, and is obtained in the limit as the cutoff frequency of the low-pass filter is lowered. Average values as produced by the low-pass filters are applied as a frequency control voltage to the carrier oscillator.

The first term in equation 8, $(P^2 - Q^2)/2 \times \sin 2\phi$, when averaged is, for small errors in carrier phase angle, proportional to the error angle ϕ with a factor of proportionality recognized as the difference in mean-squared values of the real and quadrature modulating functions, P and Q, illustrated typically in Fig. 5. This difference is always positive when the modulating signal contains energy components within the bounds of the vestigial side band since the quadrature response function, Fig. 5(C), is attenuated relative to the real response function in this band. In the present case, with a 500-kc vestigial bandwidth and a composite video wave form for a modulating function, the amplitude of Q^2 for control purposes is negligible compared with P^2.

The second term of equation 8, $PQ \times \cos 2\phi$, contains no d-c component since Q itself contains no d-c component, and all other frequency components of Q are shifted 90 degrees in phase relative to corresponding components in P. The d-c control voltage therefore is not modified by the existence of the second term of equation 8. However, the function PQ does contain sum and difference frequencies caused by the cross products of the spectra of P and Q. These frequencies in the control voltage tend to be large compared with corresponding frequencies caused by the products P^2 and Q^2 since the trigonometric multiplier $\cos 2\phi$, equation 8, is large when the phase-angle error is small. The effect of the term $PQ \cos 2\phi$ is that of phase modulation of the receiver carrier supply, and its suppression determines the characteristics required of the low-pass filter which averages the control signal. At the penalty of sluggish synchronization and restricted oscillator pull-in range, the phase modulation can be reduced to arbitrarily small values. For our purposes a pull-in range of ±20

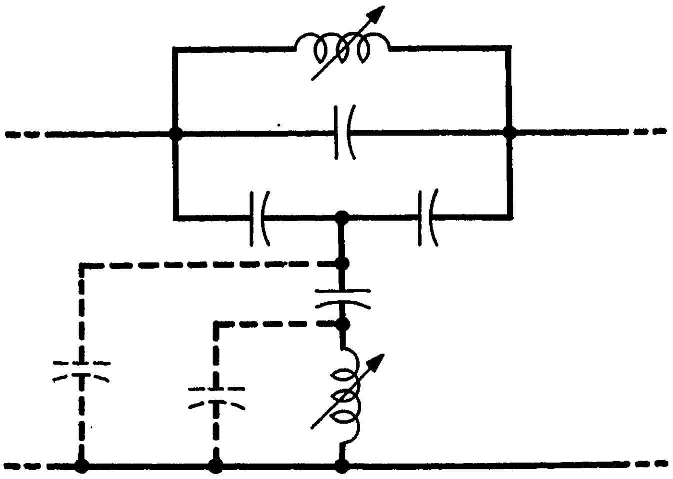

Fig. 11. Schematic of a delay equalizer section. Dotted capacitors are parasitic

cycles per second(cps) can be achieved with phase modulation less than ±0.1 degree with adequate margins.

The control voltage is applied to a tuning element in the receiver oscillator, in this case a small saturable reactor made with ferrite as a core material. This reactor is part of the series resonant quartz crystal circuit which determines the oscillator frequency, and is capable of shifting the frequency in response to the control voltage by ±20 cps, a figure chosen as safely less than the first side-band components of the transmitted signal which are ±30 cycles from carrier frequency. This precaution avoids possible synchronization of the local oscillator to a signal side-band frequency, rather than to the carrier.

Sufficient gain is provided in the carrier frequency control loop just described so that the maximum frequency difference encountered between transmitting and receiving oscillators is corrected by the phase control voltage because of a steady-state phase-angle error ϕ less than 1/2 degree. The control characteristic of the saturable reactor may be expressed

$$\Delta f = A(P^2 - Q^2)\sin 2\phi \qquad (9)$$

where

Δf = the frequency shift introduced by the reactor

A = the factor proportional to required loop gain

One other factor to be considered is the stability criterion of the frequency control circuit as a feedback loop.[7] In this case two factors contribute to loop phase shift. First, the phase-angle variation of the oscillator output in response to the control voltage is an integration process. The control voltage changes the oscillator frequency and the resulting phase change can be expressed as the integral with respect to time of the frequency shift

$$\text{phase}\ \theta = 2\pi \int \Delta f dt \qquad (10)$$

The integration with respect to time introduces a 90-degree low-pass phase shift into the control loop at all frequencies. Also the averaging low-pass filter introduces phase shift in the same direction, so that care must be exercised to avoid instability. In this case a phase stability margin of 45 degrees is provided over a wide range of frequency by designing the low-pass filter as a series of resistance-capacitance steps of loss. These are staggered in frequency to produce a cut-off rate of 3 decibels per octave with a phase shift of 45 degrees over a wide-frequency band.

The polarity ambiguity resulting from the squaring process has been demonstrated in the derivation of the phase control voltage. In equation 5 the ± designation indicates that either polarity of carrier signal might be assumed without affecting subsequent expressions. However, in the derivation of the output voltage from the main signal demodulation, equation 3, the output signal polarity reverses if the carrier, equation 2, is assumed with reversed polarity. The carrier polarity established at any given time depends largely upon initial phase conditions when signal is applied.

Correct video polarity at the receiver output is established by a new device called a polarizer which follows the demodulator. This circuit recognized video polarity on the basis of standard features in the composite TV wave form. The particular features used in this case are the vertical blanking discontinuities expected once each 1/60 second, and the duty factor of sync pulses. These two characteristics taken together form a sufficient condition for the determination of polarity of any composite video wave form independent of picture content. The polarity, once recognized to be inverted, is corrected.

Harmonic Distortion

A significant consideration in transmission problems is the generation of distortion by the nonlinear amplitude characteristic of the transmission apparatus. In the case of video transmission, nonlinearity results in the distortion of brightness values of the transmitted picture and presumably will distort chromaticity values of color TV signals. With carrier transmission apparatus, in addition to these effects, nonlinearity produces ex-

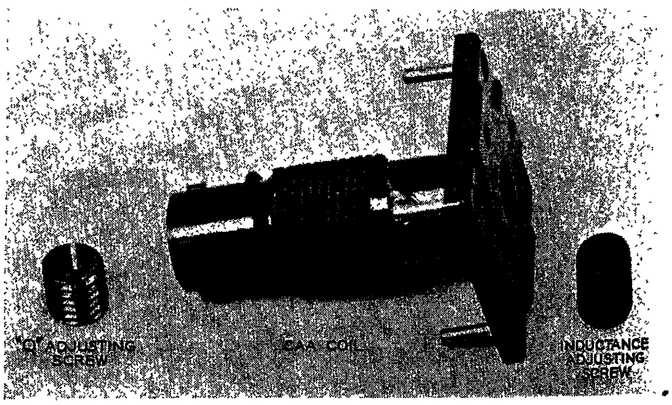

Fig. 12. Inductor with adjusting screws; Q adjusting screw on the left, and inductance adjusting screw on the right

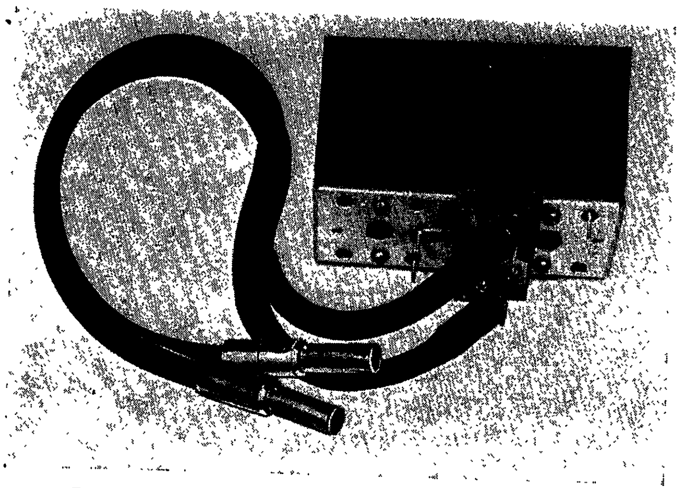

Fig. 13. Fixture for delay equalizer section adjustment

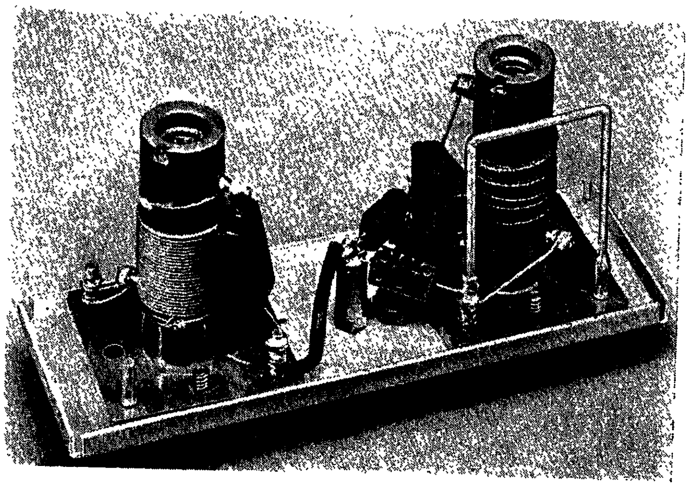

Fig. 14. Model of a typical delay equalizer section

traneous interference patterns at harmonics of the carrier frequency. In *L3*, with a carrier-modulated spectrum concentrated near 4.139 megacycles, the second harmonic distortion of line-repeating amplifiers produces a new spectrum concentrated near 8.278 megacycles, which is demodulated by the receiving terminal to the region near 4.139 megacycles. This form of distortion is considerably more disturbing in the final picture than a comparable distortion of brightness values, and constitutes a limit to transmission signal-to-noise performance.

Advantage is taken of the spectral distribution of energy of TV signals to ameliorate somewhat the effects of second harmonic distortion. A pre-emphasis network is employed in the transmitting terminal to accentuate the amplitude of high-frequency components of the signal before transmission. At the receiver, a restorer network introduces a complementary frequency characteristic to make the over-all transmission characteristic constant with frequency, Fig. 8. The restorer network, de-emphasizing the high-frequency components, likewise suppresses the second harmonic distortion signals. A limit to the amount of predistortion permitted is set by the maximum amplitudes expected of the high-frequency picture components, particularly in anticipation of a high-frequency color subcarrier in color TV systems. Tentatively, the characteristic of Fig. 8 is chosen as a compromise of these factors.

Filters and Equalizers

A low-pass filter is required before the video signal is modulated, to limit the bandwidth of the signal, eliminating possible sources of disturbing cross-products, both in the modulator and in the repeaters of the *L3* system. This filter has a cut-off at 4.3 megacycles and provides over 40-decibel discrimination to all frequencies greater than 4.8 megacycles. It consists of three *m*-derived sections and introduces about 1.3 microseconds of envelope delay distortion near its cut-off frequency. This is equalized after modulation by the delay equalizer to be described.

Following the modulator is the vestigial side-band filter which passes the upper side band, and provides 60-decibel discrimination against all frequencies in the lower side band less than 3.7 megacycles. The large discrimination is required to avoid interference with the telephone channels during transmission over the coaxial line. This filter provides a controlled loss characteristic to frequencies in the band 3.64 to 4.64 megacycles which satisfies the requirement for vestigial side-band transmission. The response function for this band is shown in Fig. 2. A flat transmission characteristic, including the effective pass band loss of the video *LP* filter, is maintained over the entire upper side band from 4.6 to 8.44 megacycles. A second low-pass filter after the modulator provides at least a 50-decibel discrimination against third and higher harmonics of the TV carrier, or 4.139 megacycles.

A 4-section high-pass filter designed by the insertion loss method[8] is used to supply 50 decibels of the discrimination at frequencies less than 3.5 megacycles. This filter has a low-pass shunt network at the input to maintain its stop-band impedance at 75 ohms. This is required because, to produce a uniform frequency characteristic, the impedance facing the modulator has to provide a reflection coefficient not exceeding 3 per cent. The remaining discrimination at frequencies less than 3.7 megacycles and the major part of the vestigial side-band shaping are provided by a group of six constant-resistance equalizer sections, as shown in Fig. 9. The low-pass filter to suppress carrier harmonics consists of two *m*-derived filter sections.

The delay distortion of the complete set of filters and loss equalizer sections is shown in Fig. 10. This includes the equivalent delay distortion of the video low-pass filter, translated in frequency for equalization after the modulator. The distortion must be equalized to a constant delay over the TV band. A delay equalizer to do this is incorporated in the filter. It was designed by a potential analogue method[9] and consists of 24 all-pass sections, each having the schematic as shown in Fig. 11. A redundant capacitor is used to avoid excessively small capacity values. The capacitors shown dotted are parasitic elements which must be compensated for by modifying the design values of the other elements. This group of sections has an insertion loss varying from 2 to 12 decibels across the pass band of the filter, caused by the dissipation of the elements. This loss, of course, must be taken into account in the design of the loss equalizer sections.

The objective is to obtain equivalent video transmission through the terminal flat to limits varying from ±.02 decibel to ±.10 decibel, depending upon the frequency characteristic of the deviation. To achieve this, close control of the dissipation loss is essential. The inductor losses which cause the major part of the delay equalizer loss characteristic vary up to ±15 per cent from nominal values. As a means for controlling inductor Q to ±0.5 per cent or better, a Q-adjusting screw is employed. The inductors are solenoids wound on molded tubes with a threaded hole through the center. A threaded magnetic dust core is used for

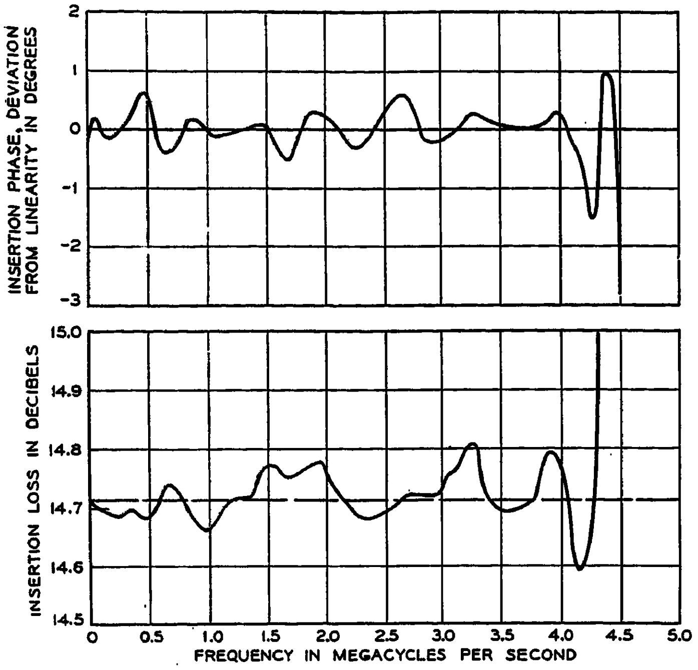

Fig. 15. Measured passband performance of a trial model of the transmitting filters and equalizer

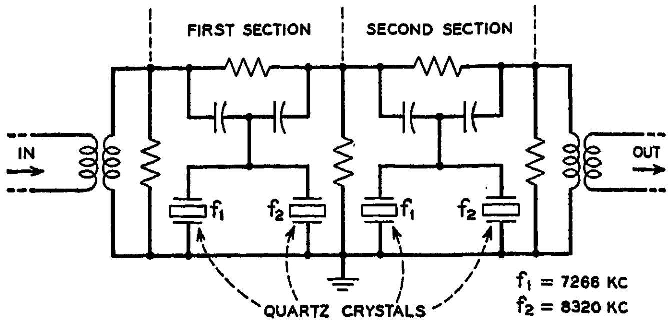

Fig. 16 (above). Simplified schematic of the pilot frequency band elimination filter

inductance adjustment. Its travel can be limited to the distance from the center to one end of the form without losing adjustment range. By introducing an additional core made of solid magnetic iron into the field of the solenoid, using the opposite end of the form, an adjustment is provided which reduces the Q in a continuous manner as the second screw is advanced into the form. The reduction in Q is caused by the losses in the iron, and normally these would cause a reduction in inductance also. However, the permeability of iron causes an increased concentration of field which tends to increase the inductance. A balance between these tendencies to decrease and to increase the inductance is obtained by controlling the geometry of the Q-adjusting core. As a result, a reduction of up to 50 per cent in Q can be obtained, accompanied by a change of less than 1 per cent in the inductance. Models of the inductor and the adjusting screws are shown in Fig. 12. This adjusting screw, in conjunction with the magnetic dust core, provides an accurate and economical means for adjusting simultaneously both inductance and dissipation in each inductor of the delay equalizer.

The flat transmission level for the upper side band and the shaped cut-off for the vestigial side band were obtained by including loss equalizer sections, assuming Q factors for the all-pass sections of about 20 per cent less than the nominal Q of the inductors. As a final step in the design, the Q factors were modified to absorb in the loss of the all-pass sections the residual loss distortion uncompensated by the loss equalizer sections. This, in effect, provided the use of 24 additional parameters for shaping the loss in the pass band, and resulted in an improved loss characteristic.

The close limits on delay distortion can be met only by close control of the adjustments on the individual all-pass sections. In order to obtain reproducible results to the order of ±0.1 degree for the phase shift and ±0.01 decibel for the insertion loss of the individual sections, a special fixture is employed to make the connection between the section and the measuring circuit. This is shown in Fig. 13. The fixture can be clamped on the network terminals quickly without soldering and provides coaxial patch cords with plugs for connection to the measuring circuit. Each section is mounted in an individual container with shielding between the inductors to reduce coupling. Each inductor is resonated with its associated capacitors, and the dissipation is adjusted by adjusting the two cores. The construction of a typical section is illustrated by Fig. 14.

An important consideration in obtaining smooth loss and delay characteristics for the delay equalizer is the reflection coefficient of each section. Poor reflection coefficients cause reflections and interactions between all-pass sections. Owing to the large phase slope of the equalizer, these tend to produce frequency characteristics with large numbers of loss and delay ripples across the frequency band for which transmission requirements are most severe. Reflection coefficients of 2 per cent or less at all frequencies in the TV band have been obtained for all delay sections by taking the following precautions:

1. Mutual coupling is limited between the two inductors in each section by use of a shield in the section container. As little as 0.1 per cent coupling coefficient can cause a reflection coefficient of 1 per cent in certain sections at the frequency of a 180-degree phase shift.
2. The Q factors of both inductors are adjusted to be equal in each section.
3. The values of the capacitors are modified to compensate for the presence of the parasitic capacitances associated with the shunt arm, Fig. 11.

The measured insertion loss characteristic and the phase shift deviation from linear phase slope for one model of the transmitting filter and delay equalizer are shown on Fig. 15. This has been reduced to video frequency to show the detailed residual distortion which results from the addition of the vestigial lower and upper side band. The delay equalization is maintained for about 200 kc above the loss cut-off to provide for at least a 30-decibel insertion loss at frequencies where the delay distortion becomes large. Without this precaution the transient response is characterized by a severe cut-off ring distortion which is a slowly damped oscillation at cut-off frequency generated by high-frequency signal components.

Variations in transmission response in the region near TV carrier cause noticeable smear distortion on the received images. These variations can be introduced by small changes in element values of the filter or equalizer sections following initial adjustment, or by other changes in both transmitter and receiver. As a means of compensating for such variations, two adjustable loss equalizers have been provided, each with adjustable maximum loss at carrier frequency. One has a half-loss point at 300 kc and the other at 80 kc from the carrier. These,

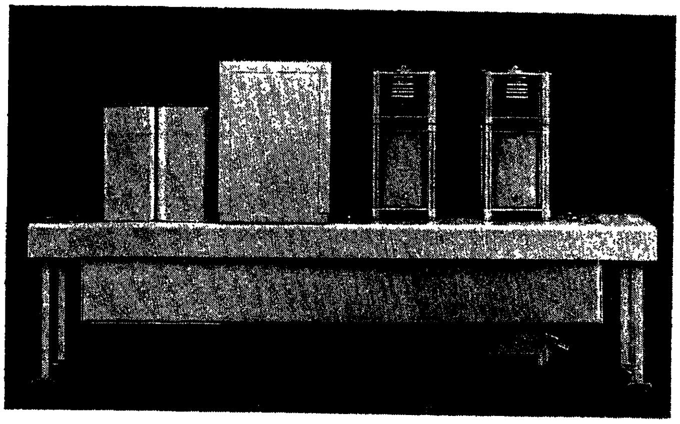

Fig. 17. Model of the carrier suppression filter

are adjusted for minimum smear at periodic intervals.

A fixed equalizer is provided in each terminal to compensate for loss and delay distortion other than that in the filters described. For convenience, this equalization is done at modulated frequencies. It is expected that additional means for periodic re-equalization of the terminal gain and phase characteristics will be necessary to achieve 4,000-mile, tandem terminal transmission quality objectives.

Pilot Frequency Filters

As described elsewhere,[1] the *L3* system has six pilot frequencies for regulating automatically the transmission characteristic of the line. Two of these, 7.266 megacycles and 8.320 megacycles, are in the TV band. At the transmitting terminal a pilot elimination filter for these two frequencies is required to prevent energy in the TV signal near these frequencies from disturbing the pilot levels on the system. At the receiving terminals, these pilot frequencies must be removed from the TV band to avoid interfering effects in the output TV signal. A discrimination is required of 50 decibels for frequencies within 20 cycles of the two pilot frequencies. Also, at the receiver a carrier elimination filter is required to suppress the residual carrier leak from the demodulator. This demands a 30-decibel suppression to frequencies within 20 cycles of 4.139 megacycles.

To avoid removing excessively broad bands of frequencies from the television band, and thereby generating visible distortion in the transmitted picture, narrow bandwidth crystal filters are used for both of these applications. The pilot elimination filter has its 3-decibel loss points at about 1,000 cycles on either side of the pilots. The carrier suppression filter has its 3-decibel loss points at 150 cycles on either side of the carrier. In the past, spurious or secondary responses in the crystal units could not be limited to sufficiently low values to permit available crystals to be used in broad-band circuits without elaborate means for suppressing the unwanted responses. In the *L1* system, for example, a balancing circuit using hybrid coils was employed for this function. Techniques for reducing unwanted responses in the crystal units by special contouring of the blanks and by precise optimum area plating have been developed recently.[10] The use of these methods has resulted in crystal units in which the unwanted responses are reduced to the extent that relatively simple filters can be used for these applications. A simplified schematic of the pilot elimination filter is shown in Fig. 16. Small ovens are provided to maintain close temperature control for the quartz crystal elements in order to stabilize the resonant frequencies. Mechanical arrangements are illustrated in Fig. 17.

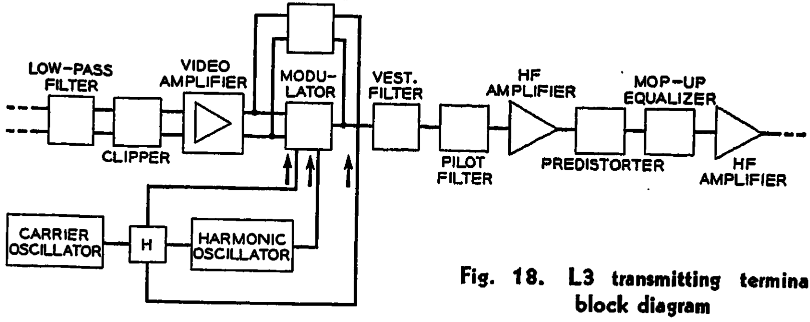

Fig. 18. L3 transmitting terminal block diagram

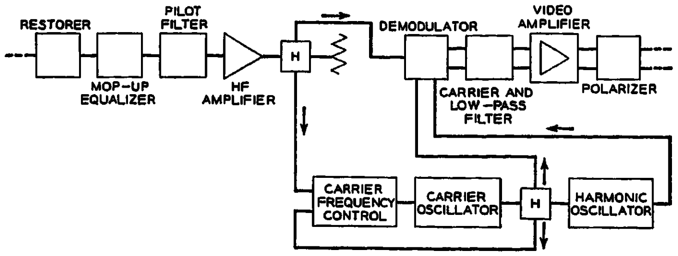

Fig. 19. L3 receiving terminal block diagram

Power Equipment

Primary power for the TV terminals is 60 cycles a-c. It is derived from the *L3* motor-alternator power equipment at main repeater stations or, alternatively, from commercial 60-cycle sources. When commercial power is used directly, a provision is made for switch-over to emergency power in the event of power failure. The emergency power supply comprises a 130-volt battery, an inverter, and automatic switch-over equipment. If during service the commercial power source fails, a switch-over to emergency power is made automatically in a period under 1/10 second.

D-c and heater power provisions involve two departures from previous practice. First, the rectifiers which supply anode and other d-c power requirements are nonregulated metallic (selenium), rectifiers. These are supplied from magnetic a-c line voltage regulators to obtain suppression of line voltage variations. The combination of the magnetic a-c regulator and the metallic rectifier provides adequate suppression of hum and line voltage variations with, it is expected, greater reliability than alternative vacuum-tube regulated rectifiers. Secondly, the magnetic a-c line voltage regulator, together with an improved heater transformer design, makes possible the operation of the vacuum tubes at reduced heater voltage to obtain increased thermionic life expectancy. This advantage can be taken only if close control of heater transformer output voltage is possible. In this case, variations in output voltage expected to occur, owing to temperature variations of the transformer windings, have been substantially eliminated by incorporating thermistor temperature compensation in the transformer primary circuit.

T3 Transmitting Terminal

A block diagram of the components of the transmitting terminal is shown in Fig. 18. The composite video signal is received from the Bell System TV operation center over a 124-ohm balanced

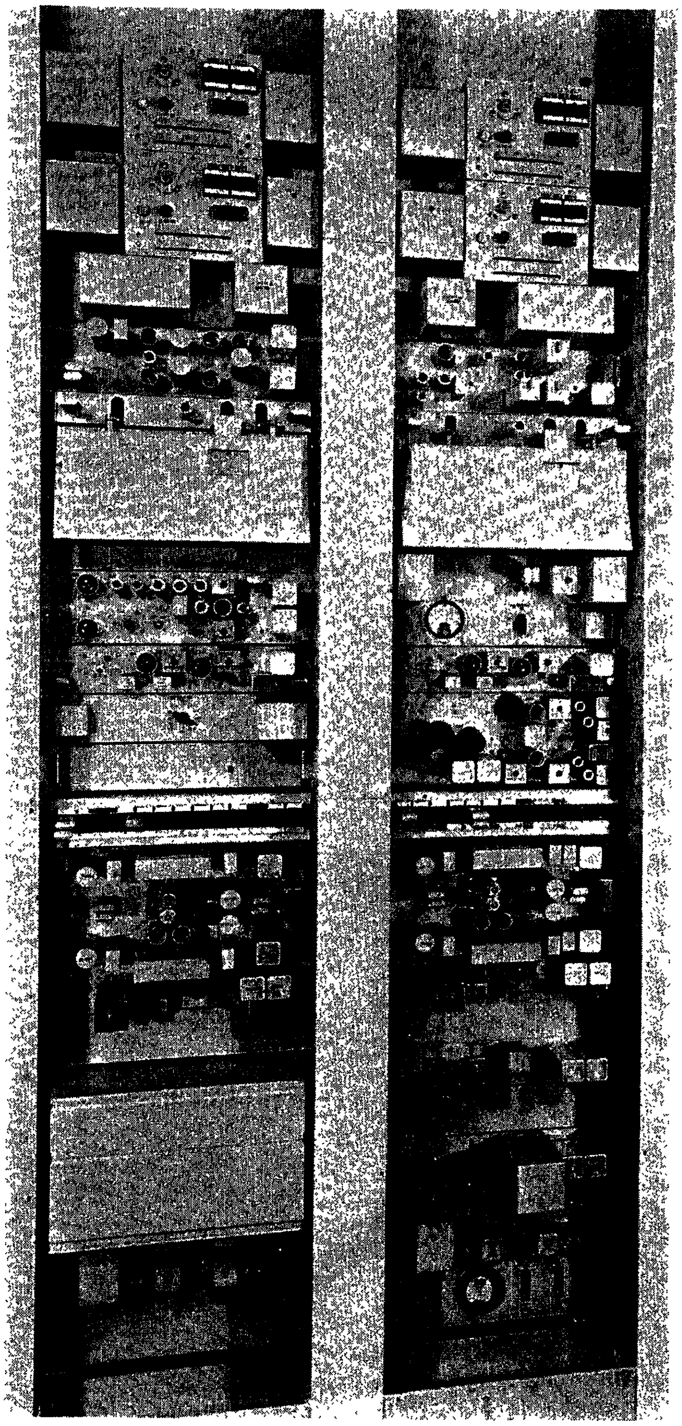

Fig. 20. Model of transmitting and receiving terminal equipments

cable, and the modulated output signal is delivered to the *L3* line facilities over a 75-ohm coaxial cable.

An input low-pass filter and a video clipper circuit place ceilings on the maximum transmitted signal bandwidth and signal amplitude respectively. The clipper circuit is required to protect the 600 telephone channels from inadvertent overloads caused by excessive TV signals. Normal amplitude signals are not affected by the clipper.

Following are a video amplifier and the modulator, together with the required carrier supplies, and the carrier level control. The latter device accurately regulates the peak carrier magnitude in the output signal and thereby preserves the desirable maximum modulation.

Following the modulator is the vestigial band filter which, together with its delay equalizer, shapes the double sideband modulator output into the vestigial transmission band. The flat loss of these networks requires that amplification be provided in the carrier frequency band to increase the signal level. The first of two high-frequency flat-gain amplifiers in the transmitter restores the signal amplitude.

The pilot band elimination filter is next provided to remove TV signal energy and other possible interference from particular frequencies allocated to the *L3* line pilot signals.

At this point occur the predistorter network for pre-emphasizing the high-frequency signal components, and a mop-up equalizer. The mop-up equalizer is to provide means for periodic correcting of the transmission characteristic. The high-frequency amplifiers, particularly, change their transmission characteristic as the vacuum tubes age. An additional high-frequency amplifier is provided to recover the loss of these networks and deliver a proper signal level to the line equipment.

R3 Receiving Terminal

The receiver demodulates the signal as transmitted over the *L3* line facilities to recover the video signal for transmission over local video circuits. As has been discussed, the demodulation is a homodyne process utilizing a local carrier regenerated from information contained in the transmitted signal.

A block diagram of receiver components is shown in Fig. 19. The first components are a group of networks; the restorer to compensate for transmitter predistortion, the fixed and variable mop-up equalizers to compensate for deviations in the receiver frequency characteristic, and a pilot elimination filter to remove *L3* pilot frequencies from the signal. A high-frequency amplifier provides amplification to compensate for the network losses.

The amplified signal is split into two branches by a hybrid transformer. Part of the signal serves as a carrier to the demodulator for detection to video frequencies, while the remainder is employed in the carrier regeneration apparatus. The carrier supply oscillator output likewise is split between the same two circuits, the portion supplied to the demodulator providing the carrier energy for demodulation, and the part sent to the carrier regeneration circuits providing means for comparison with the input signal. The carrier regeneration equipment comprises mainly the phase comparison circuit together with means for changing electronically the frequency of the carrier supply oscillator.

The phase-synchronized carrier supply, together with the associated third harmonic supply, provides demodulating carriers which translate the carrier spectrum down in frequency to the original video spectrum. The demodulator output also contains an unwanted upper side band in the 8-to-12 megacycle region. This signal and the residual carrier leak from the demodulator are removed from the detected signal by a low-pass filter and the quartz crystal narrow-band rejection filter tuned at carrier frequency. Finally, the signal is amplified at video frequencies to provide moderately high video frequency transmission levels and is transmitted through the reversing relays of the polarizer to the receiver output.

Fig. 20 is a photograph of two equipment bays, each 11 feet high, which comprise at the left the *T3* transmitting terminal, and at the right the *R3* receiving terminal.

G. C. MERGNER
ASSOCIATE MEMBER AIEE

Synopsis: This paper describes a multipurpose instrument which can measure direct voltages in high-impedance circuits, small direct currents, and high resistances with good accuracy. The basic detector is a chopper-type stabilized feedback amplifier which is entirely a-c powered.

General Considerations

IT IS desirable to measure a voltage by a null method to avoid errors due to drawing current from the voltage source. It is also desirable to measure a current by a null method, to avoid any error due to a change in current caused while inserting the resistance of the meter in the current circuit.

By using a chopper-type feedback amplifier, a null-type measurement of voltage and current can be made with good accuracy. Zero stability is achieved by the chopper type of measurement, and gain stability is achieved by having sufficient gain in the feedback amplifier.[1]

To make resistance measurements, the only additional requirement is a stabilized direct voltage of known value to connect in series with the unknown resistance in order to supply the current for measurement. The instrument to be described has all of these features.

Versatility of the Instrument

The instrument, Fig. 1, features an easily read meter, with two scales approximately $5^1/_2$ inches in length. One scale is for voltage and current, and the other for resistance. Two controls are provided, one to select the range of measurement and the other to select the type of measurement: voltage, current, or resistance. These controls make available ranges which have the full-scale values listed in Table I. The type of measurment employed eliminates the need for a zero adjusting control.

Two binding posts are provided for connecting the instrument for measurements. One of these does not require shielding, but for extremely low-level measurements, shielding of the other binding post is necessary. A receptable for a shielded plug is also provided for convenience in making connections to the sensitive terminal. Terminals are provided (*E* in Fig. 1) so that an external battery can be inserted in the circuit in order to measure resistance at any desired voltage level up to 500 volts.

To protect the user, the push button switch "*MΩ*" in its normal position applies only 10 volts to the input circuit for measuring resistances. It has to be pushed to make a measurement using 100 volts. The instrument may be used with a recorder for all ranges.

Description of the Basic Circuit

The basic circuit is shown in block diagram in Fig. 2 and schematically in Fig. 3. The input signal is converted from a direct voltage to a 60-cycle voltage by a mechanical synchronous chopper. Since it is desirable to have a high-input

Table I. Ranges of the Universal Meter

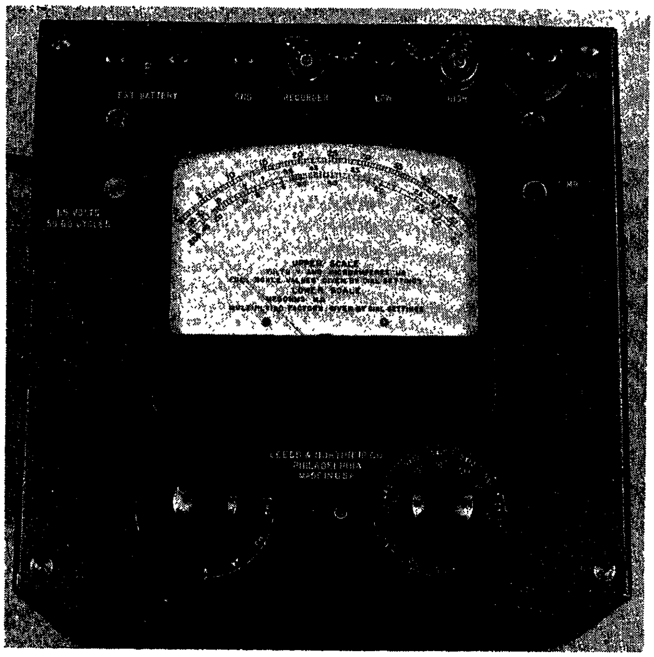

Fig. 1. The universal meter

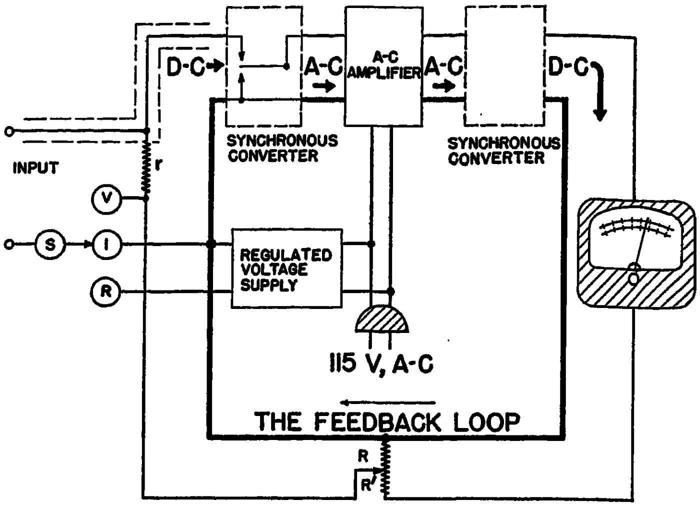

Fig. 2. Block diagram of universal meter

impedance, the input tube of the amplifier is used as a cathode follower. Following this are three stages of voltage amplification.

The resulting amplification makes the power level at the input stage so low that a d-c supply must be used for the heaters of the tube to avoid a-c pick-up from this source. It is convenient to use a d-c supply on the heater of the second tube, since this procedure serves a dual purpose: it heats the tube cathode, and it helps to filter the d-c supply for the first tube.

All tubes and their associated components thus far mentioned are contained in a shielded compartment, with external connections made through lead-through capacitors. This minimizes the effects of the radio-frequency components of line transients.

The second or output synchronous converter is electronic, and uses a duo-triode tube. The grids of both tubes are connected in parallel to the output of the last voltage amplifier stage. The plate of one triode is supplied with a 60-cycle voltage 180 degrees out-of-phase with the plate supply of the other triode. The converter triode having its plate voltage in phase with its grid voltage will conduct greater current than the other triode, which at this time will have its plate voltage 180-degrees out-of-phase with its grid voltage. The voltages produced by the corresponding plate currents flowing through the cathode resistors of the tubes are added to produce the voltage output of the electronic converter. This voltage, after being filtered to minimize the ripple, is fed back into the input circuit to stabilize the gain of the instrument.

If the voltage is fed back in series with the detector and the input to be measured, the instrument makes a null-type measurement of voltage. Referring to Fig. 2, this occurs when switch S is in the V position and r is open circuited. In this case, the voltage range is determined by the voltage drop across R produced by the current flowing in the meter.

If the voltage is fed back through a resistor and this combination is in parallel with the detector and the input to be measured, the instrument makes a null-type current measurement. This occurs when the switch S of Fig. 2 is in the I position. In this case the current range is determined by the voltage drop across R, divided by the value of r.

In order to make a resistance measurement, it is only necessary to apply a known regulated voltage to the unknown resistor, and measure the current through the resistor by the null-current method previously described. Such a regulated supply is built into this instrument. To measure resistance it is only necessary to turn switch S to the R position.

Sufficient stability is obtained for the regulated supply by using two successive stages of regulation, each stage employing a glow discharge type of regulator tube. The first stage used a type-OA2 regulator tube and the second stage uses a type-5651 voltage reference tube. Since only 1 milliampere is required, excellent regulation is obtained by this method.

Four voltage ranges are provided. The two low ranges are obtained by selecting the proper value of R, and hence, a direct measurement is made of the unknown voltage. For the higher ranges of voltage, a high-resistance voltage divider is incorporated in the instrument and used to attenuate the voltage to a value which is then measured by the low range method.

The six current ranges and six resistance ranges are obtained by changing the values of r and R; see Fig. 3.

The push-button switch which changes the regulated voltage applied to the unknown resistance from 10 volts to 100 volts provides a method of quickly checking the voltage coefficient of resistance, as well as supplying the higher resistance range. The instrument is calibrated for the high-resistance range using the 100-volt supply.

The type of circuit used makes the equivalent input resistances for the voltage ranges quite high, the equivalent input resistances for the current ranges fairly low, and greatly reduces the effect of input capacity in resistance measurements. For operating convenience, a 10,000-megohm resistor is connected across the input for all voltage ranges.

Terminals are provided so that a null-type voltage recorder with a range of 20 millivolts can be connected across part of the R resistor and used for all ranges when it is desired to record measurements. A filter is incorporated in the input circuit of the amplifier to minimize the effects of spurious a-c pick-up in the input leads.

In order to make measurements at high impedances, good insulation must be provided. Specially designed switches and terminals are employed using for insulation an acrylo-nitrile copolymer of styrene. These switches are leaf type,

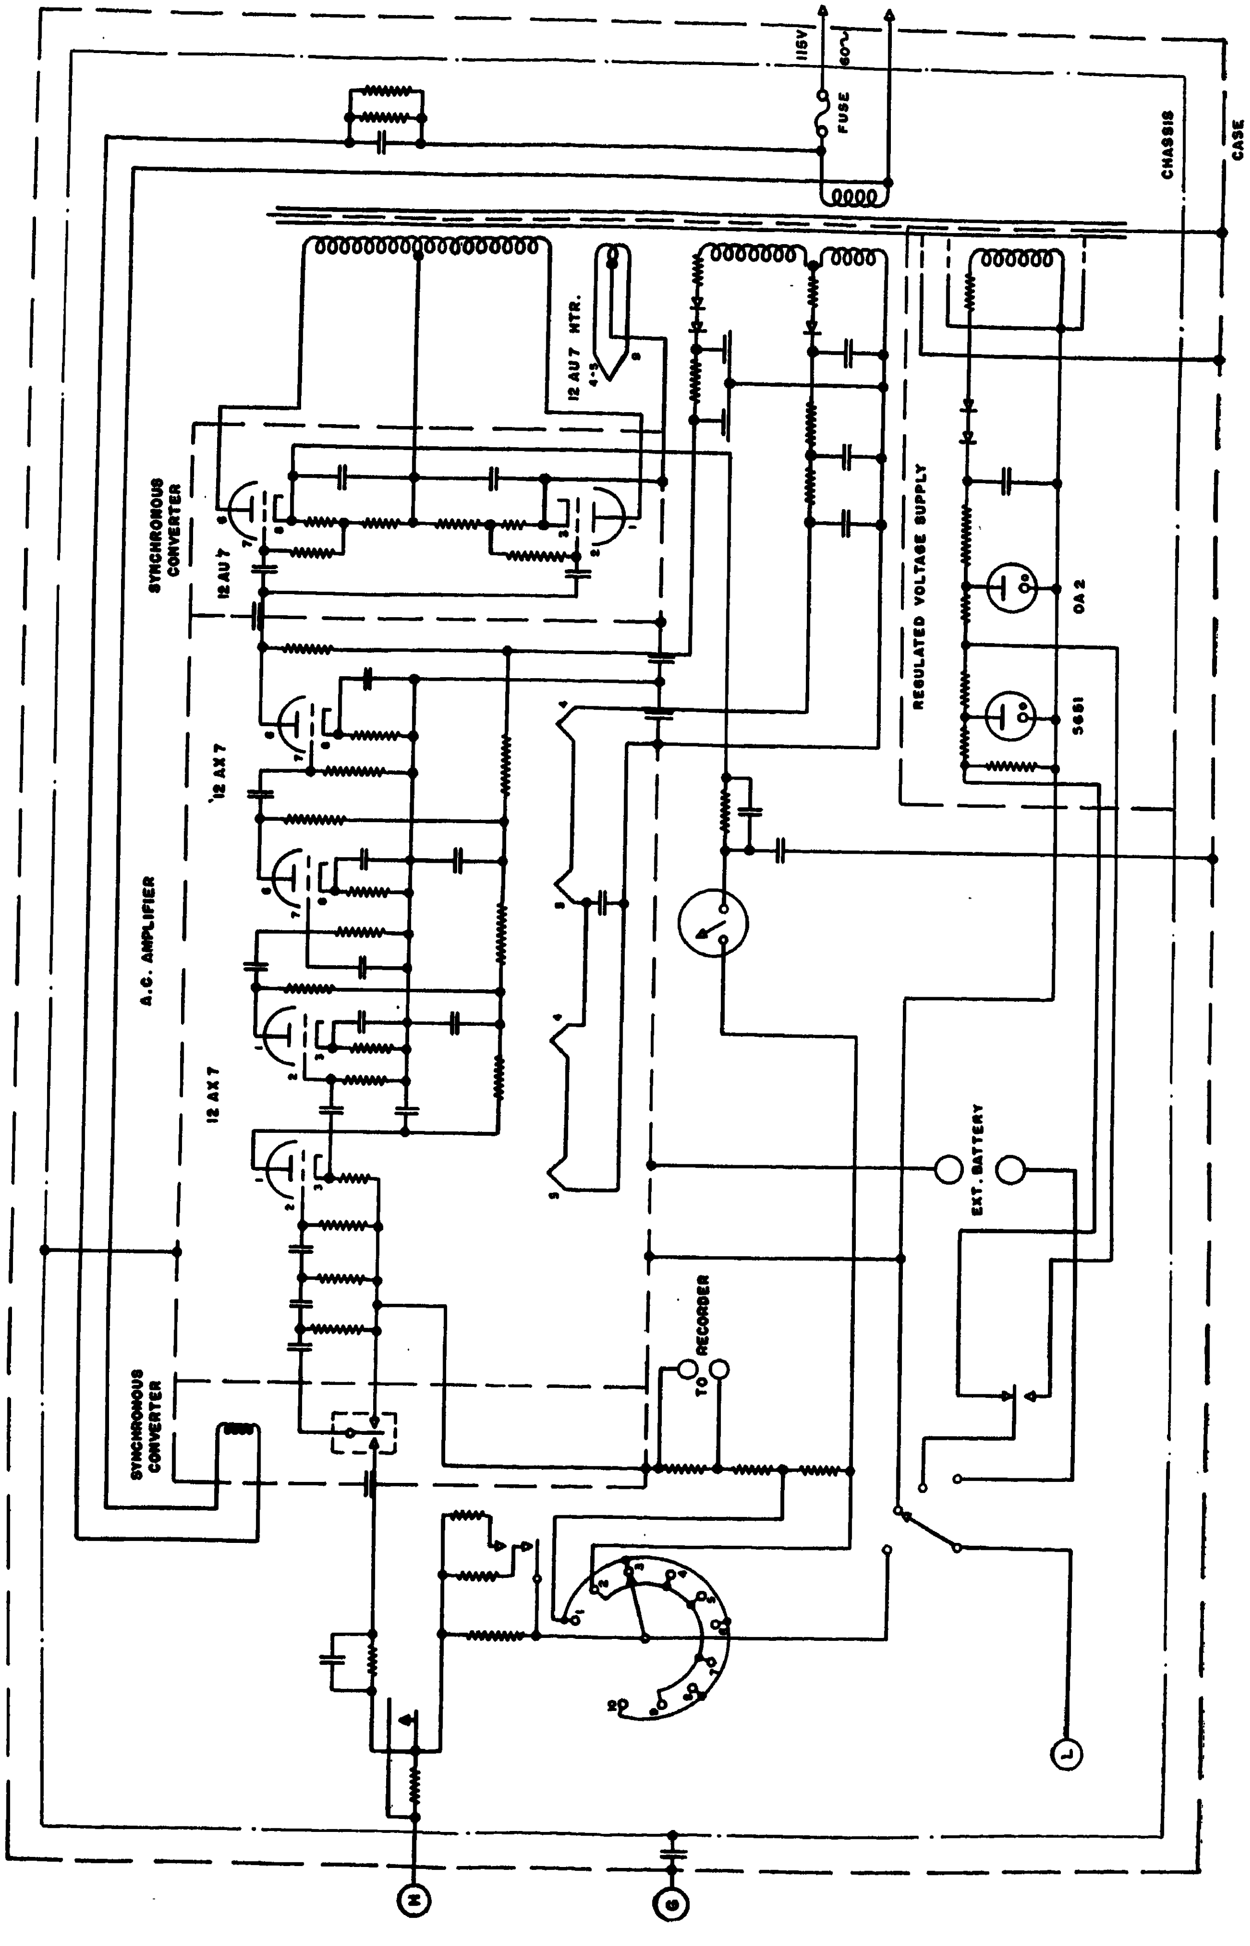

Fig. 3. Schematic diagram of universal meter

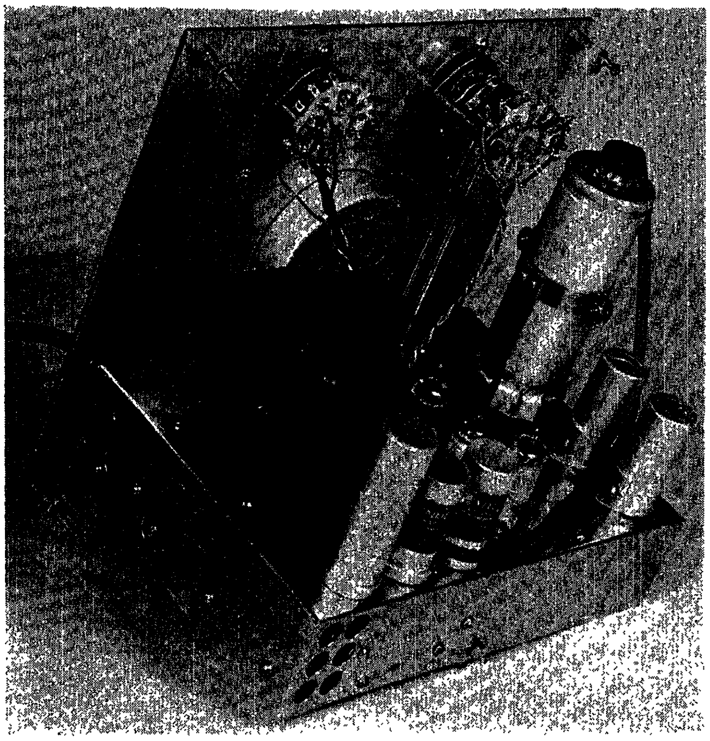

Fig. 4. Universal meter removed from containing box

isolated and shielded, and are so located that the leads from the instrument input terminals to the switch and from the switches to the amplifier input are short. The high-valued resistors of the input circuit are mounted on these switches.

Plungers, Fig. 4, with lucite insulating caps, activated by cams on the range switch, operate these switches. This arrangement provides good insulation and sufficient separation between the sensitive input-circuit switches and the switches of the higher level circuits, both of which are operated simultaneously by the range control.

Performance

Principal sources of errors in the instrument are: the deflection indicator, the amplifier, the critical resistors, and the regulated voltage supply for resistance measurements.

The deflection indicator used has a limit of error of ±0.5 per cent of full scale. The forward gain of the amplifier is about 65,000. The gain around the loop for the minimum voltage at R, 0.5 volt, is 1,200, which is sufficient to reduce the error from this source to less than 0.1 per cent.

Table II. Errors of the Universal Meter

Type of Measurement	Probable Limit of Error, Per Cent	Maximum Error at Zero
Voltage	1.5 of full scale	0.005 volt, on 0.5 and 5.0 volt ranges 0.5 volt, on 50 and 500 volt ranges
Current	3.5 of full scale	10^{-12} ampere
Resistance	5.0 of reading	

Since the grid current of the first tube is blocked out of the input circuit by capacitors, it causes no errors in the instrument reading. The input converter, due to charges generated by the motion of its contacts, may produce a current in the input circuit which would cause an error of about 1 per cent on the most sensitive ranges, and considerably less on the other ranges.

The resistor R in the feedback circuit is a precise manganin resistor, but the resistors r used to obtain the proper feedback currents in the input circuit, and the resistors used in the voltage divider for the 50 and 500 volt ranges are deposited carbon, spirally cut. They have a 1 per cent accuracy, plus a temperature coefficient varying from -0.04 per cent per degree centigrade to -0.15 per cent per degree centigrade which may provide an additional error of 3 per cent of the reading for some ranges. Table II summarizes these errors for the various types of measurements.

Because the error near zero for each current range causes a corresponding error at the high end of each resistance range, it is recommended that, for resistance measurements, a range be selected which will give a scale reading of less than 20. The resistance error includes those errors associated with the current ranges, plus errors due to the regulated voltage supply. The regulated supply errors are of two types. One is due to variation in output of the regulated supply, due to line voltage variation. This error is less than 0.1 per cent for line voltage variations of ±10 per cent. The other error is due to lack of uniformity of the regulated voltage of the *0A2* and *5651* tubes. This error can be essentially eliminated if the regulated voltage is adjusted to be 100 volts. Under this condition the maximum probable limit of error for the resistance range becomes 3.6 per cent.

Table III. Maximum Equivalent Input Resistance

Range Microamperes	Equivalent Input Resistance, Ohms (Approximately)
5	500
5×10^{-1}	5,000
5×10^{-2}	50,000
5×10^{-3}	500,000
5×10^{-4}	4,900,000
5×10^{-5}	45,000,000

The equivalent input resistance for all voltage ranges is approximately 10^{10} ohms. The value of the equivalent input resistance for the various current ranges varies as the range varies. The maximum values are given in Table III.

While some of these values of input resistance may seem high, it should be remembered that the primary function of the instrument is to measure very small currents, which, in practically all cases, originate in high-resistance sources.

When measuring resistance at 100 volts, 10 volts, or with an external voltage of 1 volt, the equivalent input resistance of the instrument introduces no appreciable error.

An input capacity of 1,000 micromicrofarads across 2×10^6 megohms has a time constant of 2,000 seconds, but the low input impedance due to the nature of the circuit permits the resistance reading to be within 10 per cent of its final value in 8 seconds.

The instrument permits measurement of insulation resistance by a 3-terminal method, since the low terminal L does not have to be connected to ground or the case of the instrument. Tubes used in the instrument are commercially available from radio supply dealers. Normal variation in tube parameters can be tolerated. Changing tubes does not require any special circuit adjustment unless it is desired to read insulation resistance to better than the accuracy stated above.

The instrument has a warm-up time of approximately 1 minute, but there will be some slight drift thereafter due to temperature stabilization. This drift, however, is less than the limit of error of the instrument.

Conclusion

Summarizing, the instrument described is a relatively simple and versatile unit, which can measure voltages up to 500 volts in high-impedance circuits, currents as low as 10^{-12} ampere, and insulation resistances up to 10^8 megohms, with a limit of error in each case not exceeding 5 per cent. The method of measurement used results in negligible errors due to insertion of the instrument in the circuits. It permits measurement of insulation resistance in accordance with approved American Society of Testing Materials methods.[2]

Technical Characteristics of FTL Type No. 20-B UHF Television Transmitter

E. M. BRADBURD
NONMEMBER AIEE

Synopsis: The technical objectives of the design of a 1-kw ultrahigh-frequency television transmitter and the methods employed for achieving the desired results are outlined. The aural transmitter is described and details are given for the design of the frequency-lock system, which insures frequency stability of the aural relative to the visual transmitter. A single crystal-controlled oscillator is used to reference the frequency-modulation aural oscillator, and to provide the necessary frequency offset between aural and visual carrier frequencies. The frequency-multiplier and power-amplifier chain in the aural is described, with particular emphasis on the reasons for the engineering choices made. Power amplification and frequency multiplication are performed simultaneously in order that the most economical and reliable design can be obtained.

The visual transmitter is described, and details of the modulation method employed are given. The radio-frequency modulated signal is generated in a broad-band amplifier stage employing grid modulation. A double-tuned output circuit is employed to realize the necessary broad-band characteristic, and to obtain good amplifier circuit efficiency. The radio-frequency power amplifier design is described, with illustrations showing the method of construction. The vestigial sideband filter and diplexer units are analyzed and the method of construction of the necessary cavities is described. Formulas for calculation of the diplexer parameters are briefly given. The cabinetry cooling and control circuitry are briefly described to illustrate the methods employed to insure ruggedness, ease of access and automaticity of operation.

THE FTL 20-B ultrahigh-frequency television transmitter is designed to furnish a nominal synchronous peak-power output of 1 kw in the ultrahigh-frequency bands from 470 to 890 megacycles. In the design of this equipment, we have attempted to exceed in performance the most stringent requirements of the Radio-Television Manufacturers Association and Federal Communications Commission for transmitters of this type. The characteristics that we particularly attempted to meet in the visual transmitter were:

1. Carrier-frequency stability better than one part per million over a period of one week;
2. Video-frequency response (visual transmitter) uniform from 30 cycles to 4 megacycles, with a variation of less than ±1 decibel;
3. Deviation from linearity of the modulation characteristic less than 10 per cent;
4. Regulation of output over one frame less than 4 per cent.

For the aural transmitter, the characteristics that were considered particularly important in the design were:

1. Distortion less than 1 per cent, from 50 cycles to 15,000 cycles.
2. Frequency-modulation and amplitude-modulation noise level 60 decibels and 55 decibels respectively, below 100-per-cent modulation.
3. Frequency variation relative to the visual carrier less than ±100 cycles per second.

In addition, the Radio-Television Manufacturers Association and Federal Communications Commission specifications with respect to impedance level for input and output connections, frequency response of the aural transmitter, linearity for the visual transmitter, constancy of black level, etc., were all carefully considered as design targets for this equipment.

We considered it quite important that the equipment utilized to the greatest extent possible identical tube types and circuits in the aural and visual transmitters; that provisions for rapid servicing be included and that the design be capable of extension for use with higher power amplifiers. In the following description of the equipment we will attempt to show how we have met these equipment design requirements. To our best knowledge we have complied with or exceeded in quality of performance all the design requirements listed above.

Description of Aural Transmitter

The radio-frequency signal for the aural transmitter is derived from a frequency locking circuit, whose function is to insure that the maximum deviation of the aural-carrier, with respect to the visual-carrier frequency, is less than ±100 cycles. At the same time, the locking system used permits the use of a single frequency-modulated modulator and frequency-control system for the entire UHF band. The method in which this is accomplished is shown in the block diagram of Fig. 1.

The visual crystal oscillator operates at a frequency of 1/96 of the transmitter output frequency. At a frequency of 1/24 of the transmitter output frequency, a signal is derived from the visual chain for locking and generating the aural-transmitter carrier frequency for a corresponding point in the aural-transmitter chain. At 1/24 of the transmitter output frequency, the frequency separation between aural and visual transmitters is

J., June 15–19, 1953. Manuscript submitted April 6, 1953; made available for printing May 13, 1953.

E. M. Bradburd is with the Federal Telecommunication Laboratories, Lodi, N. J.

The author wishes to acknowledge the support and effort of M. Silver, R. Troell, R. Alter, and many others, without whom this work would not have been possible.

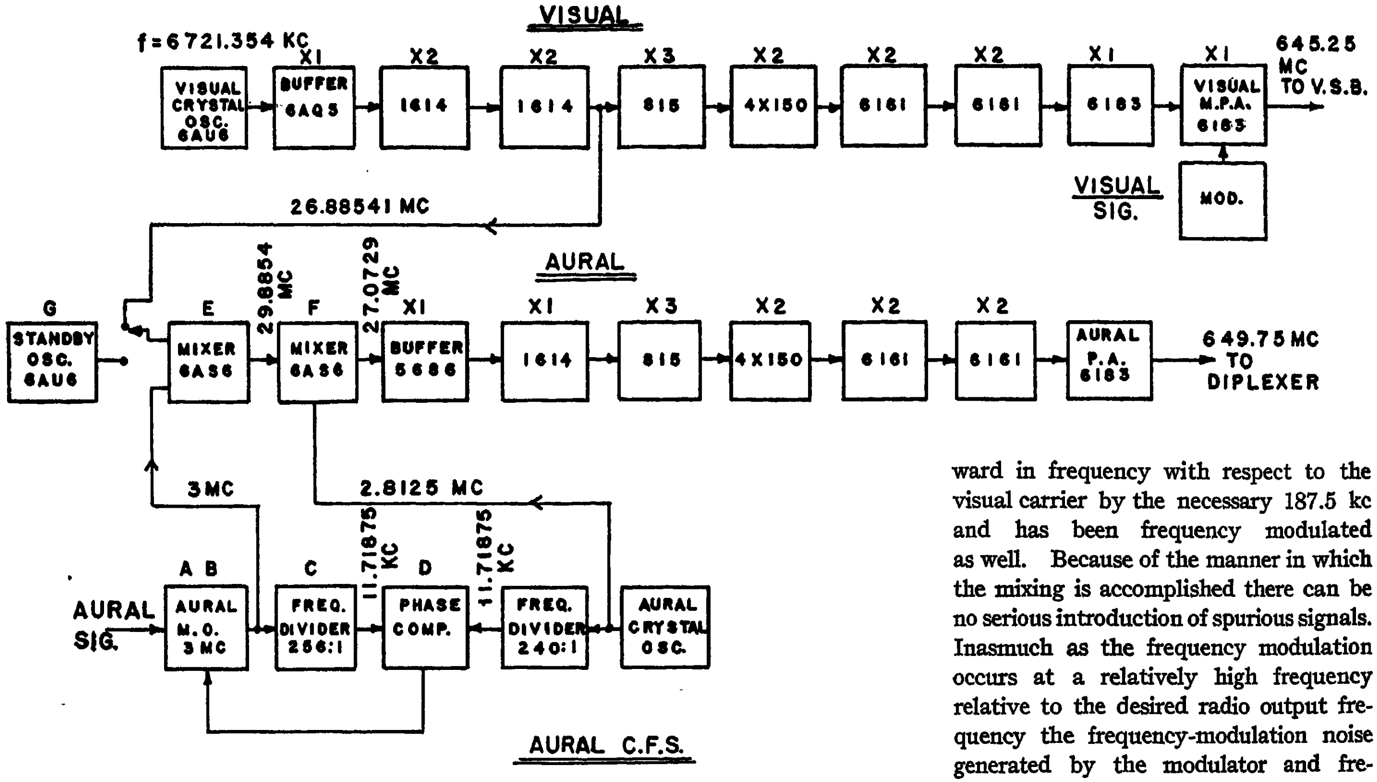

Fig. 1. Block diagram FTL 20-B 1-kw ultrahigh-frequency television transmitter

187.5 kilocycles. Therefore, the object of this locking circuit will be to add to the signal derived from the visual transmitter a frequency of 187.5 kc, which is suitable frequency modulated. Referring to Fig. 1, we see that the frequency-modulated oscillator *A* operates at a frequency of 3 megacycles. This oscillator, which is modulated by a Miller-effect modulator *B*, feeds its output to a counter circuit C, employing stable phantastron-type counters. The counter divides the input frequency by 1/256, and yields an output frequency of 11.719 kc.

The output of the frequency counter *C* is, in turn, fed to a phase-comparator circuit *D*. A reference crystal oscillator, operating at 2.8125 megacycles, is similarly fed to a counter-type frequency divider whose ratio is 1-to-240, again yielding 11.719 kc, and this signal likewise is fed to the phase-comparator circuit *D*. The error signal from the phase comparator, after suitable filtering and mixing with the desired audio modulation, is fed to the Miller-effect modulator for modulation and control of the aural oscillator. In this way, the aural oscillator, operating at a frequency of 3 megacycles, is held accurately in lock to the aural reference crystal, and is frequency modulated in accordance with the desired audio signal. The maximum deviation of the frequency-modulation signal, at this point in the chain, is approximately ±1.5 kc. This 3-megacycle frequency-modulation signal, is fed to a mixer circuit *E*, where it is heterodyned with the signal derived from the visual-transmitter crystal oscillator to yield the upper-sideband product. A suitable filter chain is used to select the desired upper side-band. It is important to note here that, because the ratio of the frequencies of the signals being mixed is always greater than 6, (hence the lowest-order undesirable-mixing product is sixth-harmonic) freedom from spurious signals and so-called crossover points is obtained.

Thus, if the visual carrier frequency were 645.25 megacycles, the signal delivered to the sum-mixer *E* from the visual chain would be 26.8854 megacycles, and the output of the sum mixer would be 29.8854 megacycles. The output of the sum mixer is then fed to a difference mixer *F*, where the 2.8125 megacycles generated by the aural reference crystal is heterodyned with the 29.8854 megacycle-signal to yield a frequency of 27.0729 megacycles. We have achieved, therefore, a signal which has been shifted upward in frequency with respect to the visual carrier by the necessary 187.5 kc and has been frequency modulated as well. Because of the manner in which the mixing is accomplished there can be no serious introduction of spurious signals. Inasmuch as the frequency modulation occurs at a relatively high frequency relative to the desired radio output frequency the frequency-modulation noise generated by the modulator and frequency-control process is relatively insignificant. The precision of the lock between the aural and visual transmitters is a function of the stability of the aural reference oscillator alone. Inasmuch as a crystal having an accuracy of 10 parts per million is readily obtained, the precision of the lock between the aural and visual transmitters is easily made better than ±100 cycles.

In the event of a failure of the visual crystal oscillator, the standby oscillator *G* is provided so that operation for the aural transmitter is possible, with somewhat reduced frequency stability. The aural-frequency modulator and locking system is contained on a single chassis, with all tubes accessible at the front of the transmitter. Test points and meters have been provided for rapid servicing of the counters and lock chain.

The output of the aural-frequency locking unit is fed to a single stage of amplification employing a type *1614* tube. The balanced output of the *1614* amplifier is used to drive a type *815*

C = gap capacitance

tube in a tripler circuit, yielding a frequency equal to 1/8 of the desired aural transmitter output frequency. The radio-frequency power level at this point in the system is approximately 1 watt. This power is used to drive the first frequency doubler, employing a *4X150A* tube in a pseudo-balanced circuit. The power output of this stage is 25 watts. It is important to note here that this tube is a critical one in the system, because of its use to yield a large power gain and also because of the fact that it is the last grid driven radio-frequency stage in the transmitter. In effect, all the remaining stages (all of the grounded-grid type) are in series with the output circuit of the *4X150A* doubler. Because of this, great care was taken to stabilize the gain of this doubler by large amounts of d-c cathode degeneration and a screen supply of poor regulation. All mechanical parts are ruggedly constructed to prevent accidental displacement of critical electrical parts.

The pseudo-balanced construction of Fig. 2 permits the use of a balanced transmission-line tank circuit, eliminating the necessity for a coaxial structure for this doubler stage. The radio-frequency power output of the first doubler is delivered next to a type *6161* tube operating in a doubler circuit of the grounded-grid type. The output power of this stage is approximately 40 watts and is utilized to drive a similar final doubler, again employing a type *6161* tube, and yielding a power output of 60 watts. These latter stages employ transmission-line types of circuits, in which the tube is completely enclosed by the outer cavity structure. Proper tuning for these stages is indicated by use of a reflectometer in the input line of the final doubler, and also through the use of suitable grid and plate ammeters in the second and final doubler stages.

It is interesting to note here that a grounded-grid doubler converts a portion of the radio-frequency drive power to second-harmonic power in the output circuit of the stage. In this respect it is identical in performance with a grounded-grid amplifier. Whereas it is difficult to obtain a stable amplifier at these frequencies using a *6161* tube in a grounded-grid circuit without the use of neutralization, the doubler circuit is completely stable and reliable in performance, with no neutralization. These frequency multipliers operate at an anode potential of approximately 1500 volts, and utilize a suitable combination of cathode and grid bias so that variations in tubes will not result in excessive variations of the radio-frequency power output. In addition, removal of the radio-frequency drive power cannot cause operation of the tube beyond its normal ratings. All tuning controls for the multiplier stages are brought out to the front panel, where meters are provided to indicate normal operation and the peak of various tuning controls. The radio-frequency power delivered by the final doubler is fed through a reflectometer to the input circuit of the aural power amplifier.

The aural power amplifier utilizes a type *6183* tetrode in a grid-screen separation type of circuit. The input circuit for this amplifier is of the conventiona coaxial type, having an electrical length of 3/4 wavelength. The output circuit for the tetrode consists of a waveguide beyond cutoff, with suitable mode suppressors and tuning stubs to furnish the proper load impedances for the amplifier tube. The output coupling circuit from this waveguide is a simple voltage probe, used as an impedance-matched transformer. For this waveguide type of circuit, Fig. 3, it can be shown that the resonant frequency can be closely calculated by assuming the circuit to consist of a transmission line operating in the transverse-electromagnetic mode, and having a width equal to 1/4 wavelength, a height equal to

Fig. 4. Constant-current to constant-voltage transformer, independent of changing load

h, and a length equal to the width of the guide. This parallel-plane transmission line resonates with the tube capacitance at a frequency given by the implicit relation

$$\frac{1}{2\pi fC}=754\frac{fh}{c}\tan\frac{wf\pi}{c}$$

The function of the waveguide on either side of this strip of the resonator is to act as a reactive attenuator, suppressing radiation from the ends of the guide. Tuning for this waveguide type of circuit is provided through motion of the side walls in or out, as required for coarse frequency variations, and by means of a discondenser for vernier frequency adjustments. The distributed capacitance of the vacuum-tube anode-to-screen assembly is in a large measure absorbed as a portion of this waveguide circuit, thereby greatly increasing the efficiency of this arrangement; circuit efficiencies of 90 per cent are not difficult to obtain.

The screen- and control-grid by-pass for this amplifier must be so made that the resultant cavity formed between screen and control grid does not resonate anywhere in the normal tuning range of the input or output circuits. If this pre-

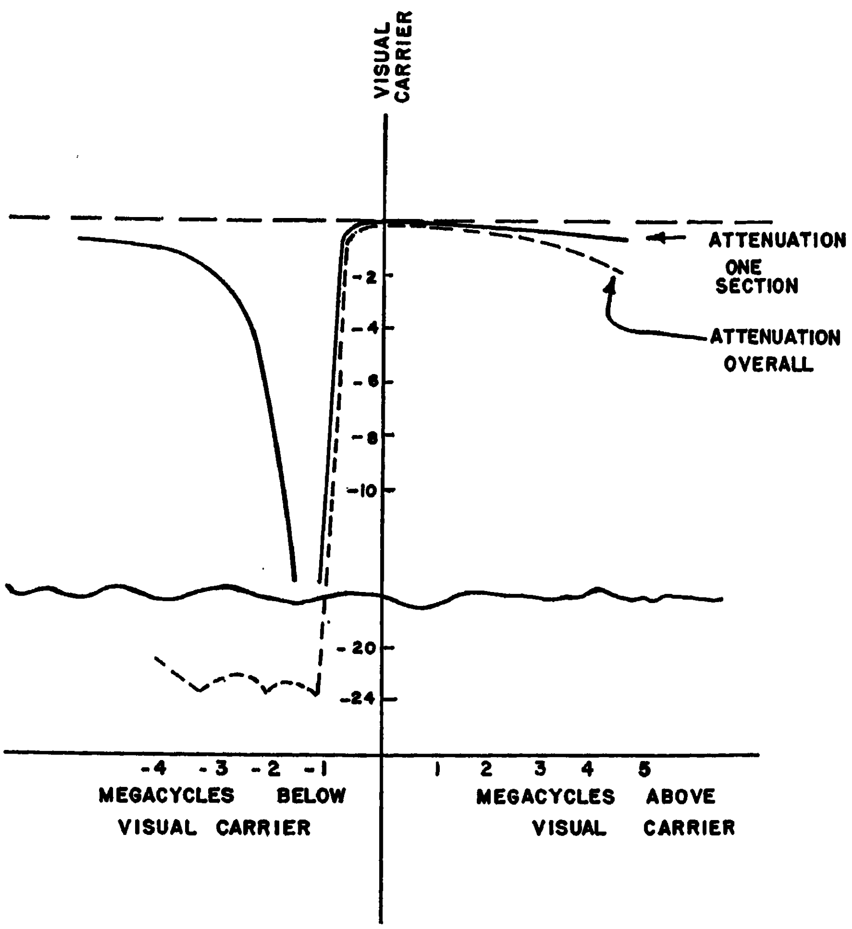

Fig. 6. (below). Attenuation characteristic vestigial-side-band filter

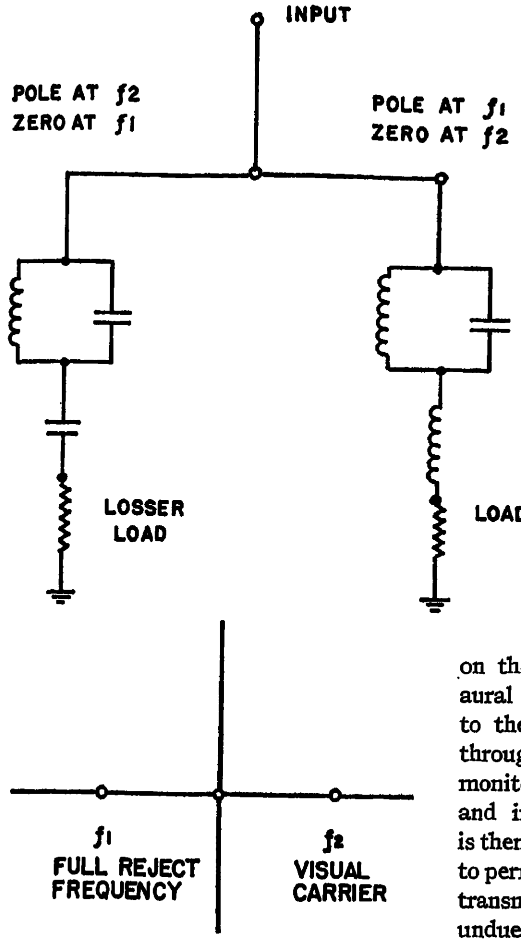

Fig. 7 (left). Low-frequency equivalent circuit of one section of vestigial-side-band filter

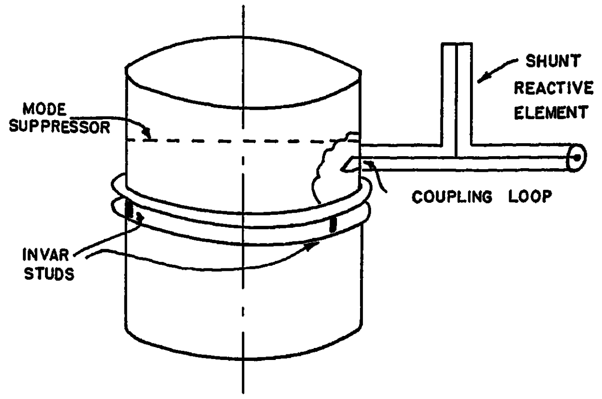

Fig. 8 (above). Typical cavity structure used in vestigial-side-band filter

caution is not observed, it is quite possible that the tube will oscillate, at a frequency determined by this screen-to-control-grid cavity. Through the suitable use of beryllium spring fingers it is possible to bypass the screen and control grids such that the cavity formed for this tube is resonant at 1,000 megacycles. This is well outside of the tuning band for either the input or output circuits of the amplifier. When the tube is utilized in this fashion, the low anode-to-cathode capacitance results in very stable operation.

This amplifier stage is arranged to operate with an anode potential of 3,800 volts, a screen potential of 500 volts, and a fixed bias of −60 volts. A combination of fixed bias and grid-leak bias is used, so that the tube cannot be damaged in the event of radio-frequency drive failure. When the aural transmitter is adjusted for maximum power output, the bandwidth is found to be in excess of 2 megacycles; hence, there is no possibility of producing frequency-modulation distortion or amplitude modulation of the aural signal. The power output of this stage is in excess of 600 watts, and the normal operating efficiency at 900 megacycles is 55 per cent. The cathode input circuit is arranged so that, by means of the directional coupler, a proper match on the drive line can be secured. The aural power-amplifier output is coupled to the main $1^{5}/_{8}$-inch transmission line through a directional coupler to permit monitoring of the output-power level and impedance matching. This power is then fed to the aural and visual diplexer to permit operation of the aural and visual transmitter on a common antenna without undue interaction.

General Description of Visual Transmitter

The visual-transmitter signal is, as mentioned above, originated in a crystal oscillator operating at 1/96 of the final output frequency. This crystal oscillator has been specially developed to secure the best possible stability with temperature, aging effects, and line-voltage variations. It is isolated from its load circuit by use of a buffer amplifier operating as a class *A* stage. Measurements made on this circuit show a long-time frequency stability better than 1/2 part per million. It has been found that the crystal employed in this circuit can be a commercial variety, having a stability of one quarter part per million per degree centigrade, and that with a suitable oven, such a crystal will yield the above-mentioned frequency stability.

The multiplier stage in the visual transmitters are in every respect identical with those employed in the aural transmitter, with the exception that two identical doubler stages operating at low frequency are required to increase the frequency of the visual oscillator to one corresponding to 1/24 of the output frequency. For these low-level multiplier stages, type-*1614* tetrodes are employed in conventional grid-driven circuits. The output of the final doubler, utilizing a type-*6161* tube, is fed to the visual-transmitter driver, which consists of a type-*6183* tetrode, again employed in a grid-driven separation type of circuit. This circuit is again in every way identical with that employed in the aural transmitter with the exception that the power level of operation is reduced, so that the output power of the driver is *350W*.

The use of a high-powered tube in this amplifier circuit enables one to obtain the following advantages of operation:

1. Large quantities of power available to obtain good regulation of drive for the visual-modulated power amplifier;
2. Good tube life for the driver circuits;
3. Uncriticalness of adjustment for the drive circuits.

The output power of this driver is delivered to the cathode-input circuit of the modulated power amplifier, which again utilizes a type-*6183* tetrode in a grid-screen separation circuit. The output cavity for this amplifier is of the double-tuned variety. This double tuning provides radio-frequency bandwidth of 5 megacycles, flat to within ±1/2 decibel. At the same time, a high load impedance can be presented to the plate-screen gap of the radio-frequency amplifier tube, so that efficient operation is possible. Thus this amplifier, at black level, has an efficiency of 43 per cent.

The control grid for this amplifier is bypassed with a radial type of transmission line, so that a low impedance is presented for the radio-frequencies, whereas a relatively high impedance can be presented to the visual modulator which is connected to this grid. This radial transmission line has an equivalent high-frequency radio-frequency impedance of 1/2 ohm, at 650 megacycles. The screen is bypassed to the control grid in the same manner as that utilized in the driver and aural final amplifier, and forms one portion of the above radial transmission line.

Fig. 9 (left). Schematic diagram of ultrahigh-frequency diplexer

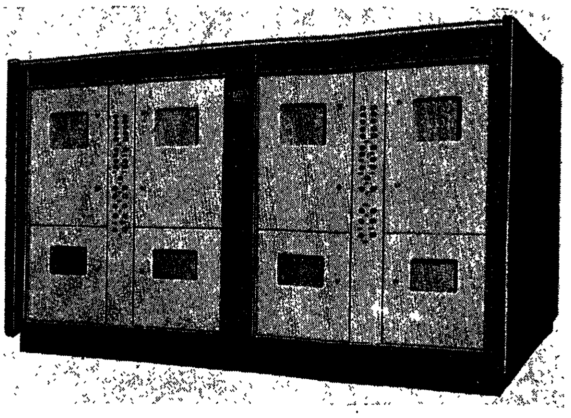

Fig. 10. FTL 20-B ultrahigh-frequency 1-kw television transmitter

The cathode circuit of the modulated power amplifier is damped by means of a radio-frequency load, which dissipates the power not utilized in the driving of the final visual amplifier. The dummy load for this purpose consists of a length of *RG14U* cable terminated in *RG21U* cable. This load is directly connected to the cathode circuit, where its position is adjustable to allow the desired ratio of power split between the cathode and dummy-load circuit.

It is quite easily shown that this kind of operation is not necessary, and that, in its place, the desired regulation of the radio-frequency drive can be secured through use of a coupling section between driver and modulated power amplifier, consisting of an odd number of quarter wavelengths of transmission line, see Fig. 4. However, the sensitivity of this kind of structure to misadjustment is such that it was felt desirable to avoid these difficulties, and to secure operation which was relatively uncritical to the setting of the driver tuning controls. With the arrangement employed in this transmitter, modulation to within 5 per cent of complete carrier cutoff is easily obtained, with excellent linearity. In addition, because of the radio-frequency loading on the modulated amplifier input circuits, the stability is greatly improved. The peak radio-frequency power capacity of the modulated power amplifier is such that 1,200 watts of synchronous peak power is easily obtained. Proper tuning of the input and output circuits is facilitated through the use of directional couplers and suitable diode-detector indicating equipment.

The modulator signal for the grid of the final amplifier is obtained from the circuit shown in Fig. 5. This modulator is required to deliver a signal having the following characteristics:

1. 100 volts peak-to-peak, with −70 volts equivalent to black level.
2. The modulator load is 200 micromicrofarads, with a peak load current, at −40 volts, equal to 130 milliamperes.
3. At −110 volts, the load current is zero milliamperes.

The modulator employed is conventional in every respect and has been described in other papers, with the exception of the output stage. The output stage of the modulator utilizes a so-called shunt-regulated amplifier circuit. This circuit has the advantage of furnishing an extremely low equivalent-output impedance. Referring to Fig. 5, we see that four type-*6BG6* tubes are arranged in parallel to drive two type-*6AS7* tubes, in this shunt amplifier circuit. This combination of tubes has an equivalent internal impedance of 50 ohms, and is likewise easily capable of supplying the peak current of 130 milliamperes at a potential of −40 volts. Furthermore, inasmuch as the load resistor required for this circuit is small, the equivalent efficiency is excellent. Thus for 5 megacycles video bandwidth, our power consumption at white picture is 300 milliamperes, at a potential of 400 volts. The modulator is insensitive to load impedance to such an extent that the output load capacitance can be increased to 400 micromicrofarads with no noticeable deterioration of picture quality. The modulator output circuit contains a considerable quantity of negative feedback as a result of the action of *R1*, see Fig. 5, so that the linearity of this arrangement is excellent. The total distortion of the modulator from 5 per-cent to 75-per-cent, peak synchronous bias is less than 5 per cent. Monitoring facilities for the modulator are provided for maintenance, servicing, and setup operations.

Vestigial-Side-band Filter and Diplexer

The vestigial-side-band filter employed in this transmitter is a factory pretuned network of the constant-resistance type, normally connected to the output circuit of the modulated power amplifier. The filter is arranged in three sections, each of which has an attenuation characteristic similar to that shown in Fig. 6. These three sections are cascaded, and the frequency of maximum attenuation is so set relative to the frequency of minimum attenuation that the over-all characteristic is similar to that shown in Fig. 6. To obtain this characteristic, a network having the low-frequency equivalent shown in Fig. 7 is required.

A calculation of the network parameters reveals that, for operation at 890 megacycles, if the insertion loss of the filter at visual carrier is to be less than 0.5 decibel the unloaded Q's of the reactive elements must be in the vicinity of 20,000. To realize circuit elements having this quality of performance it was necessary to plan on the use of resonant cavities. The most promising type of cavity appeared to be of cylindrical shape, operating in the TE_{111} mode. The theoretical Q for such a cavity, constructed of copper, and of height nearly equal to diameter, was 50,000 at a frequency of 650 megacycles. This form of structure was adapted for use in the filter and diplexer. The cavities, as finally constructed, are made of copper-clad invar sheets, and are deep drawn to size. Tuning is accomplished by splitting the structure in half, perpendicular to the cavity axis, see Fig. 8, and moving the halves with respect to each other. This gives a tuning variation of 80 megacycles per inch. The cavity halves are held together with threaded invar rods, to insure temperature stability.

The proper impedance is realized on coupling the cavity to the drive line through use of coupling loops of suitable size. A mode suppressor is employed to prevent the generation of the TE_{111} mode at right angles to the desired mode. The shunt-reactive element shown in Fig. 7 is constructed of $1^{1}/_{8}$-inch air line, and is arranged at a suitable distance from the main cavity so that the desired impedance variation can be obtained.

The entire vestigial-side-band filter consists of 6 of these cavities, supported on a rigid steel frame, in such a way that relative expansion of the frame does not apply any strain on the filter components. Each section of the filter can be individually aligned, and then all three sections couple together for the desired final attenuation curve. The dummy load for the vestigial-side-band filter consists of three 50-foot lengths of *RG8U* cable, on a reel structure. No cooling is required for this load.

The diplexer, see Fig. 9, for equivalent circuit is constructed of the same cavities as the vestigial-side-band filter, and is mounted and arranged in the same general manner. The aural insertion loss for such a diplexer is given by

$$\frac{P_{\text{in}}}{P_{\text{out}}}=\left(1+\frac{Q_L}{Q_0}\right)^2$$

where Q_0 is the unloaded cavity Q, and Q_L is the loaded Q of the cavity. For this diplexer, it was felt desirable to have the insertion loss less than 1 decibel whereas the loaded bandwidth was required to be at least 0.6 megacycle. This dictated a loaded Q of 1,000, and an unloaded Q of approximately 30,000. This was well within the theoretical capabilities of the cavity structure.

The crosstalk for the aural to the visual transmitter is similarly given by

$$\frac{P_{\text{visual}}}{P_{\text{load}}}\cong\left(\frac{1}{2EQ}\right)^2$$

where E is the interval between aural and visual carriers, divided by the operating frequency, and Q is as in the foregoing. For a ratio of −24 decibels, Q is calculated to be approximately 1,000, that is, the loaded Q is calculated to be 1,000. This value gives satisfactory insertion loss for the aural transmitter and a reasonable value of crosstalk. The loss for the visual line in the diplexer is generally negligible.

The impedance match on the visual line was easily made to have a voltage standing-wave ratio less than 1.1 and the aural line less than 1.5. The transmission line used to connect the cavities is $1^{5}/_{8}$-inch diameter. Even with 10 kw of combined aural and visual power, the heating in the short length of line employed is negligible.

Cabinet, Cooling, and Control-Circuit Arrangement

The entire transmitter is enclosed in a cabinet for shielding, structural support, and convenience in shipping, see Fig. 10. The aural and visual transmitters each occupy one bay approximately 7 feet by 5 feet by 31 inches. The front doors are split, permitting access to tuning controls without interrupting operation of the equipment. All meters are prominently displayed on a single meter panel, indirectly lighted by a single slimline florescent lamp. The lights and switches used for starting and stopping the equipment, as well as indicating normal functioning, are mounted on a central panel, which is easily removed for maintenance purposes.

The front doors of the equipment are provided with large windows, shielded with perforated metal, so that the interior of the transmitter is clearly visible when operating. The rear doors of the transmitter are of the sliding-panel type, two to a single bay. Thus, no space is required in the rear of the transmitter for swinging doors. These sliding doors can be completely removed from their raceways, thereby giving excellent access to the rear of the transmitter. Cooling for each bay is provided by a single blower-filter combination yielding 600 cubic feet per minute at a 3-inch head. A centralized duct system is used to distribute this air where needed. The control circuits are of such a nature that automatic starting and stopping of the equipment is possible through the use of a single switch. Power supply requirements for standard 1-kw plate black picture output are approximately 10 kva, 208 volts, 3-phase, 4-wire, 50 to 60 cycles at 90-per-cent power factor.

Block-Diagram Solutions for Vacuum-Tube Circuits

T. M. STOUT
ASSOCIATE MEMBER AIEE

MANY AUTHORS[1–7] of textbooks on electronics begin their discussion of feedback amplifiers with the block diagram given by Black.[8] The general gain equation

$$A'=\frac{A}{1-A\beta} \qquad (1)$$

in which A is the gain without feedback and β is the feedback fraction, is then derived, and the beneficial effects of feedback are discussed. In dealing with specific circuits, however, it is a common practice to write and solve the circuit equations, and then to manipulate the resulting gain equation into a form in which A and β can be identified. In some cases, expressions for A and β are simply stated and verified by substitution into the general equation.

In this paper, some simple amplifiers and oscillators are studied using block-diagram methods which have been applied to feedback-control systems[9] and electric circuit problems.[10] Using these methods, a block diagram based on the equivalent circuit is first drawn. This diagram is then reduced by a series of block transformations until the A and β portions of the system have been isolated.* By this procedure, the amplifier gain can be obtained in a logical and satis-

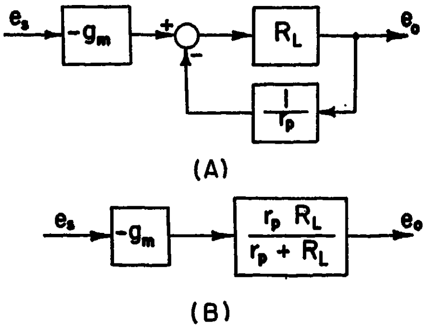

Fig. 2. Alternative method for reducing triode-amplifier block diagram

fying way without formal solution of the system equations.

With the various parts of the system clearly defined, the Routh and Nyquist stability criteria can be used with confidence. Knowing that a complete block diagram can be derived for vacuum tube circuits, the electronics specialist may be encouraged to use the highly-developed and very convenient graphical techniques of the servomechanism designer: standardized curves and templates for the common gain factors, attenuation-phase plots and the associated Nichols' charts for determining allowable gains, and a variety of compensation methods and design charts.[11-13]

The general procedures and a detailed description of the rules for block-diagram transformation are given in previous papers.[9,10] With the exception of the general feedback equation given, these rules are based on the associative and distributive laws of algebra, and can be understood from the examples given in this paper.

Amplifiers Without Feedback

In addition to providing an introduction to block-diagram methods, study of some simple amplifiers without feedback will furnish a basis for later comparison of these amplifiers with feedback amplifiers. Consider first the single-stage triode amplifier with resistive load, shown in Fig. 1(A). In drawing the equivalent circuit, Fig. 1(B), the tube is represented as a voltage generator in series with the plate resistance.

The block diagram, given in Fig. 1(C), is based on the circuit equations

$$i_p = \frac{1}{r_p}(-\mu e_s - e_o) \quad (2)$$

$$e_o = i_p R_L \quad (3)$$

(C)

Fig. 4. Block-diagram reduction for resistance-capacitance coupled amplifier stage

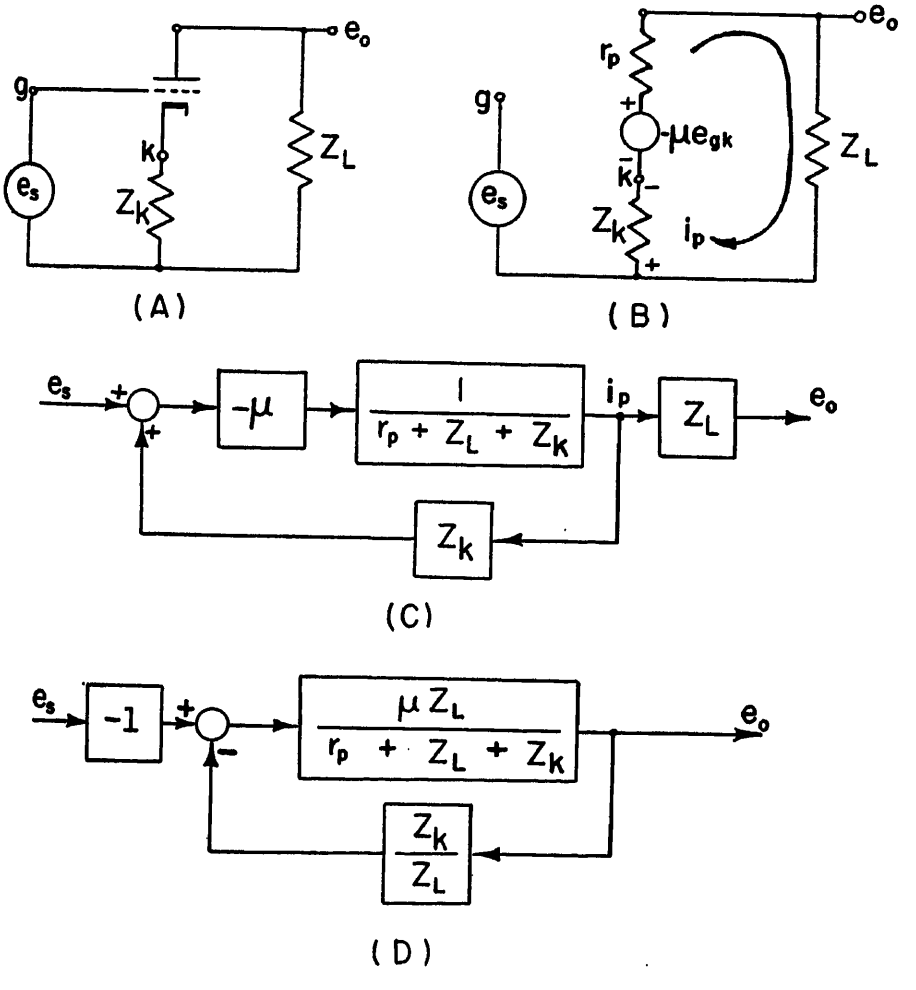

Fig. 5. Amplifier with current feedback and block-diagram solution

In reducing the block diagram, the general formula for feedback systems is applied, taking the forward gain as R_L/r_p and the feedback fraction as -1. (The negative character of the feedback is indicated by the minus sign at the summing point. Following the practice used in servomechanism analysis, the negative sign could be absorbed in the general feedback formula, equation 1, by writing the denominator with a positive sign; β would then be considered as normally positive.) As expected, the gain of the amplifier is

$$\frac{e_o}{e_s} = -\mu \frac{R_L}{r_p + R_L} \tag{4}$$

represented in block form in Fig. 1(D).

This block diagram can be reduced in another way. Since none of the circuit equations is disturbed, the small block containing $1/r_p$ can be moved to the left of the summing point and into the feedback path. Then, replacing μ/r_p by g_m, the diagram of Fig. 2(A) is obtained. From this diagram, another equivalent circuit can be drawn in which the tube is represented as a current generator supplying a parallel combination of r_p and R_L. Thus the equivalent circuit which is usually derived by means of Norton's theorem can be established by block-diagram transformation. Application of the general formula for feedback systems to Fig. 2(A) produces the final result of Fig. 2(B), showing that the gain is g_m multiplied by the equivalent resistance of r_p and R_L, as anticipated.

The voltage gain of a resistance-capacitance coupled amplifier can be obtained by a combination of procedures developed for ladder networks[10] with the ideas used in the preceding analysis. The circuit considered, and an equivalent circuit based on a current-source representation of the tube are given in Figs. 3(A) and 3(B). The block diagram, Fig. 3(C), correctly indicates the necessary equations.

Fig. 4(A), in which R_e represents the equivalent resistance of r_p and R_L in parallel, is the result of a partial reduction of the original block diagram. Three changes are incorporated:

1. The feedback loop, including R_g and C_g, has been reduced to a single block;
2. The block containing R_e has been moved to the left of the first summing point and into the upper feedback path;
3. The order of the first two summing points has been changed.

In the next diagram, Fig. 4(B), the inner feedback loop containing R_e and C has been reduced to a single block. The final block diagram, Fig. 4(C), is obtained by first combining the two blocks

in the forward path and then applying the general rule for feedback systems.

Recalling that s may be replaced by $j\omega$ to obtain the gain and phase shift as functions of frequency, it will be observed that the final block diagram, Fig. 4(C), contains all the factors necessary to account for the decrease in gain at low and high frequencies. In fact, it also includes the information required to determine the step or pulse response by operational methods.

Feedback Amplifiers

Having examined two representative amplifier circuits which appear to include numerous feedback loops, it may seem superfluous to devote space specifically to feedback amplifiers. However, the block diagram method demonstrates nicely some of the main properties of feedback amplifiers. It shows clearly, for example, that the tube parameters (μ, g_m, and r_p) occur entirely within the principal feedback loop and, to be more specific, in the forward part of the loop. It identifies plainly which passive elements enter into the transfer functions of the forward and feedback paths.

The first example considered is the case of current feedback from an element in the cathode circuit, shown in Fig. 5. With the sign conventions employed, the feedback appears to be positive, as indicated in Fig. 5(C). However, moving the negative sign associated with the amplification factor to the left of the summing point brings about, in addition to the -1, indicating the sign reversal of the amplifier as a whole, a change in sign at the summing point. The equivalent circuit could also be drawn with current leaving the cathode and a reversed voltage equal to $+\mu e_{gk}$. Using this convention, the output is taken as $-i_pZ_L$. The summing point now appears directly in the desired form, and the -1 appears at the output side of the block diagram.

Fig. 5(D) is obtained by moving Z_L into the forward path, and putting its reciprocal into the feedback path. The large block in the forward path is now the gain-without-feedback, and the block in the feedback path is the feedback fraction. Further reduction of the block diagram leads to the usual gain relation

$$\frac{e_o}{e_s} = \frac{-\mu Z_L}{r_p + Z_L + Z_K(1+\mu)} \qquad (5)$$

In some respects, the block diagram given in Fig. 5(D) is more useful and instructive than equation 5.

In a cathode follower, the output voltage is developed across Z_K, so that $e_o = -i_p Z_K$; the impedance Z_L may or may not be eliminated. The modified block diagram, given in Fig. 6(A), is reduced by moving Z_K into the forward path. It will be observed that an extra -1 appears in Fig. 6(B), making the output have the same sign as the input, and that the feedback fraction is now unity.

Amplifiers incorporating voltage feedback may also be treated by block-diagram methods. In drawing the equivalent circuit, Fig. 7(B), it is assumed that the capacitor in the grid circuit is an effective short circuit and may be ignored. The effect of an inadequate capacitor may be considered by substituting the impedance

$$R_1 + \frac{1}{Cs} = \frac{R_1Cs+1}{Cs}$$

for R_1. The effect of cathode impedance is considered in a later paragraph.

The block diagram of Fig. 7(C) has been drawn assuming that the current through R_1 and R_2 is an important part of the total tube current. To obtain the next diagram, Fig. 8(A), several steps are taken. As before, the negative sign associated with the amplification factor is moved to the left of the first summing point, and $1/r_p$ is moved to the left of the second summing point and into the upper feedback path, giving what is effectively a current-source representation of the tube. The lower feedback paths are shown separately.

If the current through R_1 and R_2 is small enough, i_1 is approximately equal to i_p, and the simplified diagram given in

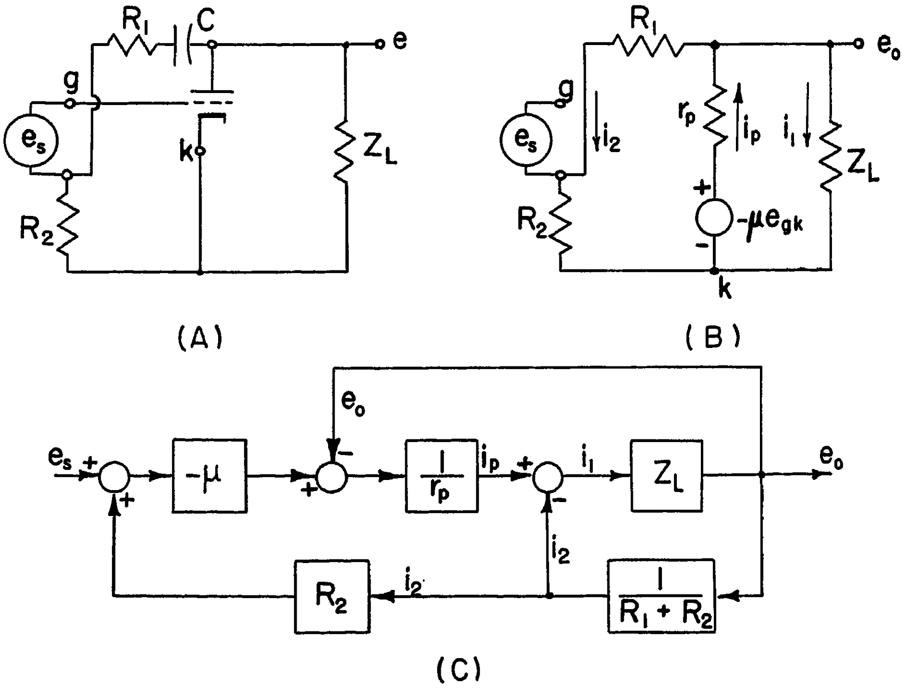

Fig. 7. Amplifier with voltage feedback and block diagram

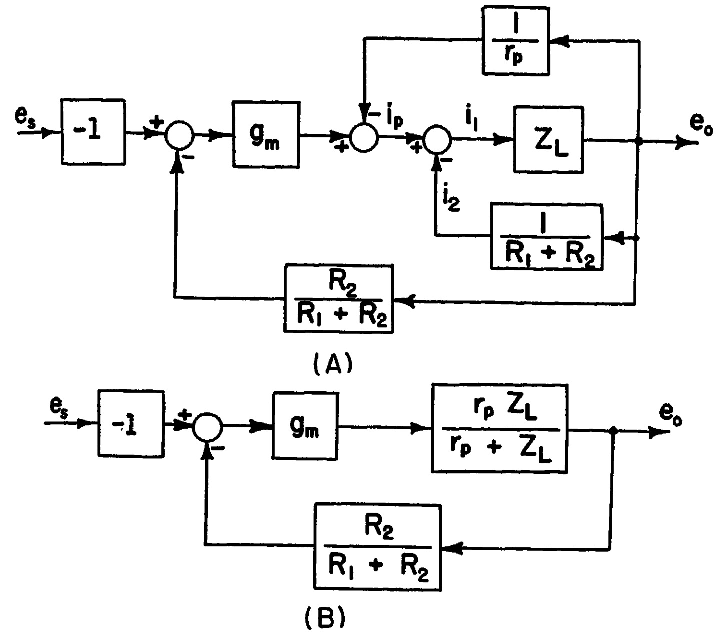

Fig. 8. Block-diagram reduction for amplifier with voltage feedback

Fig. 8(B) can be drawn. The blocks in the forward path represent the gain-without-feedback

$$\frac{g_m r_p Z_L}{r_p+Z_L} = \frac{\mu Z_L}{r_p+Z_L}$$

the resistance ratio in the feedback path is the feedback fraction, and the -1 indicates the sign change produced by the amplifier.

Compound or combined voltage-current feedback is shown in Fig. 9. For simplicity, the capacitor in the grid circuit is not included, and it is assumed at the start that the current through R_1 and R_2 is negligible. Fig. 10(A) is obtained by moving Z_L into the inner loop, moving a minus sign to the left of the summing points, and rearranging the summing points. In Fig. 10(B), the two feedback paths are combined, showing that the feedback fraction for compound feedback is simply the sum of the feedback fractions for the two types of feedback separately.

Fig. 10. Block-diagram reduction for amplifier with combined current-voltage feedback

Grid-plate capacitance and other parasitic parameters can be considered by appropriate modifications of the block diagrams. Multistage amplifiers, with and without feedback, are treated by obvious extensions of the ideas presented here.

Oscillators

Oscillators are often treated as unstable feedback systems, a procedure which is neatly justified by block-diagram methods. Consider, for example, the tuned-plate oscillator shown in Fig. 11(A). Here the similarity of this oscillator circuit to a feedback amplifier is emphasized by showing a separate signal voltage in the grid circuit. Grid current is neglected and it is assumed that any load may be represented as a shunt resistance, R; the mutual inductance may be either positive or negative, but it is assumed initially that the voltage induced in the grid circuit adds to the signal voltage.

The block diagram, Fig. 11(B), represents correctly all of the required circuit equations and follows the pattern developed in studying feedback amplifiers. After several routine steps, the diagram of Fig. 11(C) is obtained. This diagram includes the -1 which is indicative of the sign change associated with a single stage of amplification, and the signs at the summing point indicate negative feedback.

After one more block transformation

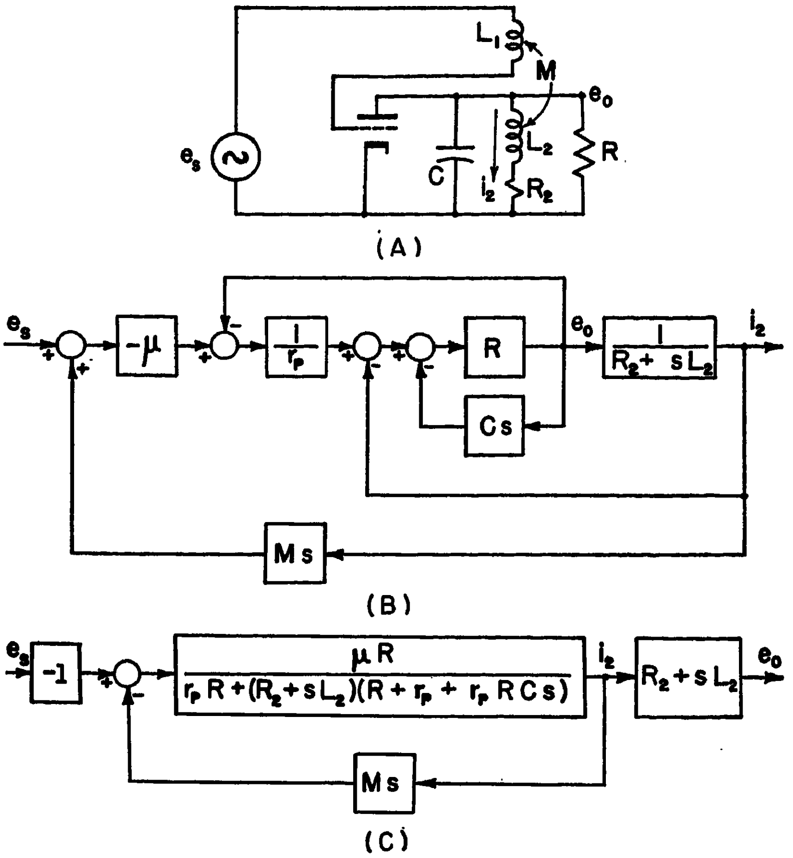

Fig. 11 (above). Tuned-plate oscillator and block diagrams

and some algebraic manipulation, the voltage gain may be expressed as

$$\frac{e_0}{e_s}=\frac{-g_m(R_2+sL_2)}{s^2L_2C+s\left[g_mM+L_2\frac{(R+r_p)}{Rr_p}+R_2C\right]+1+R_2\frac{(R+r_p)}{Rr_p}} \qquad (6)$$

If the system is unstable, sustained oscillations are possible, even with the signal absent, so that e_s plays no part in the determination of stability or instability. As shown by Routh's criterion,[13] the only condition for oscillation in this case is that the coefficient of s in the denominator be zero or negative. Since all of the circuit parameters are inherently positive except M, this requires that M be negative and that

$$|M|\geq\frac{L_2\left(\frac{R+r_p}{Rr_p}\right)+R_2C}{g_m} \qquad (7)$$

Equation 7 may also be used to estimate the transconductance needed to produce oscillations.

A similar treatment of the resistance-capacitance phase-shift oscillator[14] is

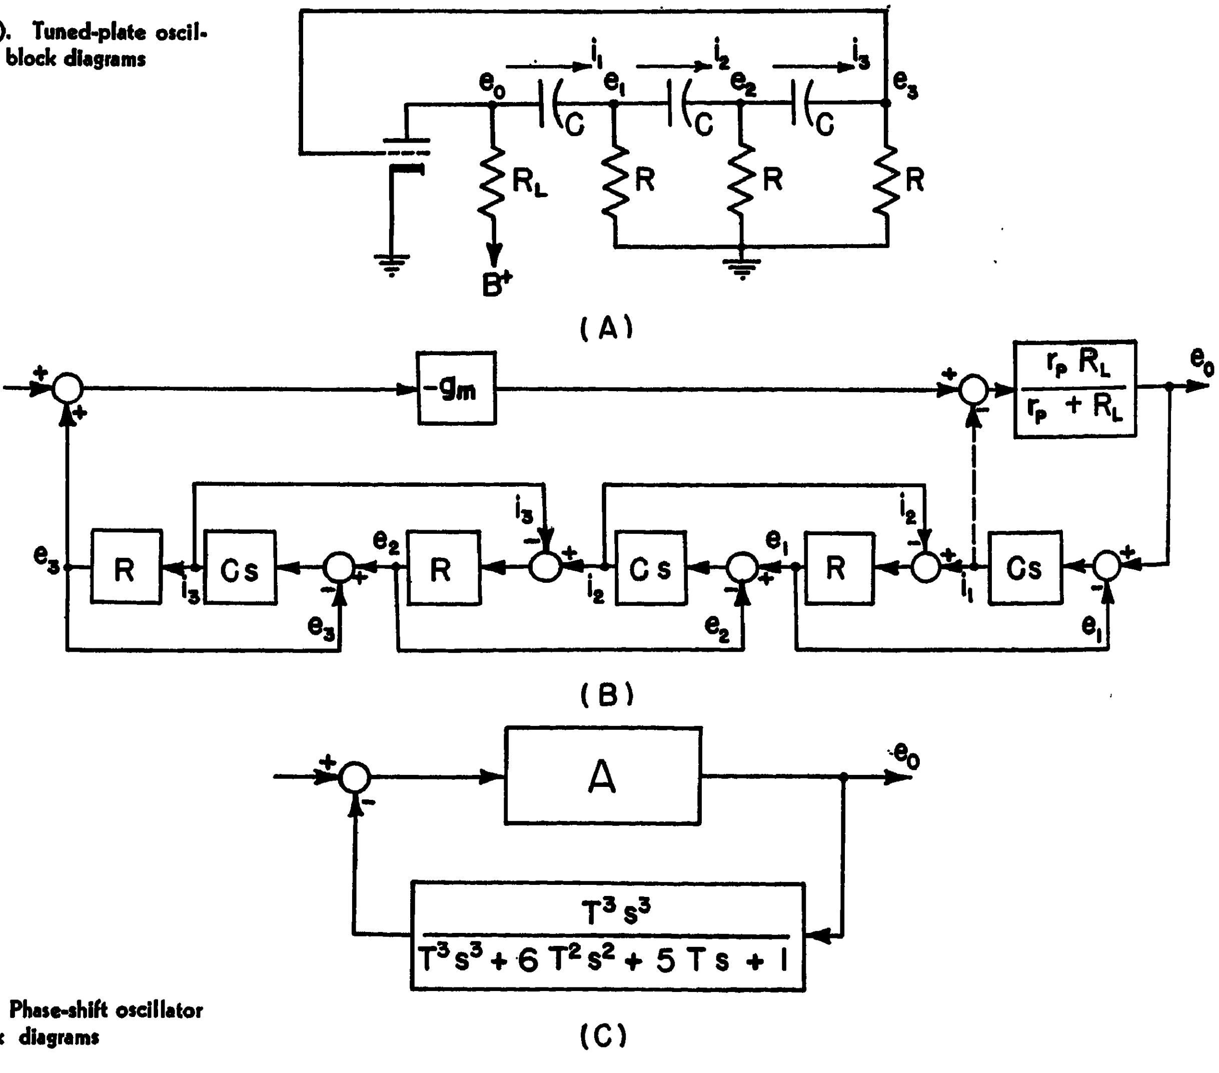

Fig. 12 (right). Phase-shift oscillator block diagrams

presented in Fig. 12. If i_1 is small, as generally assumed, the forward path in Fig. 12(B) becomes simply

$$A = g_m \frac{r_p R_L}{r_p + R_L} = \mu \frac{R_L}{r_p + R_L} \tag{8}$$

and the feedback path becomes a 3-section resistance-capacitance ladder network whose transfer function

$$\frac{e_{\text{out}}}{e_{\text{in}}} = \frac{T^3 s^3}{T^3 s^3 + 6T^2 s^2 + 5Ts + 1} \tag{9}$$

can be derived in a variety of ways, including block diagram reduction.[10] Viewed as a feedback amplifier, the system of Fig. 12(C) would have a voltage gain

$$A' = A \frac{T^3 s^3 + 6T^2 s^2 + 5Ts + 1}{(1+A)T^3 s^3 + 6T^2 s^2 + 5Ts + 1} \tag{10}$$

where $T = RC$. For this case, where the denominator is a cubic in s with positive coefficients, Routh's criterion gives the necessary condition for oscillation as

$$T^3(1+A) \geqq (6T^2)(5T) \tag{11}$$

or

$$A \geqq 29$$

as is well known.[14]

Other oscillator circuits, such as the Hartley, Colpitts, or Wien-bridge, can be analyzed by similar methods. For circuits having conductive, rather than inductive, coupling between the plate and grid circuits, the block diagrams become somewhat more complicated, however.

Conclusions

Analysis of feedback amplifiers using block-diagram methods from start to finish offers a number of possible advantages over more conventional methods. Of these, probably the most important is the straightforward manner in which the forward and feedback transfer functions are obtained. No particular prescience or algebraic sleight-of-hand is required. The function of each circuit element is better understood, and the importance of making some parameters large and others small is easily seen. With the paths clearly identified, graphical techniques and standard stability criteria can be applied with confidence.

Block diagram methods emphasize the similarity between feedback amplifiers and oscillators, encouraging joint use of techniques for analysis and synthesis.

A Progressive Code Digital Quantizer

FLOYD RAASCH
NONMEMBER AIEE

Synopsis: The analog-to-digital converter described receives analog information obtainable from a graph reader or other analog source and gives a corresponding numerical indication. A progressive coding scheme is used to lessen chances of wrong readings. Several circuits are given for obtaining digital indication, the basic principle being based on comparing the analog voltage with the sum of a finite geometric series. A readout circuit is described for converting the coded digital indication to conventional decimal form for visual reading or for punching International Business Machines (IBM) cards.

One DICTIONARY definition of the word quantize is: "To express as multiples of a definite quantity." A system which expresses a continuously variable voltage or other physical value digitally in discrete levels fulfills a function which fits this definition. Accordingly, the term quantizer has become a popular descriptive name for devices which convert analog values to digital information. A considerable amount of work has been done in this field because of the need for this type of conversion.[1–7] The quantizer described in this paper was built mainly for the purpose of obtaining a quantizer for laboratory use and duplicates the efforts of others as little as possible.

In the development of the quantizer, the objective was to have it continuously supply a digital indication of an analog voltage. The word "continuously" is used in contrast to "sampling at repeated intervals" and in contrast to a "sequential" form of output. The output of the quantizer proper is a coded indication, which minimizes transitional difficulties between those adjacent incremental values which, in more conventional number systems, involve the change of more than one digit.

A readout circuit converts the coded reading to conventional decimal readings to make the output easily intelligible for general purposes. This readout circuit operates both an indicator panel and an IBM type-*513* reproducing punch.

Need for an Appropriate Number System

Since this instrument was designed to supply an indicator continuously, it was necessary to design the equipment so that a change from one digital value to the next adjacent incremental value is not accompanied by a momentary ambiguous indication, or a wrong value. In

the more commonly used number systems, changing a value representation by a difference of one unit is often accomplished by changing several or all significant digits in that number. In some types of devices for giving digital indications of continuously variable values, some time lag exists between changes in the separate digital positions. In other devices, there is a simultaneous instant of ambiguity in all digital positions undergoing change. Where automatic means to record a reading at a given instant is to be employed, conventional numbering systems present a handicap if a reading is taken at the instant of ambiguity or erroneous indication.

Number System Employed

To overcome such a handicap, the quantizer proper converts analog voltage values into a digital indication such that any two values differing by one increment are separated by a change of only one digit. The usual decimal numbering system is rearranged to represent progressively changing values differing by one unit in such a way that in all cases only one digit is changed to represent the next higher or lower value. This new arrangement is compared with the common decimal system in Table I. After the digit in a given position has progressed from zero to its maximum value, the numbering order of the digit values in that position is reversed for the next succession of representations. In a system of tens, after a digit has progressed from zero to nine, the nine is retained to represent the value ordinarily represented by zero in the conventional numbering system. The sequence of digits is then followed in reversed order until the extreme, now represented by zero, is reached. The zero is retained to indicate minimum value, and the digits again follow in the order of the normal decimal system.

This general numbering scheme of course is usable not only for a system of tens in particular, but for numbering systems of any radix in general. When we apply the scheme to the minimum possible radix, a system based on two, a specific case is reached which has been called the Gray code or the cyclic progression code. Table II compares the Gray code with a conventional binary arithmetic system, and Fig. 1 shows this graphically.

Table II. Progressive Binary Number System

Progressive Code	Binary System	Decimal System

11011	10010	18
11010	10011	19
11110	10100	20
11111	10101	21
11101	10110	22
11100	10111	23

In all these progressive systems, the test of whether any digit represents actual value or whether it represents complement minus one is to note if the sum of the higher order digits is even or odd. If the sum of the higher order digits is even, the digit in question represents actual value. If the sum of the higher order digits is odd, the digit represents complement minus one. For example, if a progressive decimal number is expressed 126, the number can be converted to conventional decimal notation as follows:

1—Preceded by even sum (all zeros), therefore remains 1
2—Preceded by odd sum (one), therefore becomes 9−2=7
6—Preceded by odd sum (three), therefore becomes 9−6=3

The decimal number represented then is 173.

If a Gray code (progressive binary) number is expressed as 11011, its conversion to conventional binary is as follows:

1—Sum of higher order digits even (all zeros), therefore remains 1
1—Sum of higher order digits odd (one), therefore becomes 0
0—Sum of higher order digits even (two), therefore remains 0
1—Sum of higher order digits even (two), therefore remains 1
1—Sum of higher order digits odd (three), therefore becomes 0

The binary number represented than is 10010.

The quantizer described here combines the progressive binary systems and the progressive decimal systems. A group of four progressive binary digits represents a progressive decimal digit. No more than one decimal digit changes between any two incremental changes and within that coded decimal digit only one progressive binary digit changes between

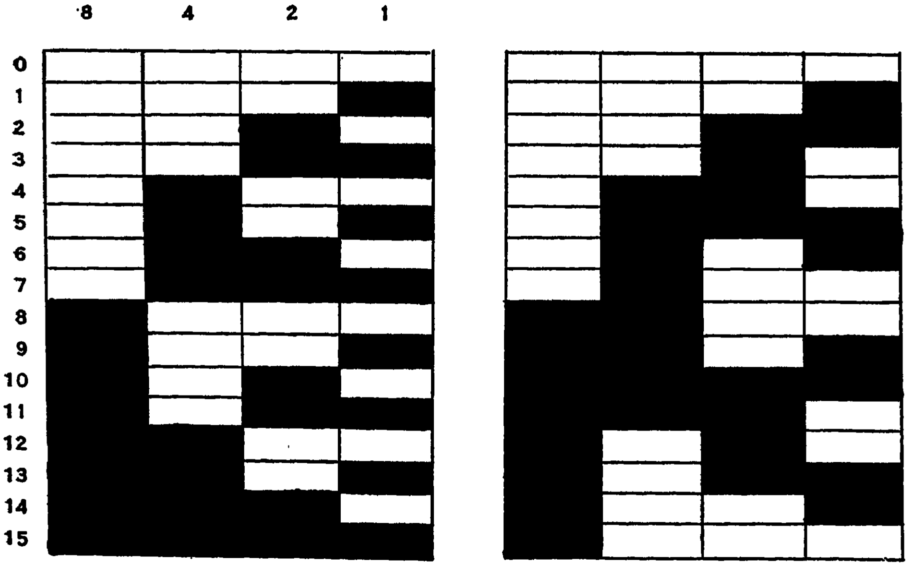

Fig. 1. Progressive binary number system. Left, binary code. Right, progressive code

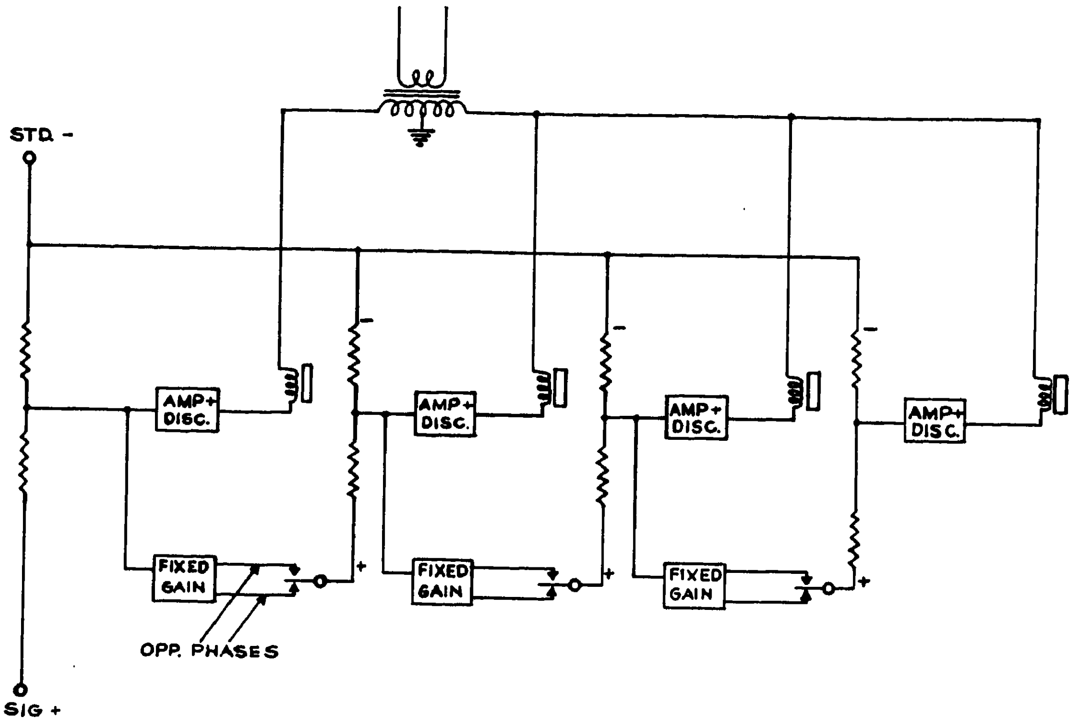

Fig. 2. Possible progressive code digital quantizer

any two values. Thus only 1 out of 12 digits in the over-all system changes at a time.

For purposes of easy reading and interpretation, a translating circuit translates this number system to a system of conventional notation. If more than one digit in the conventional indication changes between two adjacent values, this readout circuit causes these digits to change simultaneously in the translating process.

Possible Quantizers

As an approach to this problem, a quantizer was visualized in the form of a network of nonlinear elements. Such a network is possible with the voltage polarities or phases at certain points forming a digital indication of the voltage applied to the network. For example, it is theoretically possible to connect a network of squaring and square rooting devices in such a manner that the network serves as a quantizer.

Of course, nonlinear responses are not confined to curvilinear functions. Nonlinear functions also include broken-line responses and discontinuous straight-line functions. A broken straight line or a discontinuous straight line suggests a circuit which includes the operation of a switch or relay. A possible quantizer employing amplifiers and relays is shown in Fig. 2.

This circuitry gives a digital output in the form of a progressive code. If a quantizer is made in this manner for a-c signals, one engineering difficulty to be experienced is that of obtaining a good balance after the signal has experienced the cumulative distortion and phase shift of several stages. In this circuit, a signal input is compared to a reference in the first stage. When the difference between these two values changes sign, the indicator changes but the magnitude of the difference is fed to the following stage without reversal. A fixed-gain amplifier with a reversing relay to maintain constant polarity of output with reversal of input polarity is the nonlinear device which, in this case, gives a broken line characteristic. In the second stage, the magnitude, without regard to sign, of standard magnitude-minus-signal magnitude for that stage is compared with half standard. When this difference changes polarity, the second indicator changes indication; the magnitude of the difference is again fed to the following stage without reversal.

In Fig. 3 is shown an analog-to-digital converter which gives an indication in ordinary binary form in the following manner:

An unknown signal value is compared to a standard value. If the unknown is greater than standard a binary digit one is indicated and standard value is summed with one-

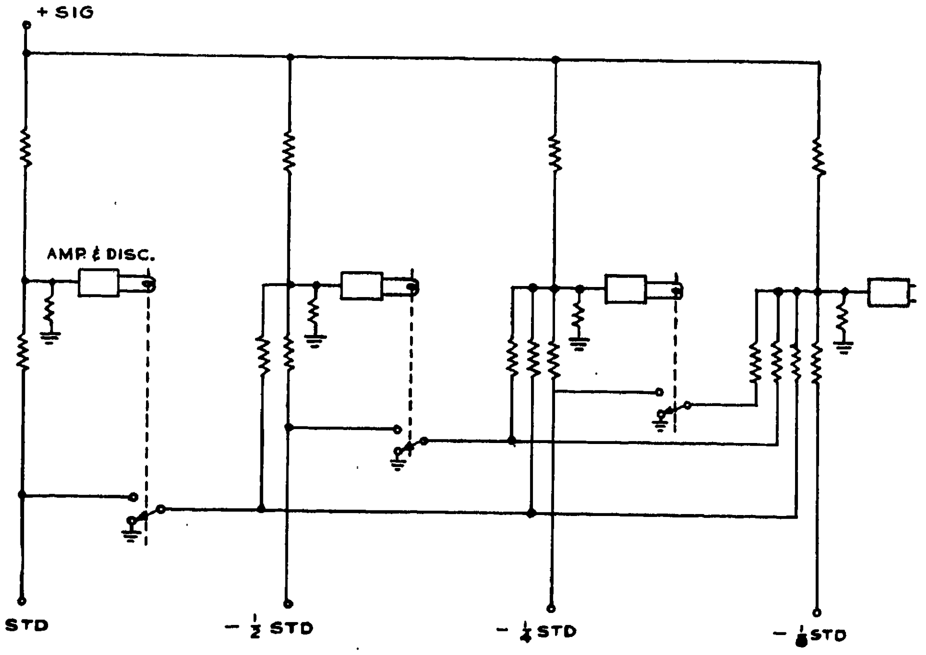

Fig. 3. Analog-to-binary digital converter

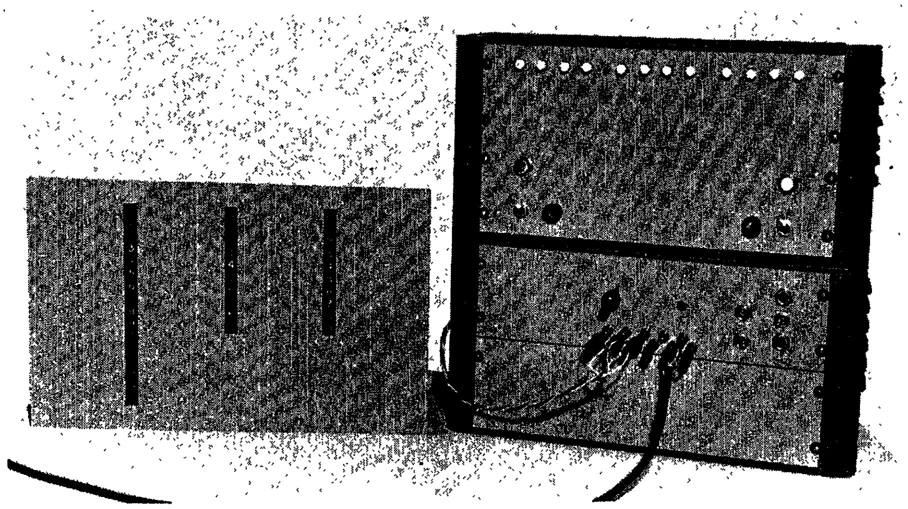

Fig. 4. Quantizer. Left, indicator panel. Right, top to bottom: quantizer proper, power supply, control circuit, and readout

half standard in the next stage of comparison, whereas an unknown value smaller than standard causes a zero to be indicated and zero value to be summed with one-half standard. The unknown value is again compared with the above sum. A signal greater than this sum again causes a binary one to be displayed while one-half standard is summed with one-quarter standard plus the zero or unity obtained from the first operation. Alternately a signal value smaller than this sum, resulting in a recorded zero, causes zero value to be summed with the one-quarter plus zero or unity obtained from the first operation.

This process, theoretically, can be continued for as many binary digits as needed. As shown in Fig. 3, signal voltage is summed against a minus standard in the first stage. A polarity (phase) discriminator establishes the appropriate binary digit and operates a switch accordingly, switching zero or standard voltage to the next summing circuits. The successive phase or polarity discriminators operate their switches accordingly. When these operations go to conclusion, the switch positions indicate the binary reading.

Model Constructed

To more readily construct a progressive code quantizer for demonstration purposes, and to minimize the number of vacuum tubes, a quantizer was constructed which effectively accomplishes the same purpose as reversing the output phase of the fixed-gain amplifiers of Fig. 2 by reversing everything else instead. This was done in a way that eliminated the need for all the fixed-gain amplifiers, with their cumulative distortion and phase shift. This quantizer is shown in Fig. 4.

Quantizer Proper

The circuitry for the first four stages of the quantizer is shown in Fig. 5. The operation of a phase-discriminator plate relay reverses the plate-voltage phase of all following discriminator plates. It also exchanges the ground potential connection with the standard voltage connection for all following stages. The four stages as shown are able to set up all 16 possible code combinations, the circuit being the same as for the hundreds digit of the quantizer shown in Fig. 4. For the tens and units coded digit, only 10 combinations of the possible 16 are used. The circuitry is modified to achieve this purpose. The 10 combinations chosen are centrally picked within the 16. The resulting symmetry allows some economy of contacts in the readout circuit.

It will be noted that the summing network of Fig. 5 is similar to the summing network of Fig. 3. By having the plate relay of each discriminator stage reverse the a-c plate supply phase of all succeeding stages, and by exchanging ground potential with standard voltage potential for all succeeding stages, an effect is produced which is similar to that produced by the circuit in Fig. 2.

Readout

The readout circuit for all three decimal digits is as shown in Fig. 6. It will

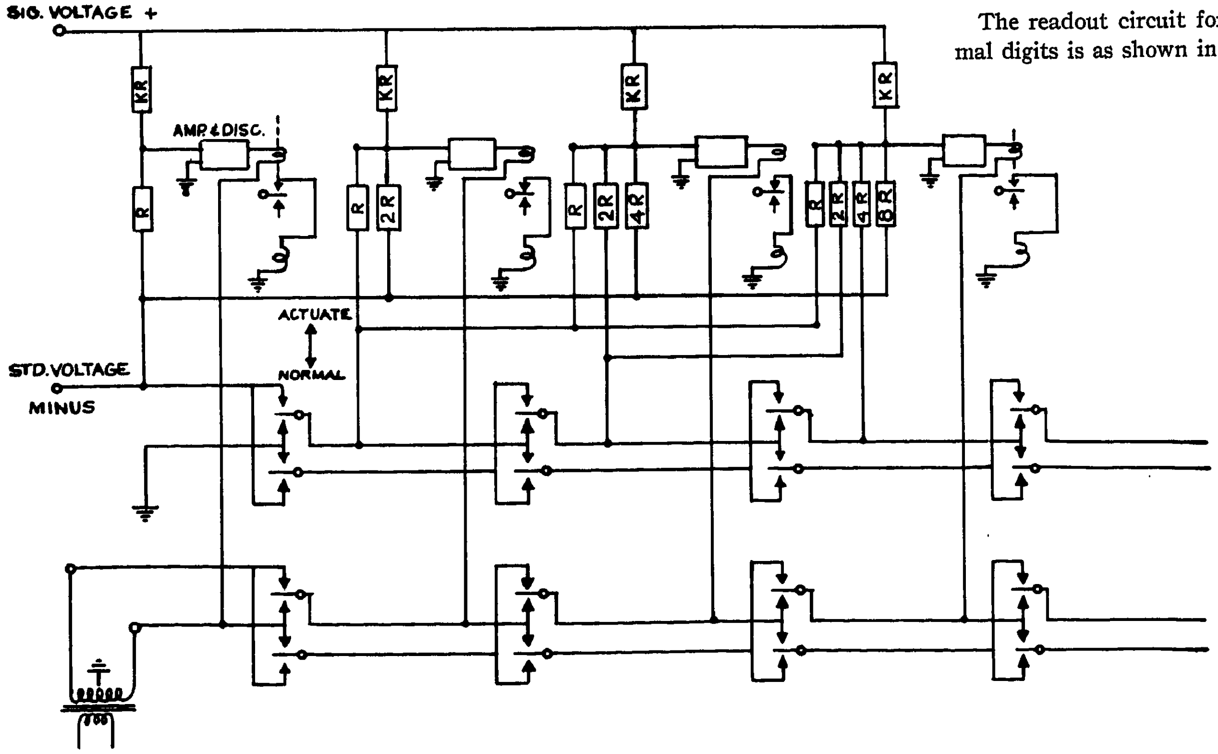

Fig. 5. Hundreds digit circuitry of quantizer shown in Fig. 4

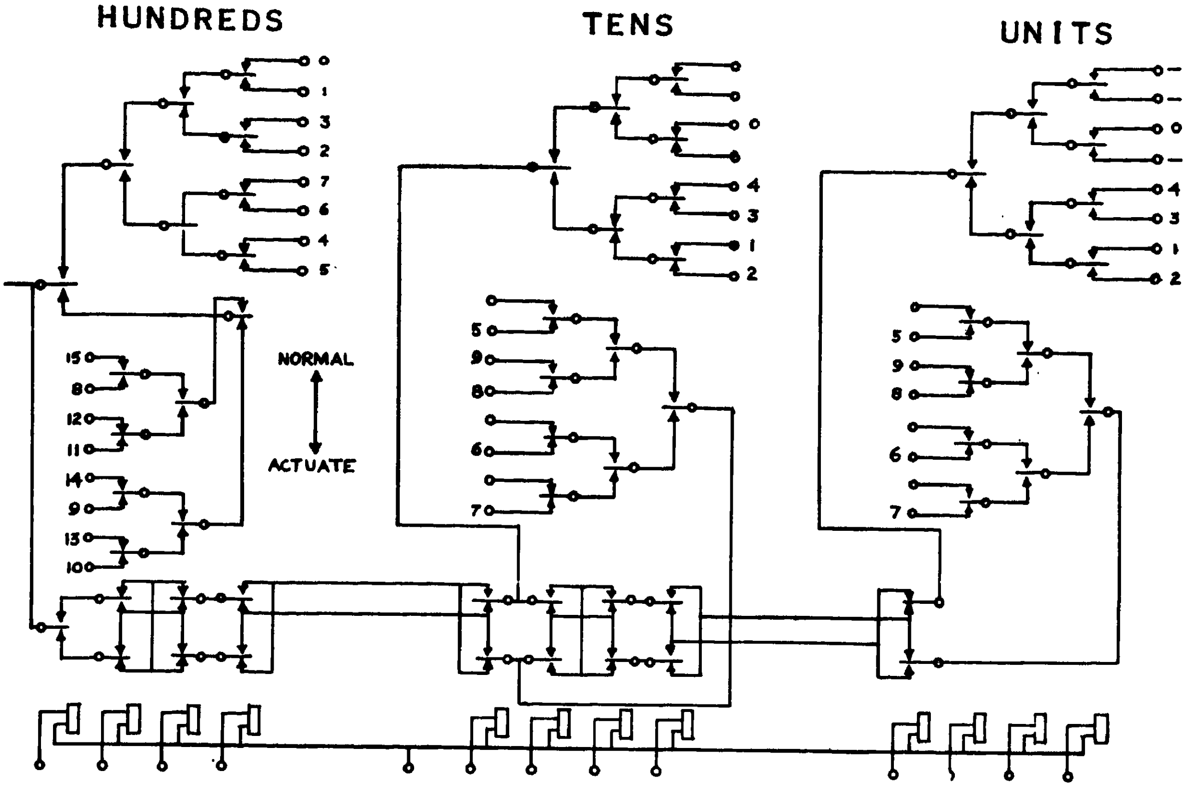
Fig. 6. Readout circuit for translating progressive coded decimal to conventional decimal indication



be noted that a choice between a number and its nine's complement for the tens and units digit output is not only determined by the highest-order Gray-code digit for that coded decimal digit, but also by the reversing contacts, which determine whether the sum of the higher order progressive decimal digits is odd or even. The operation of a single relay in the hundreds digit simultaneously affects the indication of all three decimal digits.

Holding Circuits

The quantizer as constructed also contains circuitry to hold a reading in the readout circuit to allow time for an IBM punch to function. Figure 7 shows the quantizer used in connection with a graph reader and an IBM punch. The graph reader on the left produces an analog voltage, proportional to a graph reading. When an IBM cycle is initiated, the holding circuit holds a reading in the readout. During this time the quantizer proper still follows a varying voltage in the normal manner, and the IBM reproducing punch on the right punches a card with the reading held in the readout. When a release signal is given at the end of the IBM cycle, the readout immediately assumes the setting then indicated by the quantizer.

Conclusions

As a solution to the problem of building an analog-to-digital converter, the instrument described illustrates an approach for which there are many variations. It provides an interesting study in the selection of a numbering system and illustrates the concept of nonlinear elements as the basis for a digital quantizer. It shows that a number system of any radix can be so arranged that any two numbers, only one unit apart, can be indicated by a change of only one digit. It further illustrates that, if the individual digits are indicated by a number of lower radix, the overall number system can still be such that value indications in sequence change progressively with a single digit change per unit value change.

A Permeability Analyzer for Magnetic Amplifier Cores

PHILIP SISKIND
ASSOCIATE MEMBER AIEE

Synopsis: This paper covers the theory and design of an instrument which measures, with the aid of an oscilloscope, the differential permeability of toroidal cores used in magnetic amplifiers. Additions and modifications are discussed which adapt the instrument for rapid selection of cores for production use, using a meter for an indicator. An important feature of the device is that all measurements are made before wire windings are placed on the cores.

THE LAST 7 years have seen remarkable improvements in the performance of magnetic amplifiers, due in great part to corresponding improvements in available high-permeability core materials. However, engineers involved with the manufacture of amplifiers and those concerned with producing cores are still faced with related problems arising from the inability of practical and reliable amplifier circuits to tolerate the wide variations in the magnetic characteristics of mass produced cores. In time these problems will be solved by the development of more tolerant circuits and further improved techniques of core manufacture. The interim solution, however, is the proper grading and matching of cores to control amplifier uniformity and quality.

This paper describes an instrument for measuring core characteristics, which was developed to fill the requirements of both the long range and immediate solutions. The development was carried out with the following aims in view:

1. The instrument should be capable of accurately measuring core characteristics which are theoretically correlatable with magnetic amplifier characteristics.
2. Since placing test windings on gapless, toroidal cores is a turn-by-turn process, it is time consuming and involves undesirable handling. The mechanical design, therefore, should not necessitate hand winding.
3. The instrument should be sufficiently versatile to permit its use for both laboratory and production measurements.

The resulting instrument has been used in the laboratory as an aid in a program to determine the effect of core characteristics on amplifier performance, and also to test production quantities of cores.

Nomenclature

A = cross sectional area of core, square inches
$\mathbf{B}$ = magnetic flux density, gauss
C = capacitance, farads
E = voltage (particular value), volts
e = voltage (instantaneous value), volts
f = frequency, cycles per second
$\mathbf{H}$ = magnetizing force, oersteds
I = current (particular value), amperes
i = current (instantaneous value), amperes
L = inductance, henries
l_m = mean magnetic path of core, inches
R = resistance, ohms
t = time, seconds
τ = time constant, seconds
μ_d = differential permeability
ϕ = magnetic flux, maxwells

Laboratory Version of Instrument

It has been shown by Dornhoefer[1] that the transfer characteristic (output versus input) of a magnetic amplifier approximates, in shape, the hysteresis loop of its core material. This plot of core flux versus magnetizing force is related to another characteristic, the differential permeability loop, which is a plot of its point slope, or differential permeability versus magnetizing force, see Fig. 1. Since it is a derivative, this characteristic is more sensitive to variations among cores than the hysteresis loop itself. It is for this reason, primarily, that the permeability analyzer has been designed to measure the differential permeability loop. Although the slope of the hysteresis loop, and thus its shape, may be determined from permeability data, its saturation flux may not. It is desirable, then, to provide some means for measuring this value.

A simplified diagram of the instrument as used in the laboratory is shown in Fig. 2. It consists of a single-turn winding to excite the core, a single-turn pickup winding whose induced voltage indicates the flux conditions in the core, a source of excitation current, and the required instruments for measuring the excitation current and the pickup voltage. The equation on which the design of the instrument is based, and which describes its operation, is derived in the following.

Consider a core having an excitation winding of one turn, and a pickup winding of one turn. Let the dimensions of the core be:

a = cross section in square inches
l_m = mean magnetic path in inches

Let a current of i amperes flow through the excitation winding producing a magnetizing force $\mathbf{H}$ given by

$$\mathbf{H}=0.495\,\frac{i}{l_m}\text{ oersteds} \tag{1}$$

Let the flux density arising from this magnetizing force be $\mathbf{B}$ gauss. The flux ϕ is then given by

$$\phi=6.45\,\mathbf{B}A\text{ maxwells} \tag{2}$$

The differential permeability is given by

$$\mu_d=\frac{d\mathbf{B}}{d\mathbf{H}} \tag{3}$$

Multiplying both sides of equation 3 by the quantity $A(dH/dt)\times10^{-8}$

$$\left[A\frac{d\mathbf{H}}{dt}\times10^{-8}\right]\mu_d=\frac{d\mathbf{B}A}{dt}\times10^{-8} \tag{4}$$

If values obtained for $\mathbf{H}$ and $\mathbf{B}$ from equations 1 and 2 are substituted in equation 4

$$\left[\frac{3.2A}{l_m}\times10^{-8}\frac{di}{dt}\right]\mu_d=\frac{d\phi}{dt}\times10^{-8} \tag{5}$$

The right hand side of this equation may be recognized as the voltage induced in the pickup winding by the changing flux ϕ. Calling this voltage e_μ

$$e_\mu=\left[3.2\frac{A}{l_m}\frac{di}{dt}\times10^{-8}\right]\mu_d \tag{6}$$

If the time rate of change of current di/dt is made constant, then the voltage e_μ will be proportional to the differential permeability μ_d. When the rate of change is positive, the differential permeability will be associated with the ascending arc of the hysteresis loop; when negative, with the descending arc. The standard magnetizing force will be considered as that produced by such a time-linear current. Then equation 6 will describe the operation of the instrument. The differential permeability is evaluated by measuring e_μ; the magnetizing force by measuring i. The flux in the core is proportional to the integral of e_μ, and its peak value could be read on an average-reading instrument. Unfor-

tunately, however, since the magnitude of e_μ is small and its wave form quite peaked, standard average-reading instruments are incapable of indicating its average accurately. To solve this problem of instrumentation, the voltage is integrated by an electronic integrator, whose peak output voltage is read on a peak-reading vacuum-tube voltmeter.

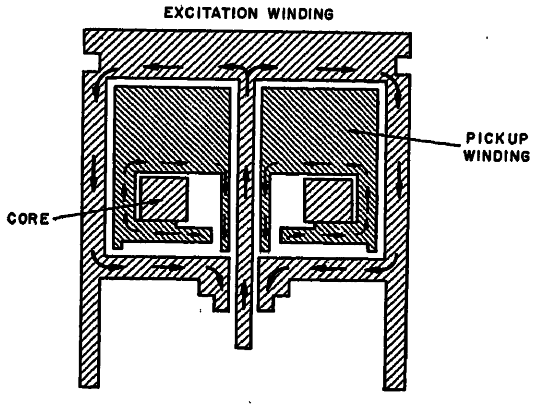
The necessary components of the permeability analyzer are:

1. The excitation clamp—This device is a mechanical arrangement for placing an excitation winding and pickup winding on the core. In order to eliminate whatever effects may be due to dissymmetry of the excitation field, the windings have been designed to produce a standard uniform field, whose direction is always tangential to the core. The windings, therefore, are made up of cylindrically symmetrical shells, nesting one inside the other, completely linking the core and coaxial with it. A cross section of the configuration showing the position of the core, the path of the excitation current, and the direction of the induced voltage e_μ appears in Fig. 3. To permit insertion of the core, both windings are made in separable parts, as shown in Fig. 4. The windings are mounted so that the cap (upper part) of the excitation winding is raised by a rack and pinion operated by a crank. The pickup winding is lifted by hand to insert the core, see Fig. 5.

2. The current source—The current is derived from a sinusoidal line voltage through a high series impedance, as diagramed in Fig. 6. The time linearity requirement is met with reasonable accuracy only at angular arguments near zero. The effect of nonlinearity at large angles is made negligible by adjusting the peak magnitude of current to insure virtual saturation of the core within a few degrees of the zero-axis crossing. The series impedance consists of a series inductance-capacitance combination, resonant at the supply frequency, and a resistor to limit the current. The resonant circuit serves to suppress both the flow of harmonic currents due to inherent distortion of the line voltage, and the pulses of counter electromotive force appearing across the excitation winding while the core is unsaturated. Calculated values of third harmonic distortion, which is theoretically the largest, are less than 0.05 percent in the existing system.

3. Indicating instruments—The quantities e_μ and i are measured with the aid of an oscilloscope. The voltage e_μ is applied to the vertical deflection system, while the voltage drop across a metering resistor, through which the current flows, is applied to the horizontal deflection system. The resulting pattern on the screen will then be a differential permeability loop similar to that shown in Fig. 1. It is difficult to record this pattern with reasonable accuracy when the horizontal gain is increased to magnify the portion of interest. Magnification causes the current peak, and often the current zero, to be thrown off the screen, leaving no simple means of determining current values. Photographic recording is unsatisfactory for the same reason, and also because comparison of a large number of curves is inconvenient. To eliminate this difficulty, the screen is calibrated only in the vertical direction, by simultaneously reading the peak value of e_μ on a vacuum-tube voltmeter, and using a device (described in the following) to transcribe the permeability loops point by point.

Fig. 3. Cross section of excitation and pickup windings



Functionally speaking, the device is made up of a dial and a pair of terminals. Across the terminals is a voltage, consisting of narrow pulses synchronous with the excitation current, which is applied to the z-axis (cathode-ray tube grid) of the oscilloscope, thus causing a blank spot to appear in the trace. The dial reading is proportional to the instantaneous value of current when the pulses occur. The trace is transcribed by recording the vertical deflection of the spot and the corresponding dial reading.

Functions of the device are performed by the equipment shown in the diagram in Fig. 7. The blanking pulse is produced by a pulse generator, which is triggered when its sinusoidal input voltage passes positively through zero. This

Fig. 4. Construction of excitation and pickup windings

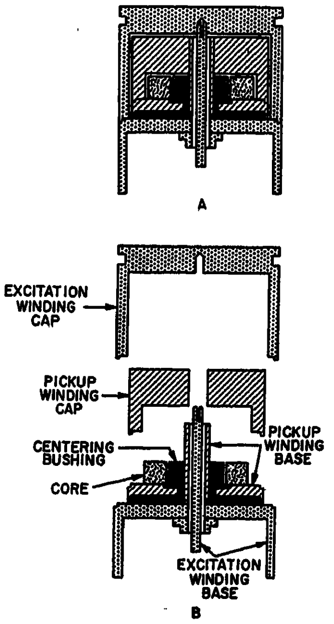

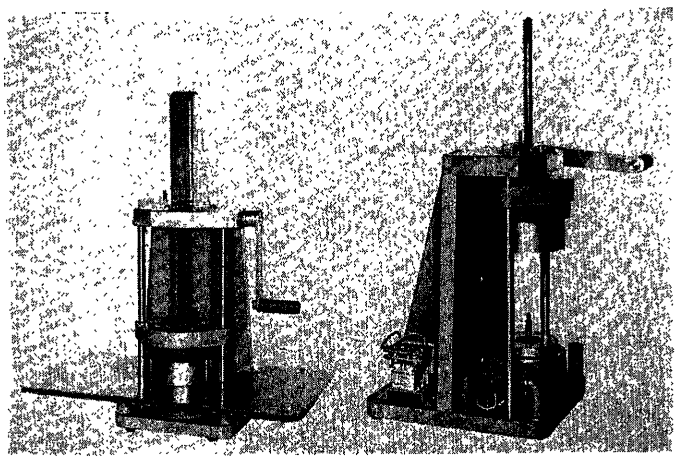

Fig. 5. Laboratory model of permeability analyzer

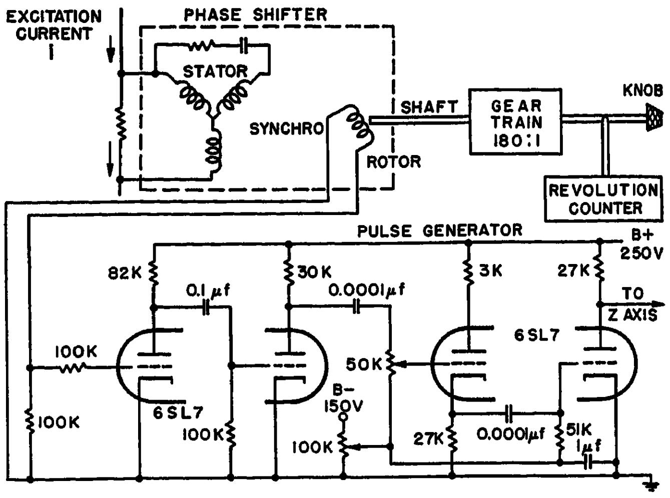

Fig. 7. Blanking-pulse producing device for measuring instantaneous current

input is a voltage shifted in phase from the excitation current by an electromechanical phase shifter whose shaft rotation is equal in radians to the phase shift. Thus, the angle at which the pulse occurs is known, and the instantaneous value of current at the time of the pulse is proportional to the sine of the angle. Values of current in the linear range are considered proportional to the angle itself.

The pulse generator is of conventional design; the phase shifter is a synchro whose stator windings are supplied with 3-phase voltages derived from the excitation current by a phase-splitting network. The rotor shaft is rotated by a knob coupled to it through a stepped-down gear train.

The integrator—a diagram of the integrator used to determine core flux is shown in Fig. 8. A brief analysis of the circuit will show its superiority over the conventional resistance-capacitance integrator.

A 4-terminal network whose output voltage e_o is proportional to the integral of its input voltage e_i is called an integrating network. The ideal form of the transfer function of such a network is

$$\frac{e_o}{e_i}=\frac{1}{\tau}\left[\frac{1}{p}\right] \tag{7}$$

where $1/\tau$ is the constant of proportionality. Practically, this function can only be approximated by one of the form

$$\frac{e_o}{e_i}=\frac{1}{\tau}\left[\frac{1}{p+\frac{1}{\tau}}\right] \tag{8}$$

The approximation improves indefinitely as τ increases, but at the same time the constant of proportionality decreases, thus reducing the magnitude of the output voltage.

Two networks having transfer functions of the form of equation 8 are shown in Fig. 9. The first is a conventional resistance-capacitance integrator whose transfer function is

$$\frac{e_o}{e_i}=\frac{1}{RC}\left[\frac{1}{p+\frac{1}{RC}}\right] \tag{9}$$

Here $\tau=RC$. The second network is a Miller-effect integrator which involves the use of an amplifier gain, G, having capacitive voltage feedback. The transfer function is

$$\frac{e_o}{e_i}=-G\left[\frac{\frac{1}{(1+G)RC}}{p+\frac{1}{(1+G)RC}}\right] \tag{10}$$

Here, the value of τ for integration purposes is $(1+G)RC$, but the constant of proportionality is

$$\frac{-G}{(1+G)RC}\approx-\frac{1}{RC}, \text{ when } G \text{ is very large} \tag{11}$$

Thus for equal performance as an integrating network, the Miller integrator has an output approximately G times that of the resistance-capacitance integrator. The effect is the same as adding an amplifier of gain G to a conventional integrator; however, variations of gain and the effects of amplifier phase shifts will be considerably reduced, as long as the gain is high enough.

The amplifier used in this equipment consists of a "starved pentode" (operated with a very high plate load) feeding a

cathode follower. Since there is only one phase inversion, the performance is similar to that of a 1-stage amplifier, and oscillation problems are considerably reduced. The gain of the amplifier is about 2,500 and its cutoff frequency 1 kc. The upper frequency limit of the integrator for 1 per cent accuracy is about 16 kc, which is about the 250th harmonic of a 60-cycle fundamental. The time constant for integration purposes is about 6.5 seconds, when the resistance-capacitance product is adjusted to cause zero attenuation at 60 cycles.

Core Testing in Production

The most stringent limitation on the variation of cores used in quantity production of amplifiers is that placed on the groups of two or four cores forming the complement of an individual amplifier. The transfer curves of the component reactors must be sufficiently alike to prevent deterioration of performance due to unbalance. It is desirable that this alikeness be achieved by using reactors with matched cores, rather than by separate bias adjustments on each reactor, since the latter procedure involves an increase in the number of components and a decrease in the reliability of the amplifier.

The principal effect of differences of peak permeability and saturation flux between cores will be differences of slope of the transfer characteristic. Far more influential is the position of the permeability peak, which causes an equivalent biasing effect on the transfer characteristic. This effect is illustrated by the curves in Fig. 10, showing the transfer characteristics and permeability loops for two cores. It will be noticed that the displacement of the transfer curves in the *H* direction corresponds in magnitude, to the displacement of the peak permeabilities.

In production, sets of two or four cores, whose characteristics are matched, are selected from run-of-the-mill stock by a 2-step process. First, the stock is divided into grades, within which variation of flux and peak permeability values is small. The second step in the selection consists of grouping the cores in each grade into the required matched sets. It is necessary, for this step, to have a rapid means of detecting differences in peak position. Using the laboratory version of the instrument to perform this function would result in a slow and relatively tedious process. This objection may be overcome by using the following technique.

A voltage is developed which is proportional to the instantaneous difference in permeability between two cores. Since cores in one grade have a small difference in peak permeability, the magnitude of this voltage will be due primarily to the displacement between the permeability loops. This is demonstrated by the curves in Fig. 11, which show the hysteresis and the permeability loops for two cores whose peak permeabilities are the same but whose loops are displaced from each other. The difference between the loops due to this displacement is plotted on the same graph and will be seen to be of considerable magnitude. Thus, limiting the values of the "difference voltage" is a sensitive means of limiting displacement. Development of this voltage involves the same equipment used in the laboratory version of the instrument, with the addition of a second excitation clamp; see Fig. 12. The two cores are compared by connecting the excitation windings in series so that the same magnetizing force is applied to each. The pickup windings are then connected in series opposition. The voltage across their combination is proportional to the instantaneous permeability difference, and its peak value is read on the peak-reading vacuum-tube voltmeter.

Examples of Data

The permeability analyzer has been used in the laboratory to measure the characteristics of more than 1,000 cores of 12 different materials, falling into the following classes:

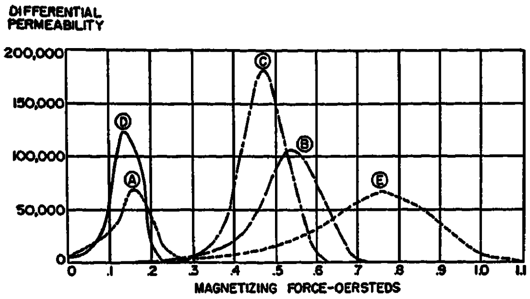

Fig. 13. Permeability loops of typical samples of five core materials

A. 80 per cent nickel-steel alloy
B. 50 per cent nickel-steel alloy
C. 50 per cent nickel-steel alloy, grain oriented
D. 80 per cent nickel-steel alloy, high purity
E. Silicon-steel alloy, grain oriented

1. 80 per cent nickel alloy (Numetal, Hymu 80, etc.)

2. 50 per cent nickel alloy (Hipernik, 4750, etc.)

3. 50 per cent nickel alloy, grain-oriented (Deltamax, Orthonol, etc.)

4. 80 per cent nickel alloy, highly purified (Supermalloy)

5. Silicon steel, grain-oriented (Hipersil)

The cores are all toroids, wound from thin ribbons, and are of several sizes.

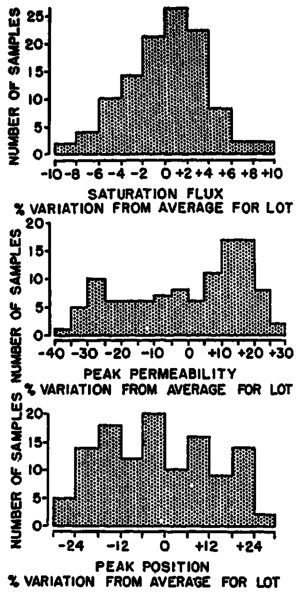

Fig. 14. Distribution of measured values for a lot of 111 cores

The curves in Fig. 13 are differential permeability loops for materials in each of the above classes, demonstrating the wide variety of characteristics presently available. (Since the permeability loops are symmetrical, only one half of each is plotted.) Of the nickel alloys, the 80-per-cent alloys will be seen to have peak permeabilities closer to the zero axis than those of the 50 per cent alloys, indicating narrower hysteresis loops. It should be emphasized that these curves are for typical cores. For cores of one size and material, values of peak permeability and its position vary over a considerable range. This fact is demonstrated by the curves in Fig. 14, which show the distribution of flux, peak permeability, and peak position values for a production lot of 111 cores of the same size (80 per cent nickel). The distribution of flux values is quite normal, and indicates a spread of ±10 per cent about a mean value. This is not surprising, since the total flux is a function of the annealing process to only a slight extent, and depends mainly on the analysis of the alloy and the amount of material in the core. On the other hand, the peak permeability and its position are very much dependent on the annealing and show variations which appear to be random over a much larger range. It is this range, especially for values of peak position, which demonstrates clearly the nature of the problem.

Forcing Function Generator Employing Conductive Plastic

L. W. NORMAN
ASSOCIATE MEMBER AIEE

Synopsis: This paper describes a forcing-function generator which uses a conductive-plastic potentiometer to provide a forcing-function signal for testing servo systems and components. The unit described gives a sine-wave signal, but methods for generating a square wave or triangular wave are also discussed. A phase-measuring device is made an integral part of the function generator, and allows output versus input phase shift to be read directly from a calibrated dial.

THE FORCING FUNCTION generator is an important instrument in a servo laboratory. Like the signal generator, which is its counterpart in the communications field, it serves as a signal source in making frequency-response measurements on servo components and systems. However, there are several important differences. The most noticeable of these is the difference in frequency range. In industrial-process control systems, the lower limits are often in the region of 0.001 cycle per second, while in other systems, especially hydraulic, the upper limit may be 50 or 60 cycles per second. However, most systems can be adequately tested with a function generator which has a range of 0.05 to 20 cycles per second.

Since the function generator's primary use is in frequency-response measurements, the most important signal it must supply is a sine wave. This signal will usually take one of two forms, a simple sine wave or a sine-wave-modulated a-c carrier.

Forcing function generators can be divided into two general groups, mechanical and electrical. From these two general groups there are an almost unlimited number of variations which can and have been constructed.[1–5] The electronic function generator may be preferable, especially when supplying a pure sine wave; but it requires additional equipment if this sine wave is to be used to modulate a carrier. The mechanical or electromechanical function generators may be divided into two additional groups. The first group includes those generators in which a rotating machine, such as a synchro, is used as the signal source. The

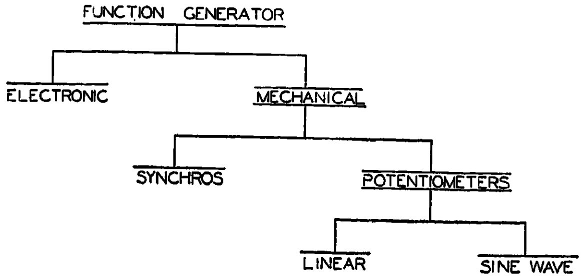

Fig. 1. Types of function generators

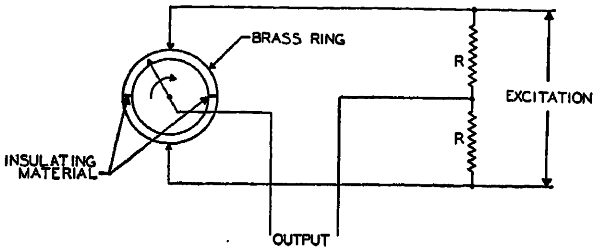

Fig. 3 (right). Method of connecting plastic for the generation of square waves

chief disadvantage of this type of function generator is its inability to supply anything but a modulated a-c carrier signal at low frequencies. With d-c excitation it has the disadvantage of phase shift at higher frequencies. Those of the second group of mechanical function generators employ wire-wound potentiometers and wipers as means of obtaining the desired signals. By applying d-c to the potentiometer, a pure sine wave is obtained; and by applying a-c, a modulated sine wave is obtained. Fig. 1 is a chart showing the various types of forcing function generators. It should be noted that the group of function generators employing potentiometers has been broken down into two additional groups. One group includes those generators which employ a scotch yoke or some similar mechanical device to drive a linear potentiometer. The second group includes those generators employing sine-wave potentiometers and other special devices. The function generator to be described is included in the latter group.

There is also a third group of function generators which might be mentioned. This is a miscellaneous group which employs special alternators, rotating discs, photoelectric cells, and similar devices.[6,7] This group is rather specialized and constitutes but a small percentage of the function generators in general use.

Because it is readily adaptable for supplying either a sine wave or a sine-wave-modulated a-c carrier signal, the potentiometer type of function generator enjoys several advantages over other types. However, it is not without disadvantages. If a linear potentiometer is employed, some mechanical linkage must be employed to produce a sinusoidal signal wave. Mechanical linkages are subject to wear. To a certain extent this objection can be overcome by the use of sinusoidal potentiometers. A second objection, not so easily overcome, is inherent in the potentiometers themselves.[8] As the wiper moves along the potentiometer, its output is a series of successive steps as the wiper moves from one wire to the next. Thus the output signal is not a smooth curve but is actually a series of steps. By making these steps very small, the approximation to a smooth curve becomes much better, but the cost of the potentiometer increases and its life decreases.

Function Generator

The mechanical function generator employing some type of linear potentiometer or sinusoidal potentiometer seems to be the most desirable from a standpoint of reliability and simplicity. The sinusoidal potentiometer is ideal except for the problem of resolution and the possibility of excessive wear. One potentially attractive solution to these problems is the use of a conductive-plastic potentiometer.

It is well known that a wire-wound potentiometer made in the form of a square card can be used to produce sine wave electrical signals with mechanical rotary motion input.[9] However, the problem of resolution still exists. By substituting a homogeneous piece of conductive plastic for the wire-wound potentiometer, the number of steps can be increased to infinity so that a stepless sine-wave signal is produced.

To obtain a sine-wave output, the plastic is connected as shown in Fig. 2. In some instances, it is desirable to generate a forcing function other than a sine wave. This will usually be a square wave or triangular wave. A square wave can be generated quite easily without the use of conductive plastic. Fig. 3 shows a circuit arrangement which might be used for the generation of a square wave. However, conductive plastic can be employed to generate a triangular wave. Fig. 4 shows the circuit arrangement which is necessary.

The type of output which is obtained from the function generator depends upon the type of excitation applied to the conductive plastic. With d-c excitation the output is a sine wave having a frequency equal to the drive shaft speed. When a-c excitation is used, the output becomes a sine-wave-modulated a-c carrier. Here the carrier frequency is the frequency of the excitation and the modulating frequency the drive shaft speed.

The circuits of Figs. 2, 3, and 4 make it necessary to provide some form of external summing circuit if the function generator is to be used in making closed-loop studies. To simplify the testing of both open and closed-loop systems, the above circuits were modified in order that closed-loop systems could be studied without the need for external summing circuits. The circuit of Fig. 5 shows the changes necessary to accomplish this. With the switch in the open position, the function generator is supplying an input signal to the servo system. This signal is independent of the output position of the servo system and gives an open-loop test. When the switch is in the closed

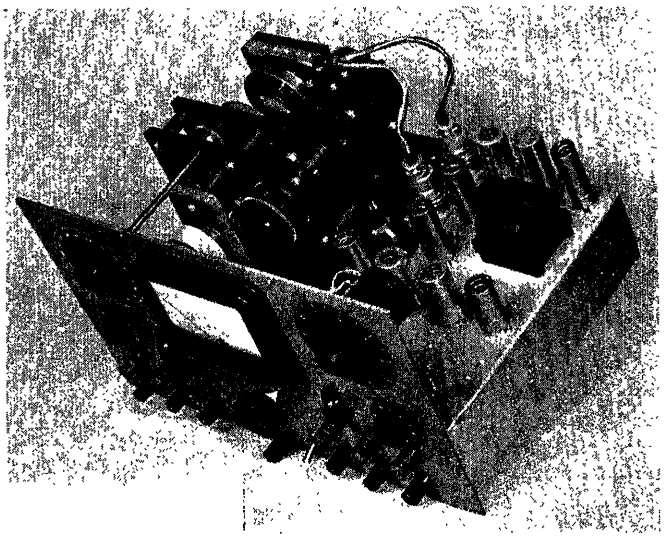

Fig. 7. Right-side view of function generator

position, the signal supplied to the servo system is the output of the function-generator series, summed with a signal proportional to the output position of the system. This gives a closed-loop test.

A 2-phase servomotor with built-in velocity generator, connected in a velocity servo system, was used as the driving motor for a function generator of the type described above. The particular motor used required approximately 7 watts per phase. The maximum speed of the gear-train output shaft was 200 rpm, or 3.7 cycles per second. By suitable adjustment of input voltages to the amplifier, the output speed could be reduced to 3 rpm, or 0.05 cycle per second. To obtain higher speeds, it was necessary to provide a second output shaft in the gear train. This shaft, which was brought out as an extension on one of the existing gears, gave an output speed range of 0.9 to 60 cycles per second. A lever was provided to shift an idler gear between the function generator proper and either of the two output shafts. Manual motion of this lever allowed selection of one or the other of the two speed ranges. Figs. 6, 7, and 8 show the mechanical details of the drive mechanism.

To help eliminate, as nearly as possible, all additional equipment needed, a-c and d-c excitation for the conductive plastic potentiometer was provided within the function generator. A frequency meter was also included to enable quick determination of the forcing frequency. Frequency was determined by rectifying the output voltage of the velocity generator and feeding this rectified voltage into a d-c milliammeter. Fig. 9 gives the complete schematic diagram of the forcing function generator and Fig. 10 shows the front panel of the instrument.

Phase Measurement*

To measure phase shift, a conventional d-c cathode-ray oscilloscope is used. The output wave, produced by a sinusoidal-potentiometer wiper positioned by the servo output shaft, is applied to the vertical deflection plates; and a sawtooth sweep voltage, taken from a linear potentiometer geared to rotate at twice the forcing-function generator's speed, is applied to the horizontal deflection plates. The resulting display consists of the positive half and the negative half of the output wave superimposed on the screen. The output-phase reference point is at the intersection of the two half waves.

Connected to the rotating shaft of the function generator is a shorting bar which provides a momentary short circuit between two brushes. If the shorting bar on the forcing-function generator is wired so as to short out the output wave momentarily, a marker depression will show on one part of the output wave. This can be made more distinct by adding a battery in series with one of the leads to the shorting bar. The position of this

---

* The method of phase measurement is essentially that contained in an unpublished memo by Frank W. Ainsworth, aeronautical research engineer, Minneapolis-Honeywell Regulator Company, Minneapolis, Minn.

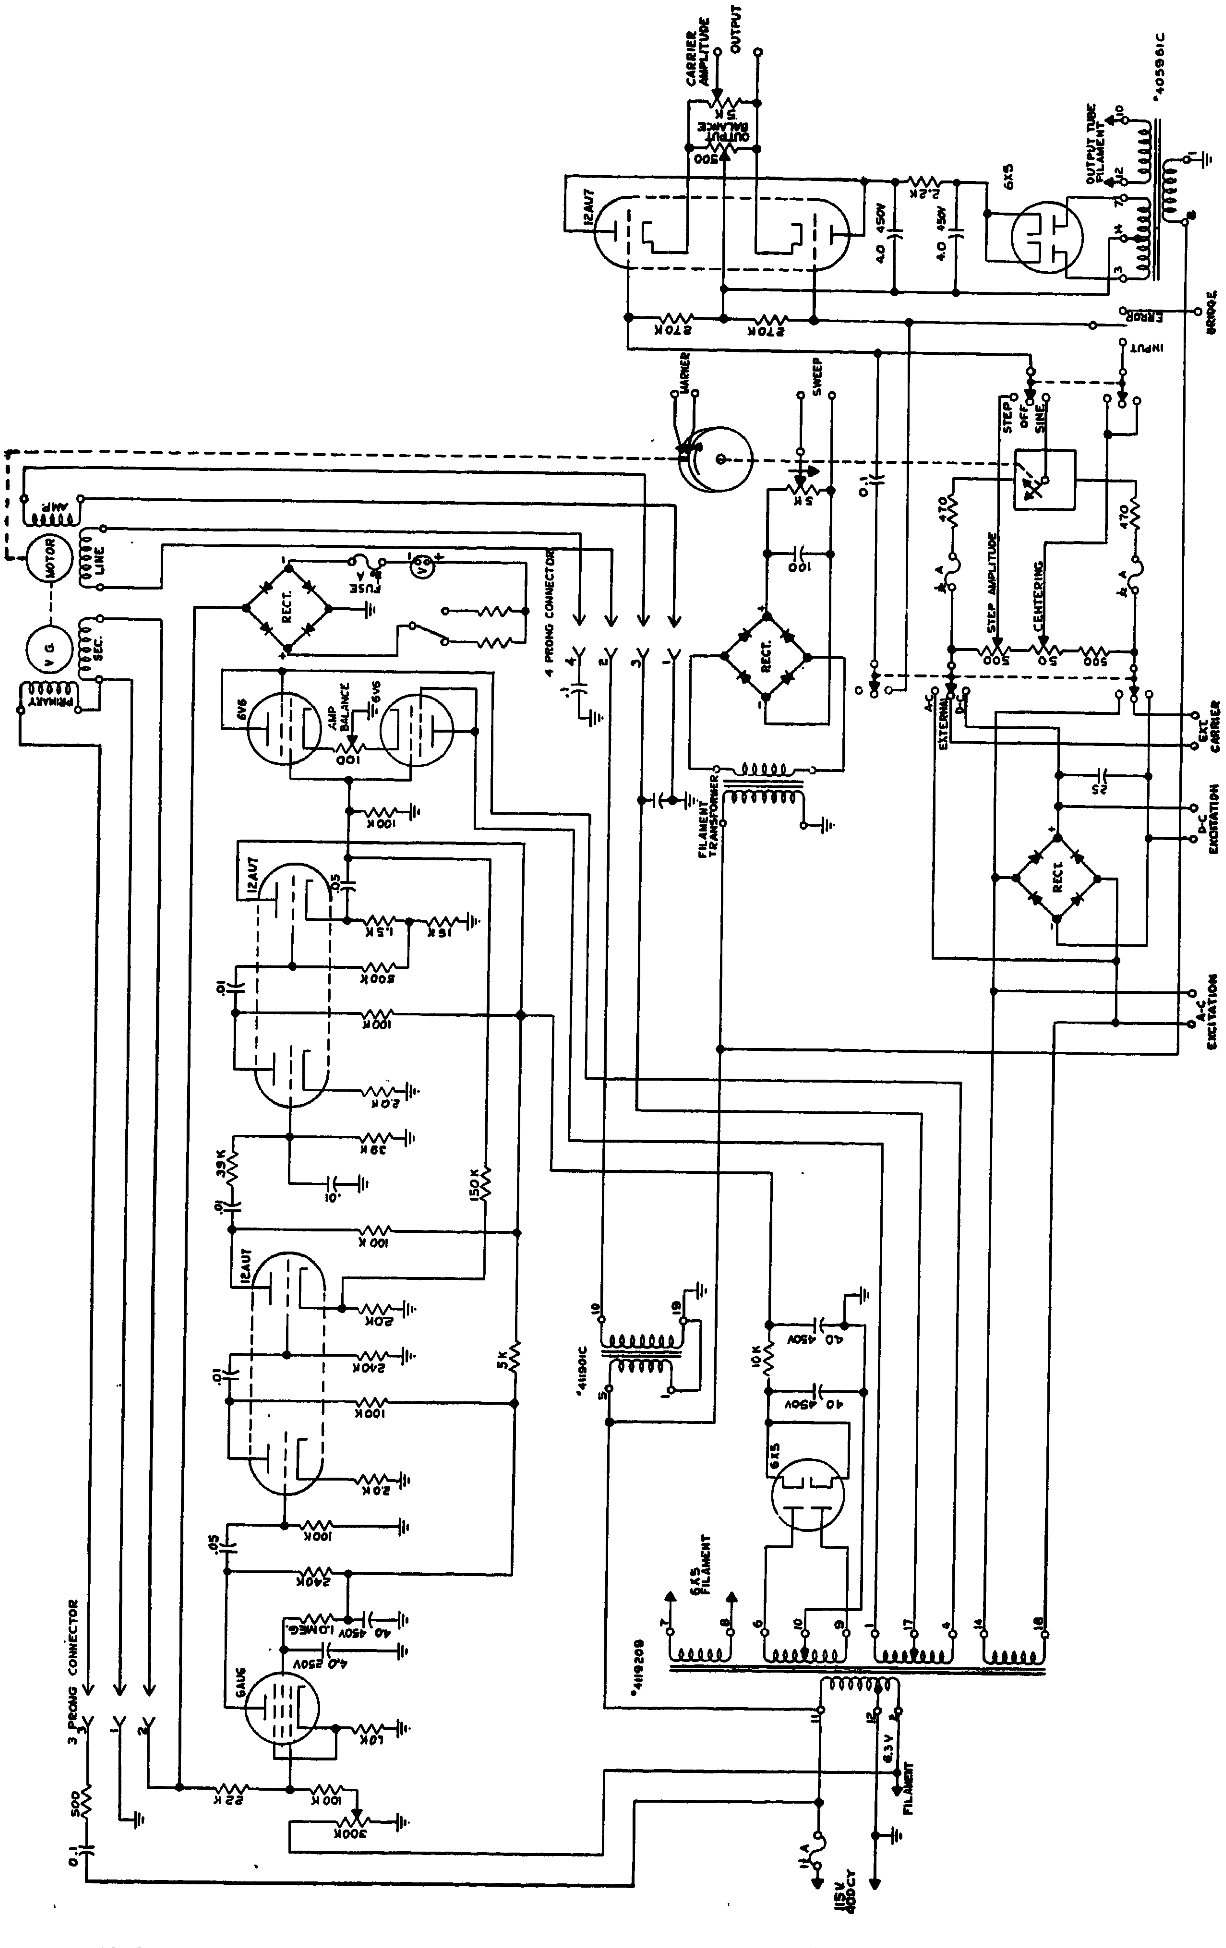

Fig. 9. Schematic of forcing function generator

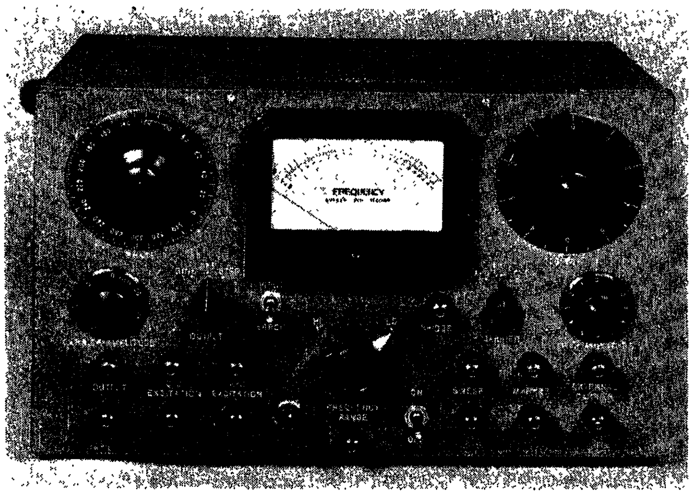

Fig. 10. Front panel of function generator

marker pip on the wave depends upon the position of the brushes, which are carried on a rotatable ring to which is attached a dial graduated in degrees. Rotation of this phase dial moves the marker pip along the wave. To measure phase shift, the marker pip is moved to the point where the two half waves cross over, and the reading of the phase dial is observed. The output-versus-input phase shift is then the difference between this reading and a similarly made reading on the input wave. For systems known to have zero phase shift at zero frequency, the reference may be the reading at the lowest possible frequency which will produce a useable image on the screen. The appearance of the display in using this method of phase measurement is illustrated in Fig. 11.

This method of phase measurement gives very good results over the range 0.05 to 20 cycles per second. The lower value is determined by the persistence of the screen. At still higher frequencies, the high wiper velocities of the sweep-frequency potentiometer cause the display to become somewhat hashy.

Conductive Plastic

The conductive plastic used in the forcing function generator is an Epoxy resin compounded and molded by the Minneapolis-Honeywell Plastics Laboratory. Major components of the plastic are:

1. Epoxy thermosetting resin
2. Inert filler (silica filler)
3. Carbon (acetylene black)

The volume resistivity of the plastic used in the function generator was approximately 900 ohm-centimeters. The linearity of this plastic is very good and in the particular piece used, was better than 1 per cent.

In making electrical connections to the plastic, an important consideration is contact resistance between the plastic and the conductor which is being attached. If appreciable contact resistance is present, the voltage gradient across the plastic will suffer a discontinuity at the edge of the plastic. For example, in a potentiometer element that has considerable contact resistance, the voltage gradient shown in Fig. 12 would exist. To keep this contact resistance as low as possible, the conductor is attached to the plastic as shown in Fig. 13. The edges of the plastic are first coated with silver paint, and a copper sheet, which acts as the conductor, is held against this paint by a rubber strip and the end plate. This method of mounting the plastic allows the contact resistance to be held to an acceptably low value.

High contact pressure is necessary on the wiper to insure uniform contact with the plastic. A spring-loaded brush riding vertically upon the face of the plastic is used and has proved to be satisfactory. This brush consists of a 0.025-inch diameter Paliney wire. It is mounted in a holder, spring-loaded to provide a contact force of approximately 75 grams.

Even though the contact pressure of the wiper is quite high, the contact resistance between the plastic and the wiper is quite appreciable. This contact resistance is actually a combination of the actual contact resistance between the wiper and plastic, and an apparent contact resistance caused by the high current densities in the plastic at the point of contact with the wiper. Because of this high resistance, which is approximately 50,000 ohms, it is necessary to insert a buffer amplifier between the plastic potentiometer and the output terminals. This buffer amplifier uses a d-c push-pull cathode-follower circuit.

Fig. 11. Wave shapes for determining phase shift

Conclusions

The conductive-plastic potentiometer has been found to function very well in the forcing-function generator. Because it is homogenous there are no steps in voltage such as are encountered in wire-wound potentiometers. The conductive-plastic potentiometer has been found to present as great a wear problem as the wire-wound potentiometer, but its design allows much easier replacement of the wiper.

It is anticipated that conductive plastic can be useful in a linear potentiometer to replace the wire-wound unit currently used to generate the sweep frequency. Preliminary tests have indicated that the conductive plastic will function very well in this application.

Synchronized Magnetic Tape Recording

R. H. RANGER
FELLOW AIEE

MOTION PICTURES have obviously required synchronized sound to match picture and words in all released prints. Perforated film has been the usual answer to this requirement ever since sound was added on film. But now that magnetic recording has shown such tremendous opportunities in quality and economy, the use of this facility for sound for motion pictures is immediately attractive. One answer has been, of course, the use of normal photographic film stock, coated however with iron oxide instead of the usual silver emulsions. And again perforations accomplished the lock-in. But 1/4-inch tape without sprocket holes is so much more flexible because of its thinness, takes up so much less space, and gives top quality with so little effort that its use would certainly be ideal if synchronism might also be accomplished.

Control Track Recording

Instead of relying on mechanical lock-in to accomplish synchronism with 1/4-inch tape, electronic lock-in has been a most satisfactory answer. Among the several methods proposed, the methods here described consists in recording on the same 1/4-inch tape not only the normal longitudinally-magnetized audio record, but also a control track consisting of a transverse magnetization from the 60-cycle power driving both the tape machine and the camera at the time of the picture shooting. This makes for maximum simplicity in recording, gives two channels, one for the normal audio in the normal manner, and the other for the control track, with no interference by the control track on the audio channel.

The object of having the control track is to provide means on playback for automatically controlling the speed of the tape machine so that the audio track will remain in synchronism with the film, regardless of the absolute speed of the film.

It is easy enough to record a transverse flux in step with the 60-cycle power, using a head turned at right angles to the normal audio heads. This means that the control recording head shown at *A* in Fig. 1 is turned at right angles to the direction of the motion of the tape and is normally placed to record directly in the center of this tape. Gap width in most magnetic heads is of an extreme fineness—of the order of half a mil. The first answer to recording the control track was to use this fine gap exactly in line with the tape movement and register a 60-cycle track in the center of the tape. But this required a relatively short gap in the direction of motion of the tape such that the recording of the 60 cycles where the tape first contacted the gap in the head would not be cancelled out when this same portion of the tape hit the trailing end of the gap. To avoid this, and also to make the alignment of tape with head much less critical, the gap *T* is tiled at an angle of 6 degrees as shown on *A* in Fig. 1. This means that as the tape moves to the right and a small voltage from the 60 cycles is applied to the coils of head *A*, the various phases of the recording cycle are put down in shingle fashion over each other along the tape as indicated at S. This tilt as selected is downwards from left to right looking at the front of the head with the tape passing over it from left to right. It could, of course, have been exactly the other way just as well. In fact it is possible to place two independent control tracks on a single tape, one tilting downwards and the other upwards.

In order to prevent this shingled magnetic recording track from affecting the audio track, the length of the tilted gap is most important. The primary standard tape speed for professional tape work is 15 inches a second, with $7^1/_2$ inches a second as the secondary standard. At 15 inches a second, the tape moves forward 1/4 of an inch for every 1/60 second representing 1 cycle of a 60-cycle power source. It is seen that at any instant a vertical gap would cut across a succession of these shingled phases. The resolution of the flux F_0, for the 360-degree point is shown at the left of the gap *V* in *B* of Fig. 1, with F_2 the flux which alone would affect the audio gap *V*. But the summation of all these small F_2 fluxes from zero to 360 degrees would add vectorially to zero to give no effect magnetically on gap *B*, provided this gap is cutting only from zero to 360 degrees of the shingled fluxes. This will happen if the effective length of the recording gap in the direction of F_2 along the tape is 1/4 inch.

To be sure that the effective magnetic length of the gap is 1/4 inch, the matter was checked very completely by using a fixed gap length which was accurately measured physically at 1/4 inch. Then, with the 60-cycle control-recording current held constant, the tape speed was varied and the pickup in the audio head *B* was measured. Fig. 2 shows resultant curve made by calculating equivalent gaps based on speed variations. A definite minimum was established in this crosstalk in the audio channel which was down at least 10 decibles from what the normal 15-inch speed would have given without this accurate speed adjustment. The speed turned

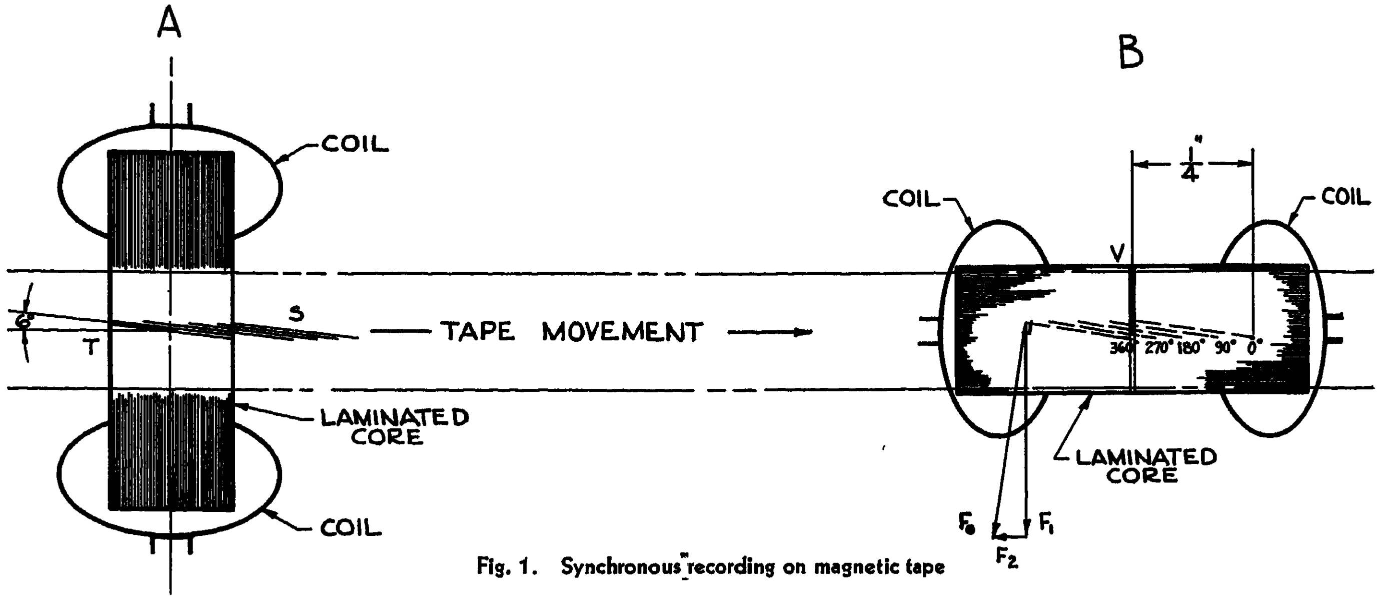

Fig. 1. Synchronous recording on magnetic tape

out to be 15.45 inches per second for this minimum reading. This showed that with the physical length of the gap of 0.250 inch the actual recording was spreading out to be 15.45/60 = 0.2575 inch.

By interpolating from this, it was determined that the actual gap length along the tape should be 0.00242 inch instead of 0.0025 inch, for minimum crosstalk at the regular 15-inch-per-second speed.

With an impedance of approximately 200 ohms at 60 cycles on the recording head, 0.25 volt gives an ample record of the 60-cycle pulse on the tape; 150 microvolts are easily obtained directly off the control playback head. On the audio pickup head crosstalk from this control track will be of the order of 53 decibels down from the normal audio signal.

The synchronizing playback-control head is made very similarly to the synchronizing record head, except that the angle is increased to 10 degrees, which merely means that the tape can have greater excursion up and down. The gap width for control recording is 2 mils and for playback is 9 mils.

Tape Path

In order to provide a very smooth controllable tape path, which will have a minimum of flutter, the tight loop drive has been initiated on 1/4 tape on this equipment, as shown in Fig. 3 for the top plate. The tight loop is the small section in the center from the drive capstan in the very center down to the flywheel at the bottom. This tight loop has been used for motion picture film for several years, except that with tape there can be no sprocket wheels to maintain the loop. The rubber idlers hold the tape in contact with the capstan on each side, and the rotation of this casptan communicates itself to the tape and the tight loop down to the flywheel and back. It would seem that the amount of tape going in would be exactly equal to that going out so that there would be no tension on tape in the tight loop. But it is surprising to see that the tape in the tight loop actually tightens up even with only the single diameter on the capstan. This is because there is an actual tension balance in the tape going in and going out, determined practically entirely by the tension on the tape accomplished by the drag of the supply reel in the upper left of the top plate.

This tension is accomplished by applying the right amount of direct current to the induction motor connected to the supply reel. This makes the tape tension at the capstan, where it enters on the left, greater than that on the right, where the tape leaves. This tension means that the tape will actually be stretched slightly at entering more than it is on leaving. Therefore, it takes more rotation of the capstan to put tape into the loop than it takes to pull it out. The net result is that the amount of tape in the loop decreases up to the time when a balance point is reached when the tension on the inside of the loop equals that of the tape entering from the supply reel.

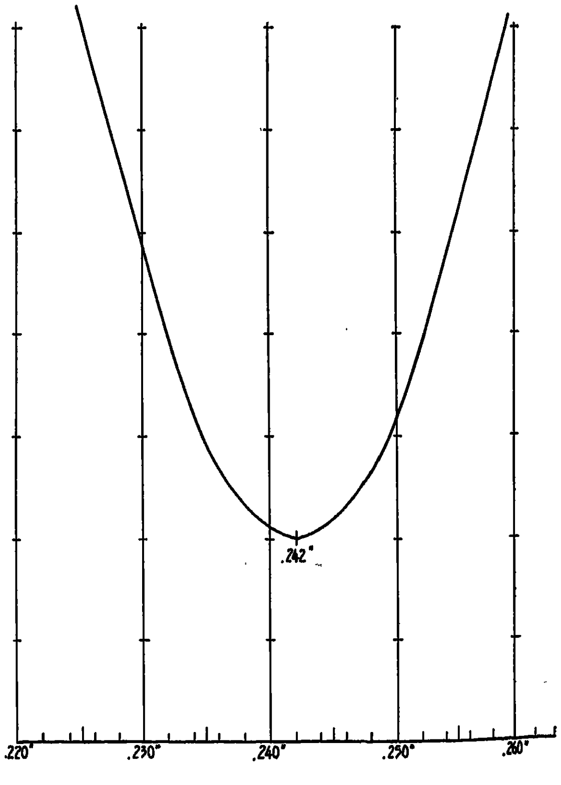

Fig. 2. Crosstalk as a function of recording gap length

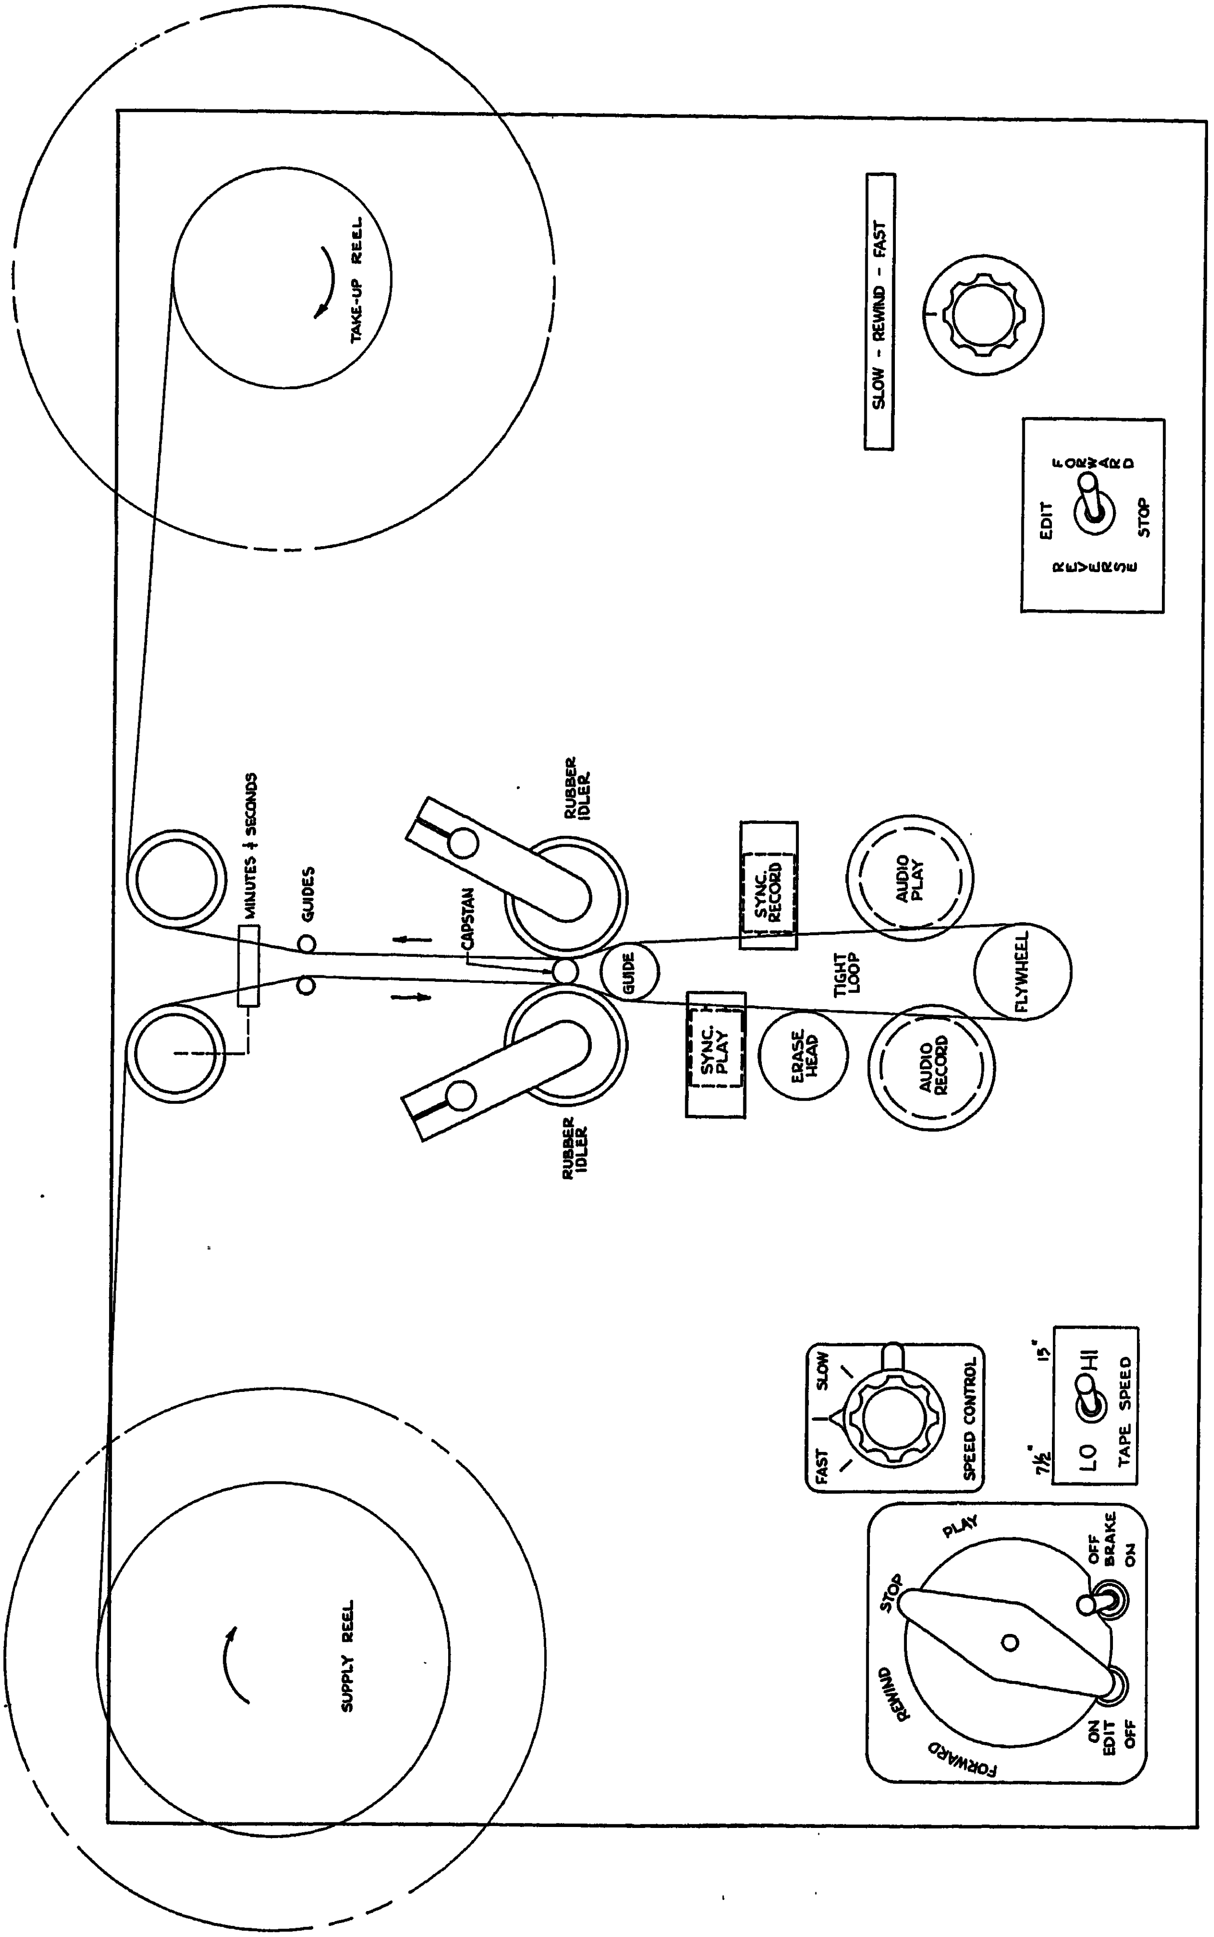

Fig. 3. Top plate showing tape path

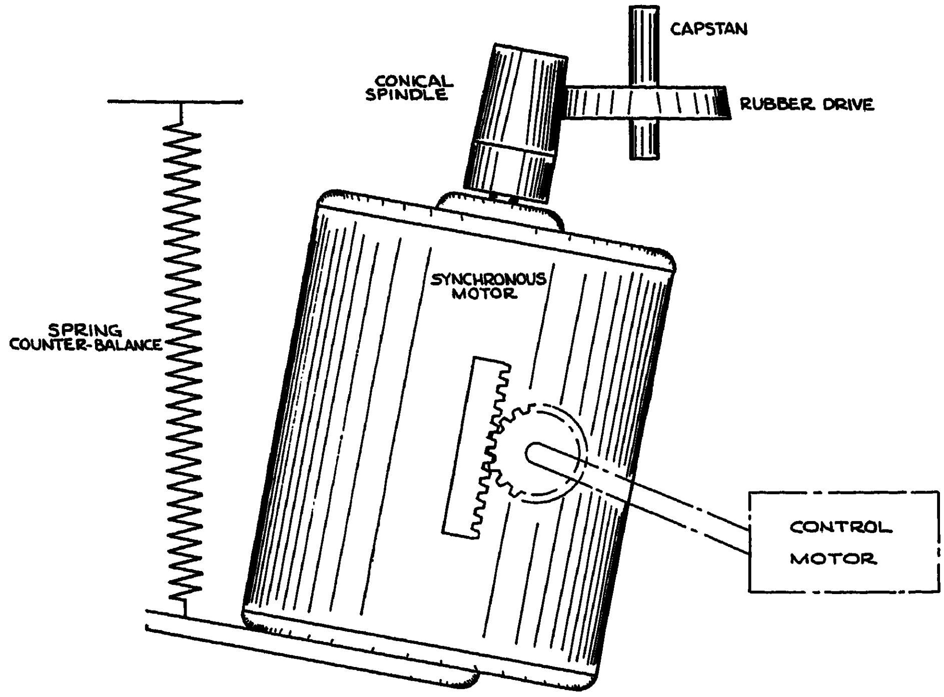

Fig. 4. Variable speed drive

After this point is reached the tape tensions remain in balance, and the loop stays tight.

For effective operation, the heads are put in the following sequence: first, the synchronous playback head, followed by the erase head. The reason for putting the synchronous playback head first is so that it will pick up a synchronizing signal if one has already been made on the tape. This will hold the tape at exactly the speed in which the original sync recording was made. If a new recording is to be made, the tape then passes on by the erase head. The erase head has a transverse wide gap supplied from a high frequency source: 80,000 cycles is currently used. This completely erases audio and synchronizing signals from a tape that is already recorded. The tape then passes on to the audio record head, which has a very narrow gap of the order of half a mil in thickness, and then the tape passes around the flywheel.

The tape passes on to the audio play head, which again has a narrow gap, and finally leaves the tight loop by passing the synchrónous record head which gives the shingled recording previously described from low-voltage 60-cycle power. This new synchronous recording will match the spacing of the original recording because the latter is being used to hold the tape speed during this operation.

Speed Control

To control the tape speed, it is possible to use a synchronous motor driving the capstan, and change the frequency of the power driving the synchronous motor. But this takes considerable power, which is hard to generate from vacuum tubes, and a far more practical answer has been set up on this equipment, as shown diagramatically in Fig. 4. The synchronous motor is connected directly to the normal 60-cycle power. But the capstan is driven from the synchronous motor by means of a conical spindle on the motor, and a conical rubber drive wheel on the capstan shaft. So the actual rotational speed of the capstan is determined by the effective diameters of the motor conical spindle and the rubber drive, where the two contact.

Now, if the whole synchronous motor is moved up and down it is seen that the effective diameter of the conical spindle where it contacts the rubber drive will vary, and as a result the speed ratio between the capstan and the synchronous motor will change. A three percent plus or minus speed change from the 15-inch normal tape speed may be accomplished with the equipment as set up. The actual movement of the synchronous motor up and down is accomplished through a clockwork gear reduction from a very small a-c induction control motor. Or it may be accomplished manually, as shown by the speed control dial on Fig. 3 in the left center. A spring is used to counter-balance the weight of the synchronous motor.

A large operating switch is in the lower left hand corner of the top plate, Fig. 3, with positions as shown. In the position shown the control knob is at stop. Twisting it to the right puts the machine in play. In this position, the tape will play back a previously recorded signal and the speed of playback will be determined by the control signal. While the machine is in the play position the edit on-or-off switch may be flipped into the slot in the cam attached to the control knob, which then brings into action the edit switch on the lower right of the top plate.

This edit switch has three positions, center for stop, right for forward, ane reverse for backward. With this switch, the tape moves at normal speed forward and back which facilitates picking out spots on the tape, because their pitch will be normal even though the tape may be going backwards. A separate push button for recording (not shown) is then necessarily pushed to do recording, and a red light above the erase head shows that it is in operation, and a green light above the synchronous record head shows that it is putting the control track down on the tape.

For rewind, to take the tape back from the takeup reel on the right to the supply reel on the left, the control knob is turned to the position at the left of stop and then the knob on the far right lower part of the top plate may be used to change the speed of the rewind, so that selections, may be approached slowly when necessary. Then on turning the control knob to the extreme left the tape will go forward under this same right hand control knob, either slow or fast. The heads are assembled on swivel mounts, so that on rewind the mounts are turned back out of contact with the tape so that the tape does not wear them out unduly. The wear upon heads increases rapidly with tape speed. The rubber idlers in the center of the top plate are solenoid driven and are in position only when the control knob goes to play. This again relieves the tape tension on the idlers, capstan and heads on rewind.

Synchronous Playback

Finally there is the matter of picking the control signal off a recorded tape and making it hold the tape absolutely in step with the film, even though the tape may be stretched because of humidity or temperature changes. This is accomplished by changing the capstan speed, as previously described. The equipment that does it automatically is a synchronizer of special design, shown in Fig. 5. Starting with the synchronous playback head *a* in the upper left, the signal which should be 60 cycles from the tape has a value of anything from 150 to 1,000 microvolts, which is built up in amplifier *b* to 5 volts. It is then doubled in frequency at *c*.

One of the purposes of doubling it is to minimize splicing junction errors. Obviously, if two sections of tape are joined together the chances that the 60-cycle recording would be absolutely accurately joined would be most problematical. However, if the frequency is doubled, the consequent out-of-phase error which may come from splicing will be just half as serious, because with the frequency doubled the effect is the same whether a plus or a minus half of a 60 cycle pulse reaches this point of the circuit. The maximum error in splicing will thus be half a cycle or 1/120 second, which is only 1/5 motion-picture frame. Whenever a signal from the tape reaches this point, it releases a relay *e*, which turns on a green light indicating that the synchronizing signal is present. This also puts the entire control operation into action. Obviously, there should be corrective action only when the synchronizing signal is present and a purposeful correction is indicated. The 120 cycles as doubled at *c*, then goes on to an amplifier-limiter at *d*, which establishes a fixed level of 20 volts up to this point, whenever the sync signal is present. An oscillator is driven by this 120-cycle signal at *f*. This oscillator is nominally at 60 cycles, and the 120 cycles input locks it in very nicely. Again it is advantageous to have 120 cycles for this junction because wave form variations in this 120 cycles have much less effect in the wave form of the oscillator at 60 cycles than it would if they both were at 60 cycles.

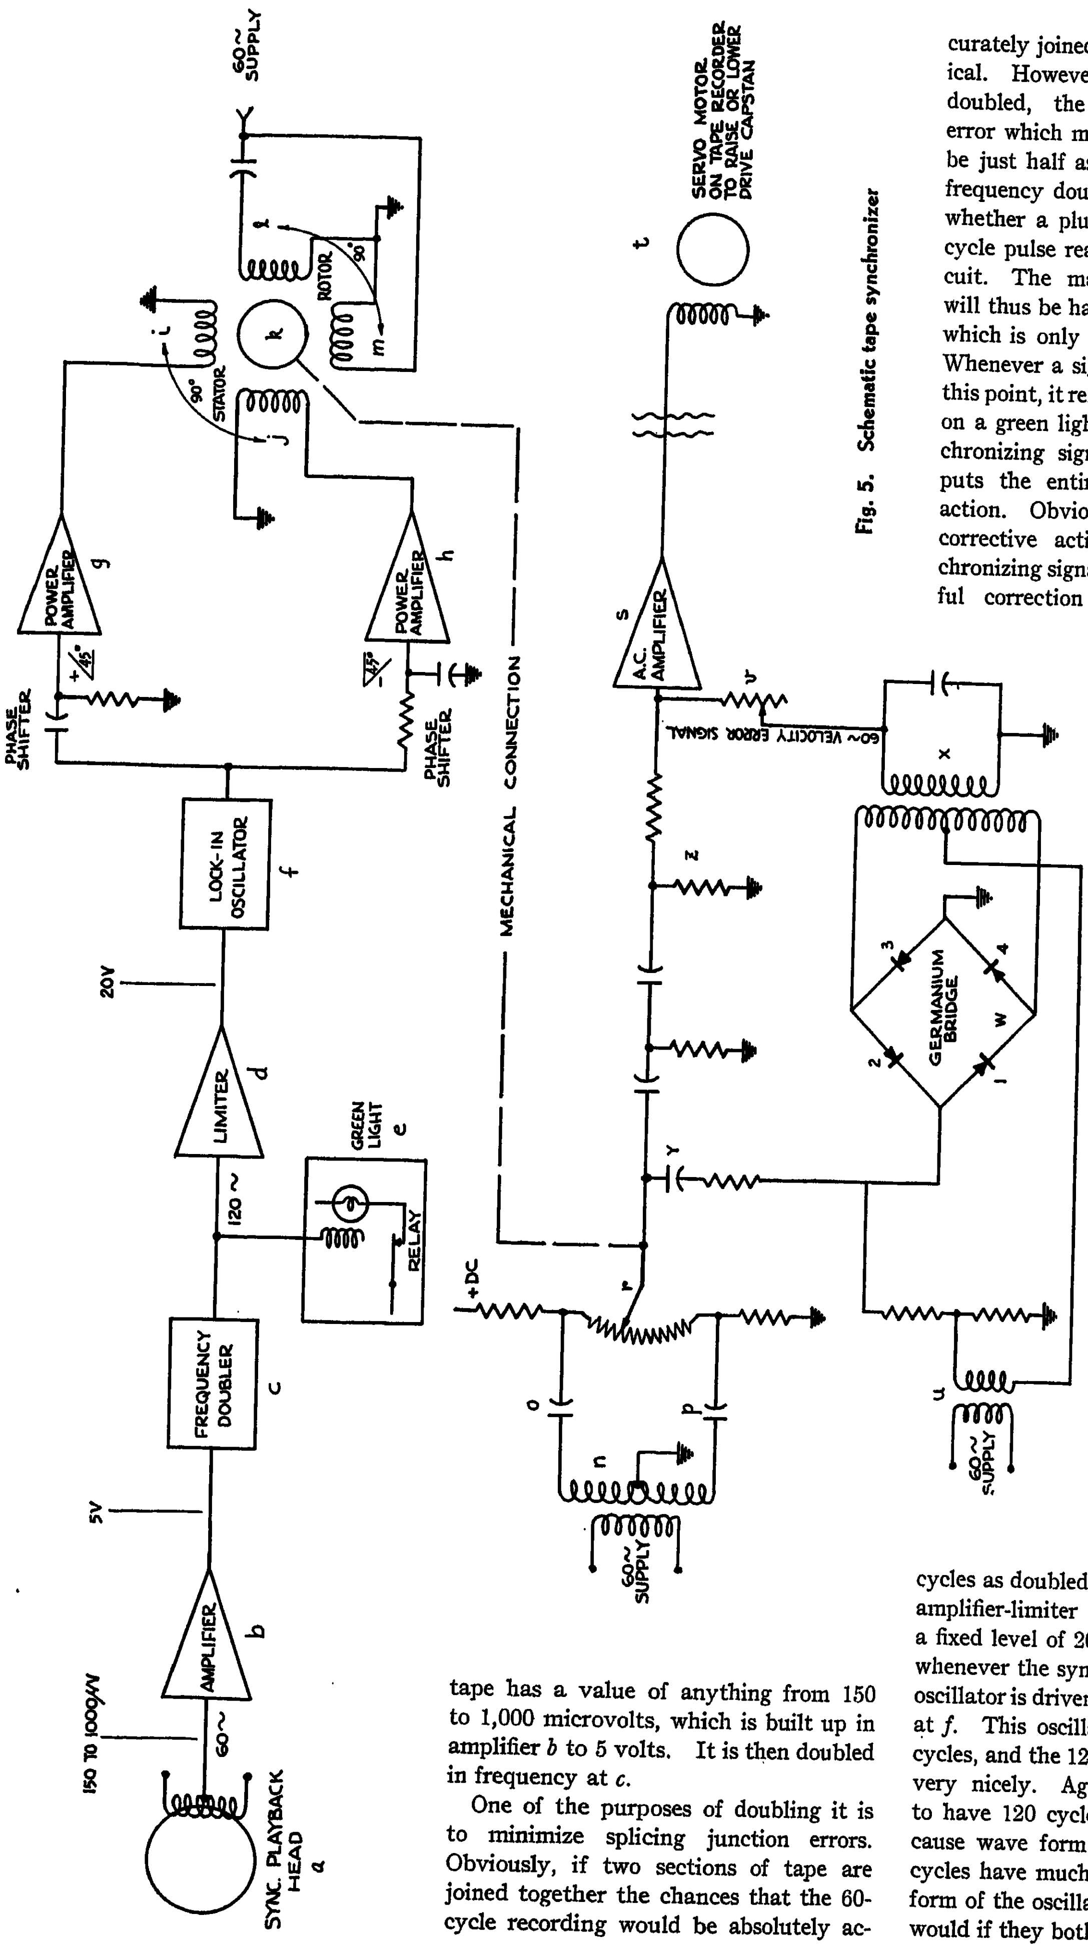

Fig. 5. Schematic tape synchronizer

After oscillator f, the circuit is split with a phase shifter; the top half advancing the signal 45 degrees, and the bottom retarding it 45 degrees, using the appropriate capacitor-resistance combination. Power amplifiers g and h follow these phase shifts, and these, in turn, activate the 90-degree separated coils of the stator of the resolver k. The rotor of this resolver is, in turn, supplied with straight 60-cycle power, again with a phase differentiation accomplished by a capacitor in coil l, while coil m is fed directly.

These phase-shifting networks on both stator and rotor make the resolver have two rotating fields. If these two rotating fields are identical, meaning that the 60 cycles as picked up from the head is exactly in step with the 60-cycle power then being used, there will be no resultant motion of the resolver. However, if the frequency of the tape pickup is lower than that of the 60-cycle reference, the rotor will move in such a direction as to compensate for this discrepancy, meaning that the rotor will actually slow up to place it coils in line with the more slowly energized coils of the stator. Conversely, if the synchronizing signal from the playback is ahead, the resolver will move in the other direction.

The motion of this resolver k is transmitted mechanically, through a very high gear reduction, to a potentiometer at r. The purpose of this potentiometer is to apply normal 60-cycle power to what amounts to a bridge leading to amplifier s. When potentiometer r is in its center position, there will be no resultant voltage from the transformer n through the high pass filter z to amplifier s. If the mechanical motion of the resolver calls for the potentiometer r to move upward, the 60-cycle balance will be upset, and one phase of the 60 cycle will carry on through to amplifier s.

This amplifier, in turn, drives a very small induction motor t which, through a very high gear ratio, moves the main synchronous drive motor (Fig. 4) up and down to control the speed of the capstan on the top plate. If arm r moves down, the opposite phase of the 60 cycles will be applied to motor t and this will then rotate the motor in the other direction. It is to be noted that the 60-cycle voltage is proportional to the displacement of r, and this in turn regulates the speed of the correction motor t.

If this were all there was to the control, the whole system would hunt forward and backward about the neutral position. In order to avoid this hunting, a velocity-error signal must be introduced, which is proportional to the rate at which the potentiometer moves. For this purpose, potentiometer r picks up a d-c voltage from the plate power line to ground. When the potentiometer arm r is moving, the d-c charge on capacitor y is changing and causing transient current pulses, which are proportional to the rate of change to flow through the germanium bridge w.

This bridge w is also fed by 60-cycle power from transformer u, which is balanced through the bridge to ground, so there will be normally no 60-cycle output in transformer x on the right. Any output of transformer x appears at the junction point of amplifier s, which is carrying the normal a-c signal from the potentiometer arm r into the small induction motor t on the extreme right. Now, however, if a pulse does come through capacitor y by the movement of arm r, this pulse will carry into the bridge w. If this pulse is negative, it will carry through the bottom half (1 and 4) of the bridge w; if it is positive through the top half (2 and 3).

In so doing, it will upset the normal balance of the 60 cycles coming into the bridge w from transformer u. If the pulse is positive, it will go down arm 1 and up arm 4 of the bridge w. In so doing, it will add to the plus half cycles coming from the 60-cycle transformer through arm 1, and actually oppose the other half cycles which carry up from ground through arm 3. The net result is to give stronger half-cycle pulses in the lower half of the primary of transformer x than in the upper half. This in turn will produce 60-cycle pulses in the output of transformer x, which are led up through a variable resistance v to be in phase or not with the 60-cycle power coming through the 60-cycle filter, as determined by the position of r. The output of transformer x is tuned to 60 cycles with a capacitor. The net result of these actions is to pass additional 60-cycle power into the amplifier s in accordance with the operation of potentiometer r.

A linear alternating current, either in phase or out of phase, will be combined with the alternating current coming directly from the potentiometer r, when the latter moves. In other words, when the potentiometer has moved in one direction and then begins to move back, the backwards movement will pass alternating current from bridge w, which will be out of phase with that originally coming from the unbalanced conditions set up by potentiometer r and the transformer n. This decreases the a-c power on the motor t when the corrections have started to take effect.

This is, of course, the well known setup to prevent hunting by making a velocity correction which precedes the position correction coming directly from potentiometer r. By changing the value of the resistor v, the amount of this control may be adjusted to make hunting a minimum. The gear reduction on the motor t to move the main drive motor up and down is made so high that the tape correction speed will be relatively slow. It takes something like 3 seconds to accomplish a 1/24 second actual change in the tape movement, which would correspond to one frame of a motion picture, running at 24 frames per second. This change is so slow that it never affects music; correction may be applied constantly and strict synchronism with the picture will result. Actually in practice the normal movement of the correction when conditions have once been stabilized is of the order of about ±1/10 frame, and this again means a very slow rate.

Conclusion

With these facilities, the top quality characteristics of 1/4-inch flexible tape are put at the disposal of motion picture producers to enable them to provide synchronous sound absolutely in step with the film. Joining tape lengths together does not interfere with the normal correction process. So an effective overall inexpensive recording medium has been established, which has forwarded the motion picture art, and is being particularly applied to motion pictures for television, as well as educational, religious, and industrial films.

No Discussion

Protection of Wire Communication Facilities Serving Power Stations and Substations

T. W. ALEXANDER, Jr.
FELLOW AIEE

THIS DISCUSSION has to do with protective devices provided in the telephone system to furnish protection to telephone equipment and to personnel having occasion to use or maintain this plant. Particularly, the discussion will deal with protection available for use on circuits serving power stations and substations.

The primary reasons for installing protective devices in telephone plants are:

1. To protect employees and customers from injury;
2. To prevent fires in telephone central offices or customer's premises;
3. To protect telephone apparatus from damage.

With the exception of power used with certain carrier and radio equipment, where special procedures are in effect, the normal operating voltages and currents used in the operation of the telephone system are not dangerous to persons or property, but protection is required against lightning and potentials or currents which may be impressed on the system due to induction from or accidental contact with other electric facilities. Good construction, looking towards the maintenance of proper clearances from the facilities of other wire-using companies, is the first essential in our protective scheme. The use of protective devices provides a final safeguard to persons and property.

Two general types of protective devices are employed in telephone plant:

1. Devices to limit the potential or voltage in the plant to be protected;
2. Devices to limit the current in the plant to be protected.

For a large majority of the telephone plant, limitation of voltage is accomplished through the use of carbon-block protectors, and limitation of current by fuses and heat coils. Other special devices are used in specific cases, and those used with circuits serving power stations and substations will be discussed in detail. Fig. 1 shows the units which make up the protector assemblies most commonly used in telephone central offices and at customers' premises.

Typical systems in use by the power companies which use leased facilities include remote-control and supervisory systems, telemetering systems, pilot-wire relaying systems, and electronic devices.

It is impracticable to specify maximum permissible values of current and voltage for leased-facility operation, but experience has shown that the values listed in Table I are generally acceptable from the standpoint of preventing injury to personnel, damage to plant, and also of avoiding interference to telephone facilities. They are also representative of the current and voltage ranges within which normal telephone equipment is designed to operate. Therefore, these values for normal operating conditions should not be exceeded without special consideration.

It is not anticipated that many cases will be encountered where the customer desires to operate circuits at currents or voltages substantially higher than those mentioned, and many manufacturers have designed their equipment to meet these requirements. However, these values do not represent inflexible limits, and all pertinent facts in specific cases will be considered in determining the course to be followed.

In the many types of systems using leased facilities, a wide variety of terminal equipment may be employed. Telephone conductors are often connected to the input and output circuits of electronic equipment, connected to the secondary of a potential or current transformer, coupled to a power line through a capacitor, or connected to the contacts of a relay whose windings are in a power circuit. Consequently, in order to prevent voltages substantially higher than normal from being impressed on the telephone facilities, in the event of some equipment failure, it is important that any transformers, relays, or other apparatus connected between the telephone facilities and sources of power meet the requirements of the American Standards Association (dielectric strength of twice the line voltage, plus 1,000 volts). Apparatus listed by the Underwriters Laboratories meets these requirements.

In cases where the circuit arrangement or construction of the customer's equipment indicates that the apparatus may not meet the American Standards Association requirements, and that abnormal voltages are likely to be impressed on the telephone circuit, an isolating transformer having the necessary dielectric strength may be used. Carbon-block protectors having a separation of 3 mils between the line and ground blocks, and having a breakdown voltage of approximately 350 volts, installed between telephone conductors and ground at or near the customers' equipment may also be used. When leased conductors are classified as exposed, these protectors are required in any case. Telephone circuits are considered exposed when there is a possibility of contact with other circuits operating at more than 300 volts. As a rule, all telephone plant not in underground construction is considered exposed.

In general, the same protective arrangements would be applied to leased facilities and equipment as would be used for telephone circuits and equipment under the same conditions. An exception concerns the use of heat coils or 60-type fuses, as follows:

1. On leased circuits which merely loop through a central office, heat coils are not required;
2. Where a leased circuit enters a building other than a central office, the protection will normally be the same as for trunks serving a private branch exchange. However, the 60-type fuse may be omitted in cases where the terminal equipment directly associated with the leased circuits has no path to ground.

Stations at remote locations served by open wire such as at isolated substation locations, may be subject to service interruptions because of permanent operation

Table I. Maximum Permissible Voltages and Currents

	D-C	A-C (RMS)
Maximum voltage, conductor to conductor	270 volts with midpoint grounded	120 volts
Maximum voltage, conductor to ground	135 volts	120 volts
Maximum current in any conductor	0.35 ampere	0.35 ampere

Paper 53-203, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted February 4, 1953; made available for printing March 30, 1953.

T. W. Alexander, Jr., is with the Bell Telephone Company of Pennsylvania, Pittsburgh, Pa.

Fig. 2 (above). Short-circuiting relay

of station protectors due to lightning surges. In these cases, consideration can be given to the use of additional protector blocks between the open-wire conductors and ground, at a point about $^1/_4$ mile from the station. These additional protector blocks would have a separation of 10 mils between the line and ground blocks, and would drain off the higher voltage surges and prevent them from being impressed on the station protector. The breakdown voltage of the 10-mil blocks is approximately 1,000 volts.

In some cases, the customer may wish to use his own station protective devices to protect his equipment, or he may even wish the telephone company to omit the station protectors entirely, on the basis that his equipment can withstand any likely abnormal potentials without failure or that it will interfere with the correct functioning of the circuit. Where all the equipment connected to the leased circuit is owned and maintained by the customer, arrangements such as those mentioned will be considered if adequate protection is assured for telephone personnel and plant in event of customer-equipment failure. However, in such cases, it will be important that a record of any special arrangements agreed upon be maintained. Where the telephone company owns and maintains any or all of the equipment involved, the protective equipment required will be determined after special consideration of all factors.

Grounding practices for protective equipment associated with leased facilities are the same as those normally applied to station protection. The order of preference is:

1. Public water system.
2. Public gas system.
3. Private water system.
4. Grounded metallic structures.
5. Multigrounded neutral power system electrode.
6. Ground rod.

It is, of course, desirable that the telephone protector employ the same grounding medium as that employed by the electric light or power service for the building. In cases where separate ground electrodes are used for the telephone and power services, it is desirable that they be bonded together so as to limit any difference in potential that may exist between grounded or protected parts of the two systems.

Certain circuits, because of the nature of the intelligence they transmit, require special protection considerations in addition to the leased-facilities protection as outlined above. An example of this type of circuit is the pilot-wire relaying circuit employed by power companies to sectionalize line faults. In this case, even momentary interruptions, caused by operation of protector blocks, may result in false operation of the power-line relaying and switching equipment, with corresponding serious interruption of the power circuits. Special protective arrangements, to be applied in any particular case,

depend upon the type of system to be operated over the leased facilities and whether such factors as ground potentials, low frequency induction, lightning, or a combination of these effects are significant. Some of the protective measures applicable in such situations include the use of:

1. Short-circuiting relay protector, to prevent permanent grounding of protector blocks;
2. Direct drainage, which practically eliminates even momentary operation of protectors;
3. Insulating transformer;
4. Neutralizing transformers.

Short-Circuiting Relay

A short-circuiting relay is a device used to place a short circuit around the blocks in an ordinary carbon-block protector within a very short time after the original discharge, thereby relieving the blocks of the duty of carrying the discharge current during a large part of the discharge interval. They are used principally on open-wire lines exposed to low-frequency induction.

Experience has shown that severe cases of induction may permanently ground protector blocks on exposed telephone circuits and cause interruption to service. Where the protector blocks are located along the telephone line or at outlying offices, it may take an appreciable amount of time for maintenance people to visit these locations and replace the carbon blocks. In these cases the interruptions to service may extend over a period of time which would be objectionable. The relay protector preserves the protective features of the carbon-block protectors and, at the same time, reduces very greatly the chance of permanent grounding.

The relay protector also provides substantial benefit from the standpoint of acoustic shock since, if the discharge current through the protector blocks is sufficient to operate the relay, both sides of the circuit are brought to the same potential after a very short time, and no circulating current results in the telephone circuit after the relay operation.

The relays in the short-circuiting protectors will short circuit the protector blocks in about 0.025 seconds after the initial block operates. Fig. 2 shows a schematic of the short-circuit relay protector, connected across carbon protector blocks on a telephone circuit.

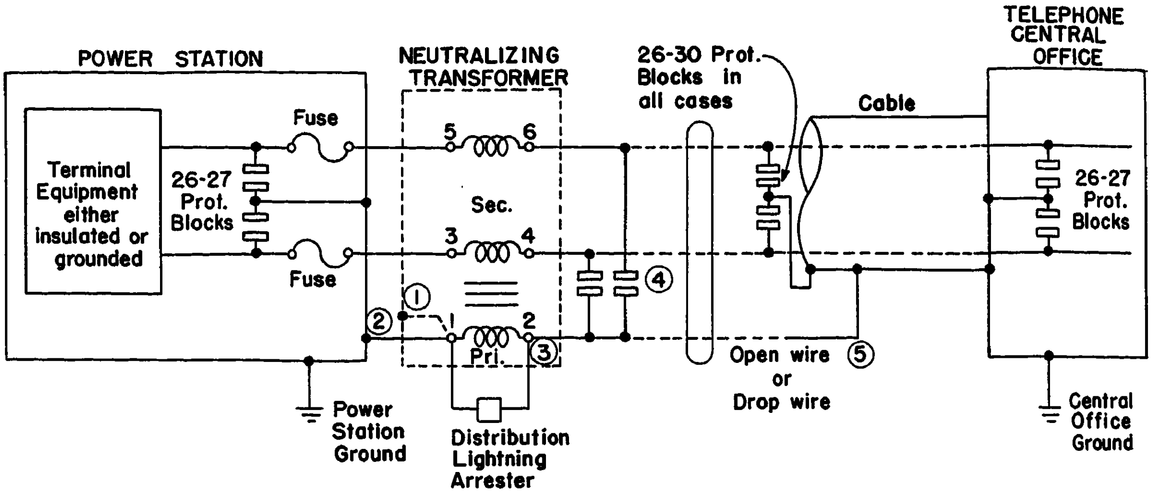
Direct Drainage

During thunder storms, substantial voltages to ground may be induced on the conductors of an open wire line. The usual protectors provided at the ends of the line serve to relieve these high voltages by discharging them to ground. There is always, however, a certain amount of dissymmetry between the two protectors on a pair of wires, either in initial breakdown voltages, discharge characteristics, or both. Because of these differences, when the lightning currents discharge through the protectors, a pulse appears in the metallic circuit, whose magnitude depends upon the size of the voltage induced by the lightning and the degree of dissymmetry between the protectors.

Fig. 6. Three-winding neutralizing transformer

① Odd terminal of primary to be bonded to case when transformer is installed

② If conductors between transformer and power station are in cable, the sheath may be used to connect transformer primary to station ground



③ For pole installations, if cable from the central office extends to transformer, odd-numbered primary terminal (bonded to case) should be connected to cable sheath on the central office side of transformer and odd-numbered secondary terminals to conductors leading to the central office sheath toward power station should be insulated from case and sheath toward the central office

④ 26 and 31-A protective blocks in 83-A mounting. Omit only if transformer is located on same pole as cable terminal

⑤ Remote ground used if no cable is available within a reasonable distance

These resultant surges may cause false operation of carrier-telegraph equipment and clicks in telephone circuits.

In order to minimize the effects of these surges, an equipment arrangement has been devised to keep the voltage on the circuit below the operating voltage of the protector blocks. This is accomplished by bridging a coil having its center point grounded across the open-wire circuit at its junction with the entrance cable. Fig. 3 shows the method of applying this drainage coil.

While this method provides a large measure of relief from the effects of atmospheric disturbances, the low impedance to ground which is required for satisfactory drainage prevents the operation of grounded telegraph over the circuit, and the use of d-c testing. It also affects the characteristic of voice-frequency repeatered circuits at the lower frequencies and introduces some modulation effects in the carrier system working over the particular pair. To obviate these disadvantages, an arrangement has been developed in which protector blocks are connected between the drainage-coil windings and the line wires. The drainage coil is thus kept off the circuit until a surge has broken down the protector gaps. Tests have shown this protector-drainage arrangement to be almost as effective as the direct-drainage arrangement.

Fig. 4 shows the arrangement of protector blocks between the coil windings and the line wires. The nos. 26 and 27 blocks shown in this figure have 3-mil separation and operate at approximately 350 volts; the nos. 26 and 30 blocks have 6-mil separation and operate at approximately 700 volts.

Insulating Transformers

Whenever an abnormal condition on a power system results in a current through the ground between a power station and some other point, the potential of the ground at the power station will differ from that of the distant ground and, if the difference is great enough, protection may operate on communication facilities serving the power station.

In order to guard against circuit outage due to protector operation at locations where it is expected that excessive voltages may be experienced, the communication circuits may be equipped with insulating transformers. Under this arrangement, a transformer is inserted in each telephone circuit at such location as to isolate the effect of the power-station ground from any distant ground. Gap protectors and fuses are installed on the line side of the transformer and standard station protection on the station side.

The disadvantages of the insulating transformer arrangement are:

1. Direct-current signaling and supervision over the circuit require the use of supplemental equipment;
2. The use of remote metering and supervisory control circuit employing direct-current, varying in magnitude at a slow rate, is usually prevented;
3. The insulating transformer has a transmission loss of from 0.7 decibels to 1.2 decibels, depending on the type of coil used;
4. Reduces ringing range.

The insulating transformer may also be used to protect telephone facilities against voltages which may be impressed on them by highly exposed circuits of the customer, as for example circuits routed on higher voltage transmission lines. In these cases, transformers are usually installed at the junction of the customer owned and telephone company circuits. Usual types of transformers have breakdown voltages of approximately 25,000 volts between primary and secondary windings, and between primary or high winding and the case. Fig. 5 shows the arrangement of this transformer.

Neutralizing Transformers

Neutralizing transformers are also used to protect against excessive ground potential at a power station. A 3-winding neutralizing transformer is one having one primary winding and two secondary windings. The primary winding should be connected between the power-station ground and an outside ground, which is

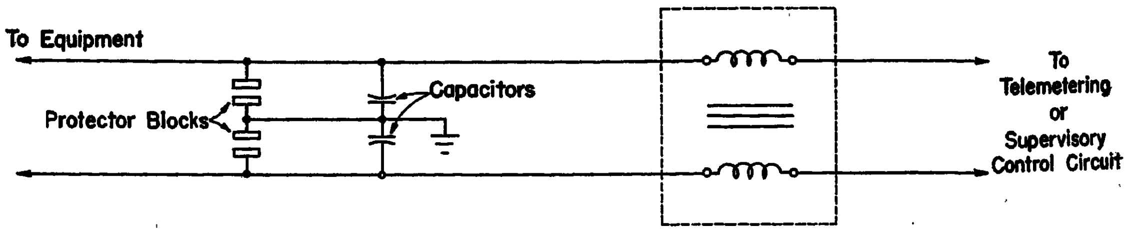


Fig. 7. Two-winding neutralizing transformer

sufficiently removed from the influence of the power-station ground so that practically all of the station ground-potential rise is impressed across the winding. If the telephone facilities are in cable outside the power station, it is desirable to use the cable sheath as the remote ground unless it is materially affected by power-station ground potentials. The secondary windings are connected in series with the telephone conductors and, by transformer action, a voltage is induced in these windings from the primary that is nearly equal and opposed to the voltage directly impressed on the conductors. Fig. 6 shows the method of installing a 3-winding transformer on a telephone circuit.

The 3-winding neutralizing transformer may also be used as a 2-winding neutralizing transformer by making use of only the line windings in series with the telephone conductors and connecting capacitors from each side of the line to ground. The midpoint of the capacitor circuit is connected to the station ground so that the capacitors and transformer windings are subject to the full difference of potential between the station ground and the distant ground. The coils act as impedance or choke coils to prevent the establishment of voltages which might operate the carbon protectors. These connections are shown in Fig. 7. The neutralizing transformer has a loss of about 0.8 decibels at 200 cycles and 1.6 decibels at 3000 cycles.

It again should be pointed out that the use of protective equipment in the telephone plant is for the purpose of protecting all personnel using or maintaining the equipment, to guard against starting fires in customers' premises or telephone company offices, and to protect the telephone equipment from damage in so far as economically feasible. Special cases often require individual attention and while protective procedures which have been discussed should be followed generally, there are no inflexible rules which cannot be modified under proper supervision. Every effort is made to arrange for protection which will adequately serve its purpose and, at the same time, will not interfere with the service which the power company wishes to provide over the telephone facilities.

◆

Discussion

Gordon Y. R. Allen (Osborne Electric Company, Ltd., Toronto, Ontario, Canada): Mr. Alexander's paper is one which should invite wide interest and discussion. The subject of communications protection in its many aspects and phases certainly warrants more technical papers. In general, I agree with the author's analysis, although I do feel that these problems need some elaboration.

Basically, the paper appears to be written from the viewpoint of leased telephone circuits, whereas the problems are equally common to electric-power utility-owned and -operated wire circuits. It is apparent that the use of the protective devices detailed and illustrated in the paper is Bell Telephone practice, and no mention is made of the several other common protective devices widely used. Particularly I am concerned with the omission of the Osborne telephone protector which is in common use in the United States, Canada, and the Latin American countries, as well as in many other foreign countries.

In the list of protective devices in use today, the combined isolating and drainage transformer is not indicated. This type of transformer has been in common use, stretching over a period exceeding 20 years. It forms the heart of the Osborne telephone protector. This transformer, along with the associated apparatus, is shown in Fig. 8, and it is interesting to recall that patents were issued to R. W. Osborne many years ago on this device.

Referring for the moment to the question of induction, it is important to remember that there are two types, that is, the electromagnetic and electrostatic or, in other words, voltage induced between the conductors of the telephone line, and voltage induced between the conductors and ground. The voltages and currents are not necessarily of the same magnitude, and it is often necessary to analyze these components. This is particularly the case where a telephone company jointly uses the same poles as a power line for varying distances. One therefore must consider the characteristics of the power line. The question of possible co-ordinated power line and telephone line transpositions must also be considered.

In recent times much consideration has been given to the co-ordination of the operation of the telephone protective devices with those protective devices employed on the power lines. The voltage, current, and phase of the power lines, along with their circuit breakers or fuses, determine to a great extent the time voltage rise and resulting currents on the telephone lines. The telephone protective devices therefore must be able to withstand the fault voltages and currents prior to the time at which the power line protective devices operate or the fault is cleared. At least the telephone protective devices, if expendable, must prevent voltage from appearing across terminal apparatus.

With reference to the use of an isolating transformer, I call attention to an important difficulty in the case of a fault. If a telephone line becomes unbalanced or grounded on one side, the transverse impedance of the line remains unchanged. Any extraneous potential in the grounded side, for instance, a power line conductor becoming grounded, is impressed on the equipment in shunt with the line. If an insulating transformer is interposed between the line and telephone, it transforms the transverse potential to the saturation point of the transformer core, above which excessive exciting current will damage the primary winding. The voltage across the transformer secondary may be very high, depending on the frequency of the extraneous potential.

With respect to the use of a drainage coil alone, I agree with the limitations where direct current is involved. It is not difficult to protect the a-c apparatus involved but it is difficult to protect adequately the d-c equipment. In any event, under severe disturbances, unless both ends of the drainage coil are simultaneously grounded, it will simply burn out because of its inability to sustain heavy currents to ground. Carbon-block protectors will not protect a drainage coil where severe faults are encountered. In actual practice, I have seen a drainage coil which exploded when a 110-kv conductor came in contact with a telephone line at a distance of 1 mile.

The design of the drainage coil can be such as to obviate the complaint regarding its effects on voice frequency and carrier. For instance, bridging loss can be held practically flat at less than 0.02 decibels to 200 Kc. The drainage coil therefore offers only partial protection in many cases, while in others it may be adequate.

The short-circuit or grounding relay mentioned is somewhat slow, and no data are given on its current carrying capacity. Unless it can withstand currents of the order of 500 amperes for 3 seconds, it has little value in applications where high voltage lines are concerned. The Osborne Electric Company in Toronto has a grounding relay capable of withstanding 650 amperes for 3 seconds. It has been known to have the contacts completely disintegrated where the relay was used to protect a telephone line exposed to a 220-kv transmission line. More will be said about this relay later.

I should like to suggest an important personnel hazard which was not mentioned in the paper in connection with the lineman who uses a portable telephone on exposed open-wire circuits. Usually these portable telephones are fitted with carbon-block protectors which in many cases are most inadequate. Far better protection can be had with the use of an isolating transformer which could be considered expendable if damaged as a result of overexcitation. The Osborne company manufactures a 10-kv insulated plastic-moulded portable isolating transformer weighing only $2^1/_2$ pounds. The transformer has a very low bridging and transmission loss and is a ring-through type for use with a magneto.

To circumvent the difficulties of straight isolating transformers, drainage coils, and grounding relays used separately or independently, a combined isolating and drainage transformer, as mentioned previously, has been developed. This transformer is the heart of the Osborne telephone protector. When such a transformer is interposed between line and telephone, the neutral point of the primary or line winding is connected to ground. This lowers the impedance to ground to a very low value without normally altering the transverse impedance. Any unbalance in the telephone line, or

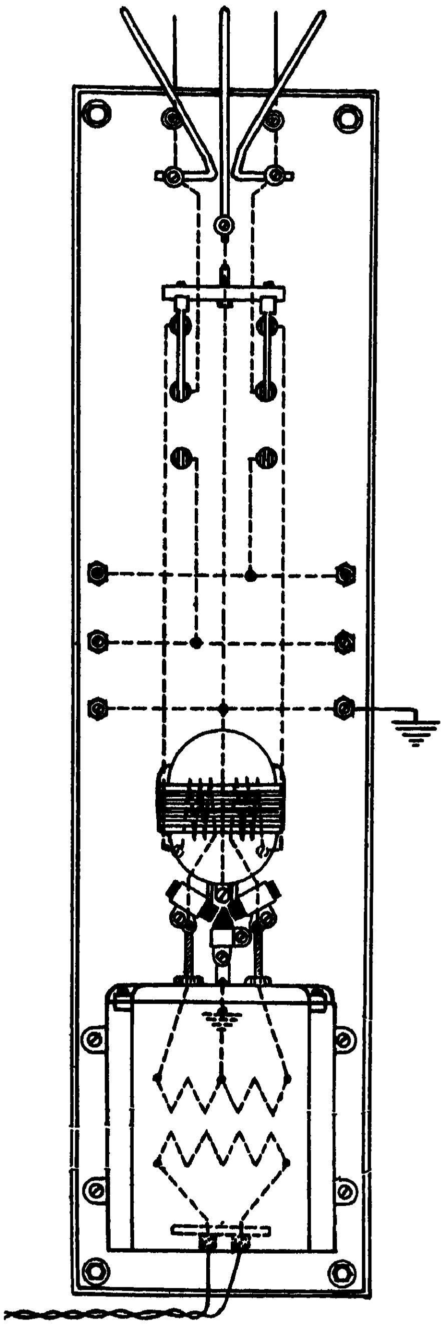

Fig. 8 (left). Type-DC telephone protector

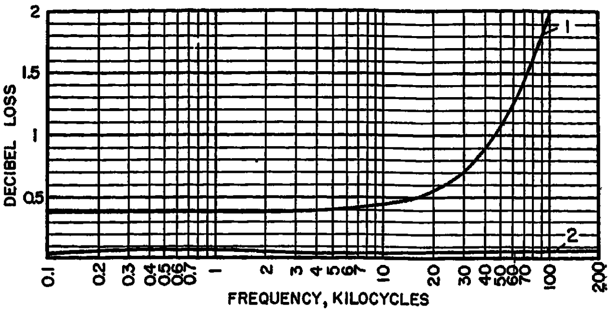

Fig. 9 (right). Osborne telephone transformer

Curve 1—Insertion loss of carrier transformer

Curve 2—Bridging loss of carrier transformer (at 6.66 megawatts on 600 ohms)

ground to one side, affects the total impedance to ground only negligibly, but greatly lowers the transverse impedance. This is because the transformer neutral ground and line ground constitute a short circuit of one half of the primary winding, and the transverse impedance therefore becomes the impedance of the transformer under such short-circuit conditions. The design of Osborne transformers is such that the short-circuit impedance is very low, so that the transverse voltage appearing across the secondary winding will be of low value. To maintain this condition, any circuit opening or short-circuiting device must operate on both sides of the circuit simultaneously. Any transformer or drainage coil has a certain capacity, and so it is with the drainage capacity of the Osborne transformer, which will drain 3 amperes continuously. However, to protect this transformer, a grounding relay is used which will short-circuit the line to ground when current through the transformer exceeds its capacity.

The Osborne grounding relay is of a repulsion-induction design for gaining fast operation, as little chatter as possible, and a quick release. Residual magnetism has no effect on the relay, and the relay has the same operating characteristic from power line fundamental to harmonics. The operating force is linear throughout the travel of the armature and is slightly greater when the armature is open. This relay will handle 650 amperes for a period of 3 seconds without damage, and the relay coils serve as chokes to facilitate discharge at a set of horn-gap arresters.

Fig. 8 shows the complete protector, while Fig. 9 shows the characteristics of the transformer. Note the very low transmission and bridging losses as compared to the losses of the 0.7 to 1.2 decibels mentioned in the paper.

Recently, the Osborne company designed a system of protection to serve a line carrying voice-frequency 4-channel carrier, and railway d-c block signalling. The line is in joint use with a 23-kv single-phase power line 360 miles long. This system will go into operation shortly. It is installed in the far North of Canada, where it is subjected to severe climatic conditions.

H. T. Seeley (General Electric Company, Philadelphia, Pa.): From the standpoint of the maker or the user of pilot-wire relays, the policies set forth in this paper represent a distinct advance over those frequently encountered in the past. The regional telephone companies have often required carbon-block protectors connected to the station ground from the line side, either of insulating transformers or neutralizing transformers, and therefore the pilot wires have become short-circuited at the only moment when the pilot-wire relays have a chance to justify their installed cost of $2,000 or more for a pair of terminals. The result is that the relays, according to one scheme, are useless because they fail to trip when they should; or that, according to the other scheme, they trip when they should not, which would render them worse than useless, in the opinion of most power companies. This pilot-wire trouble is one of the reasons why the operating record of pilot-wire relaying[1] is the poorest of any modern form of power-system relaying, and the record on pilot circuits that are leased is worse than that on such circuits that are privately owned.

The new policies are encouraging to the manufacturer because they open the possibility of taking advantage of a 1-second or 2-second rating for maximum current and voltage. They are encouraging to both the manufacturer and the user because they open the possibility of designing the pilot channel protection so that it will not operate for longitudinally induced potentials and ground-potential difference, but only for direct lightning strokes or crosses with power circuits. I should like to have the author advise to what extent these more liberal policies are than those of the American Telephone and Telegraph Company, so that we may know what may be expected in other areas than his own.

The ideal pilot circuit from the viewpoint of the relay engineer has been described recently[2] as one insulated to withstand 20 kv to ground for 1 minute, or 1.5 kv between conductors momentarily; this is being installed for several circuits, some as long as 16 miles.

While we can hardly hope to meet this high level simply by proper design and application of special terminal equipment on facilities designed primarily for other uses, the new policies give promise of meeting the requirements of the majority of pilot-wire relay installations.

T. W. Alexander, Jr.: While our practices require the carbon-block protectors on the line side of the transformer, it should be pointed out that the ground associated with these blocks is remote ground and not station ground.

Also, it should be noted that the omission of carbon-block protection applies in cases where all the equipment connected to the leased circuit is owned and maintained by the customer, and adequate protection is assured for telephone personnel and plant in the event of customer equipment failure.

Where telephone company equipment is connected to the facility, carbon-block protection will in general be required, since that form of protection best meets our requirements. However, these blocks should not operate unless the facility is disturbed by lightning or contact with power circuits high enough in magnitude to operate the lightning arrestor protecting the neutralizing transformer.

The protection arrangement set forth in this paper was developed with the concurrence of the American Telephone and Telegraph Company and should be acceptable in all locations except where local conditions require modification.

The Map Method for Synthesis of Combinational Logic Circuits

M. KARNAUGH
NONMEMBER AIEE

THE SEARCH for simple abstract techniques to be applied to the design of switching systems is still, despite some recent advances, in its early stages. The problem in this area which has been attacked most energetically is that of the synthesis of efficient combinational that is, nonsequential, logic circuits.

While this problem is closely related to the classical one of simplifying logical truth functions, there are some significant differences. To each logical truth function, or Boolean algebraic expression, there corresponds a combinational circuit which may be constructed from a given set of appropriate components. However, minimization of the number of appearances of algebraic variables does not necessarily lead to the most economical circuit. Indeed, the criteria of economy and simplicity may vary widely for different types of components. A general approach to circuit synthesis must therefore be highly flexible. What is perhaps most to be desired is a simple and rapid technique for generating a variety of near-minimal algebraic forms for the designer's inspection.

Boolean algebra,[1] or the calculus of propositions, is a basic tool for investigation of circuits constructed from 2-valued devices. Its direct application to synthesis problems is, nevertheless, not completely satisfactory. The designer employing Boolean algebra is in possession of a list of theorems which may be used in simplifying the expression before him; but he may not know which ones to try first, or to which terms to apply them. He is thus forced to consider a very large number of alternative procedures in all but the most trivial cases. It is clear that a method which provides more insight into the structure of each problem is to be preferred. Nevertheless, it will be convenient to describe other methods in terms of Boolean algebra. Whenever the term "algebra" is used in this paper, it will refer to Boolean algebra, where addition corresponds to the logical connective "or," while multiplication corresponds to "and."

The minimizing chart,[2] developed at the Harvard Computation Laboratory, represents a step in the desired direction. It makes possible the fairly rapid derivation of near-minimal 2-stage forms. By a 2-stage form is meant a sum of products of the elementary variables, or else a product of sums of the elementary variables. These expressions may then be further reduced by algebraic factoring. The chief drawback to this method lies in the necessity of writing, and perhaps erasing, on a chart that, for n variables, contains 2^{2n} entries. Thus, we must keep track of 1,024 entries for five variable problems and 4,096 entries for six variable problems.

E. W. Veitch[3] has suggested a method whereby results similar to those yielded by the minimizing chart can be obtained from an array containing only 2^n entries in a more rapid and elegant manner. The map method, which is explained in this paper, involves a reorganization of Veitch's charts, an extension to the use of 3-dimensional arrays, and some special techniques for diode and relay circuits.

Maps

Let the active and inactive conditions of the inputs to a combinational circuit be designated by assigning the values 1 and 0 respectively to the associated algebraic variables. An assignment of a simultaneous set of values to the n variables for a given problem will be called an input condition. There are 2^n possible input conditions.

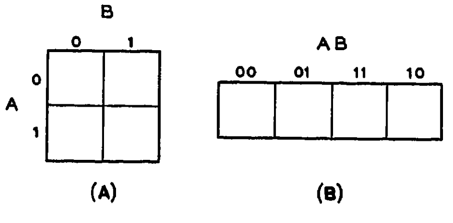

Fig. 1. Graphical representation of the input conditions for two variables

(A) Along two axes
(B) Along a single axis

For example, with only two variables, there are four input conditions. They may be represented graphically by the four squares in Fig. 1(A). Here, the values of variables A and B have simply been plotted along two perpendicular axes. It should be noted that squares which are adjacent, either horizontally or vertically, differ in the value of only one of the variables.

If Fig. 1(A) is cut along its horizontal midsection and the bottom half is rotated into line with the top, as in Fig. 1(B), then a representation of the input conditions for two variables is obtained along a single axis. Let us consider the squares at opposite ends of the row to be termed adjacent, as if it were inscribed on a cylinder. Then, as before, adjacent squares differ in the value of only one variable. Conversely, if two input conditions differ in the value assigned to just one of the variables, they are represented by adjacent squares.

If one also makes use of the vertical axis, one can represent the input conditions for three variables as in Fig. 2(A), and for four variables as in Fig. 2(B). In the latter case, opposite ends of each row or column should be considered adjacent, as though the figure were inscribed on a torus.

The labels on the diagrams may be simplified as shown in Fig. 3. The rows or columns within a bracket are those in which the designated variable has the value 1, while it is 0 elsewhere.

A combinational circuit of the type under consideration has a 2-valued output which is a function of the input condition. The synthesis problem may be said to begin with the specification of this functional dependence. Such information may be represented on a map as follows: Place a 1 in each square which represents an input condition for which the output is to have the value 1. The other squares may be imagined to contain zeroes.

Synthesis of 2-Stage Forms

Consider the function mapped in Fig. 4(A). Its algebraic realization is the product $A'BC'D$, where the primes indicate negation or complementation, for $A'BC'D=1$ if, and only if, $A=0$, $B=1$, $C=0$, and $D=1$.

Let us define a complete product to be a product in which each of the variables appears as one factor, either primed or

The author wishes to express his indebtedness for many valuable suggestions, help, and encouragement to E. F. Moore, K. Goldschmidt, and W. Keister, all of the Bell Telephone Laboratories.

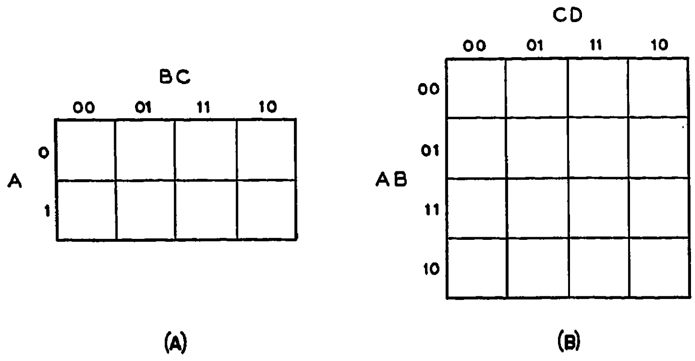

Fig. 2. Graphical representations of the input conditions for three and for four variables

not. Then any function whose map contains a single 1 may be represented by a single complete product. Each factor is primed if, and only if, it has the value 0 at the square in question. Because each square that contains a 1 gives rise to a product, such squares will be called p-squares.

If the map of a function contains k p-squares, then the function may be represented by the logical sum of the corresponding k complete products, each selected by this rule. This form of representation is the complete disjunctive normal form of the calculus of propositions. It is often the starting point for algebraic simplification.

However, it is usually possible to write down a more economical representation than a complete normal form by direct inspection of a map. Consider the function whose map is shown in Fig. 4(B). Its complete disjunctive normal form is $AB+A'B$. This is easily reducible algebraically: $AB+A'B=B(A+A')=B$. Now note that the p-squares on the map are precisely that set for which $B=1$.

Let us define a subcube to be the set of all squares on a map over which certain of the variables have fixed values. A subcube formed entirely of p-squares will be called a p-subcube.

Each p-subcube may be regarded as the map of a product formed according to the rules:

1. The factors of the product are those variables whose values are fixed within the subcube.
2. A factor is primed if, and only if, its value within the subcube is 0.

Fig. 5 shows some typical p-subcubes and the corresponding products. Each p-subcube may be thought of as a simply connected square or rectangular group of p-squares, if it is recalled that opposite ends of columns and rows are adjacent.

If m variables are not fixed in a given subcube, it is said to be m-dimensional, and it contains 2^n squares. A single square is thus a zero-dimensional subcube. Note that the larger p-subcubes correspond to products having fewer factors, since fewer variables are fixed in them.

It is now easy to see how to obtain economical 2-stage forms from maps. The rules are:

1. Choose a set of p-subcubes which includes every p-square at least once. In general, it is desirable to make the selected subcubes as large and as few in number as possible.
2. Write down the sum of the products which correspond to the selected p-subcubes. This gives the desired expression.

As an example of this procedure, we can, for the function mapped in Fig. 6, make the selection

$$f=AC'+A'CD+BCD$$

An alternate procedure is possible that leads to a product of sums, that is, a conjunctive normal form instead of a sum of products. First, this procedure is used to obtain an expression for the negative of the function mapped. This is done by considering the empty squares to be the new p-squares. In the case of Fig. 6

$$f'=A'C'+CD'+AB'C$$

The function desired, which is the negative of this, is now obtained by the simul-

taneous interchange of primes and non-primes, and of multiplication and addition signs.

Thus

$f=(A+C)(C'+D)(A'+B+C')$

Both of these procedures have been proposed by Veitch.[3]

Minimal 2-Stage Forms

In combinational diode circuits, there is usually one diode per input lead to every stage. For 2-stage circuits, this means one diode per appearance of each algebraic variable plus one diode per product, or per sum, of these variables. It is often a simple matter to minimize rigorously the number of diodes used in such a circuit.

Consider Fig. 7(A). The dotted lines correspond to the choice of p-subcubes.

$f=B+AC$

Now note that asterisks are placed in two of the p-squares, so chosen that no single p-subcube includes both of them. Hence at least two p-subcubes are required. Furthermore, the selected p-subcube containing each asterisk is of maximum possible dimensionality. Hence each of the corresponding products contains the minimum number of factors.

The same kind of proof must be carried out for the alternate procedure, as illustrated in Fig. 7(B). Here we have

$f'=A'B'+B'C'$
$f=(A+B)(B+C)$

This is not as good, however, as the previous result, which we have now proved to be minimal in

1. Number of terms
2. Appearances of the variables
3. Diodes

This proof depends upon the fact that no one pair of asterisks lies in the same p-subcube. In some cases it may be found that only k asterisks can be placed on a map in this manner, and yet more than k terms are required to represent the function. When this occurs, a proof that at least $k+1$ terms are necessary can be carried through by contradiction. When the attempt to associate a p-subcube with each asterisk is made, it will be found impossible to include all p-squares in the k p-subcubes so selected.

Factoring by Inspection

When circuits are not restricted to the 2-stage variety, it is sometimes advantageous to reduce further the 2-stage forms by algebraic factoring. It is of some importance to show that factoring may also be carried out directly by inspection of a map.

For example, the function mapped in Fig. 8 is

$f=A'B'+B'C=B'(A'+C)$

Since both the chosen p-subcubes lies within subcube B, the presence of the common factor is established by inspection.

Occasionally, observation of the possibilities for factoring will determine the selection of subcubes and lead to a better circuit than would otherwise be obtained. In the case of Fig. 6, the choices

$$\begin{aligned} f&=AC'+A'CD+BCD=AC'+CD(A'+B)\\ f&=AC'+A'CD+ABD=A(C'+BD)+A'CD\\ &\text{or}\quad =AC'+D(A'C+AB) \end{aligned}$$

lead to equally good 2-stage forms; but the former yields the best factored form. Inspection of the map indicates that p-subcube BCD lies in CD along with $A'CD$, thus providing two common factors, while the alternative choice of ABD will give only a single common factor in either of two ways. When inspecting the map, it is not necessary to think of these subcubes by name as we must in the text, but merely to observe their relations, as sets of p-squares.

Even more extensive use of the set theoretic union (our $+$) and intersection (our $\cdot$) relations is possible. Consider Fig. 9. Algebraically, we get

$$\begin{aligned} f&=A'B'C'D+A'B'CD'+ABC'D+ABCD'\\ &=A'B'(C'D+CD')+AB(C'D+CD')\\ &=(A'B'+AB)(C'D+CD') \end{aligned}$$

But it can be seen directly that the four p-squares form the set which is the intersection of the union of $A'B'$ and AB and the union of $C'D$ and CD'. Thus $f=(A'B'+AB)(C'D+CD')$, as illustrated by the dotted lines.

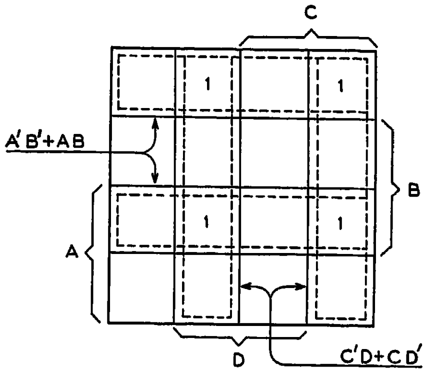

Fig. 9. Set theoretic interpretation of a map

"Don't-Care" Conditions

Very often, the output of a circuit is subject to less rigid restriction than the assignment of a definite value, 0 or 1, for some input conditions. The simplest such case is that of no restriction at all. This may occur because the input conditions in question never are realized in practice, or because the output has no effect in those cases. We shall designate

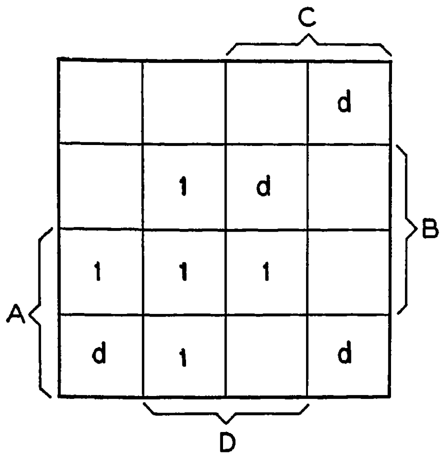

Fig. 10. Map of an incompletely specified function

such don't-care conditions by placing the symbol d in the appropriate squares.

It is usually quite simple to make an economical assignment of values to the d-squares by inspection of a map. Since these are at the disposal of the designer, it is to his advantage to employ them so as to simplify the resulting circuit.

The best 2-stage form for the function in Fig. 10 is

$$f=AC'+BD$$

obtained by setting the two d's on the right equal to 0, and the other two equal to 1.

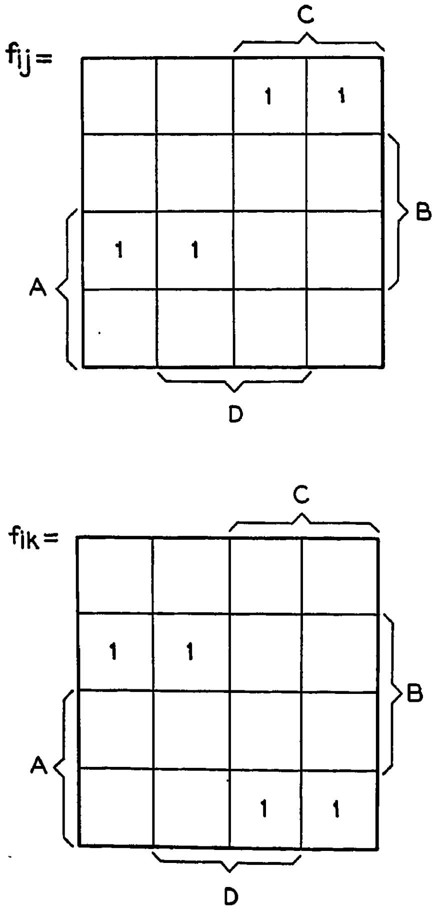

Fig. 11. A 2-output problem

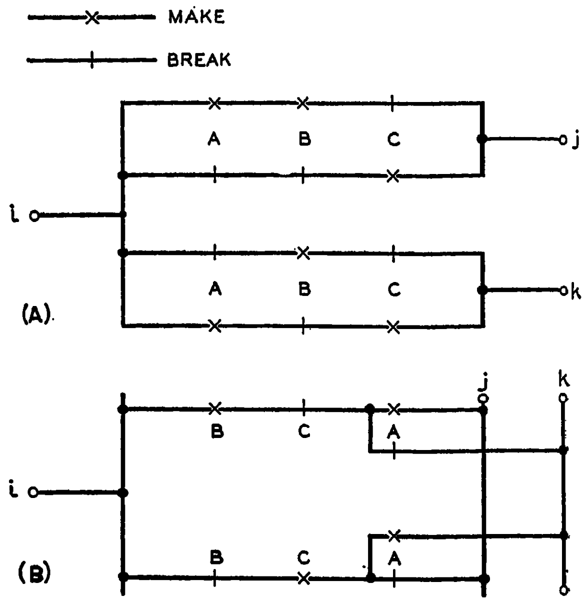
Fig. 12 (right). Synthesis of a 2-output circuit

(A) Two separate contact networks
(B) Networks disjunctively combined



The rule for making such choices is as follows: Assign values to the d's which enlarge and combine the necessary p-subcubes as much as possible but do not make necessary the selection of any additional subcubes.

The ease with which don't-cares can be properly evaluated is one of the major advantages shared by the minimizing chart, Veitch chart, and map methods in varying degree.

Disjunctive Combination in Relay Nets

The map method, inasmuch as it yields expressions in Boolean algebra, can be used to design 2-terminal, series-parallel relay contact networks, but not bridge-type 2-terminal networks. Hence, many 2-terminal contact networks designed by means of the map method will not be minimal in contacts or springs. This will be true, in particular, of the symmetric circuits.[4]

However, in the case of complicated, multioutput networks, the map method may be a very effective tool. Suppose that terminal i is a ground, to be connected through networks f_{ij} and f_{ik} to the output terminals j and k respectively. The specifications for f_{ij} and f_{ik}, which are networks on the contacts of relays A, B, C, D, are mapped in Fig. 11. If each net is synthesized separately, there results the circuit of Fig. 12(A). In Fig. 12(B), it is shown how, with a slight rearrangement, parts of the upper paths to j and k can be combined, as can parts of the lower paths. This results in a saving of four contacts.

The second circuit is completely equivalent to the first, for the transfers on relay A prevent any sneak paths between terminals j and k. While disjunctive combinations of this sort are certainly not new to the relay art,[5] this section is included to show how they may easily be recognized on maps, and hence how they play a part in the selection of subcubes.

Note that the paths ABC' and $A'BC'$, which give rise to one of the combinations, differ by only a prime on A. The corresponding subcubes in Fig. 11 are seen to be related by a simple displacement. The same is true for the other pair of p-subcubes.

A little practice will enable the designer to evaluate the various possibilities for factoring and disjunctive combination by inspection of the maps. It will then be a simple task to make a good choice of p-subcubes.

Unnecessary Contacts

It is of interest to note that for any given function some of the variables or their primes may be unnecessary. That is, it is possible to find an algebraic representation of the function in which these variables, or negated variables, do not appear. Hence the corresponding relay

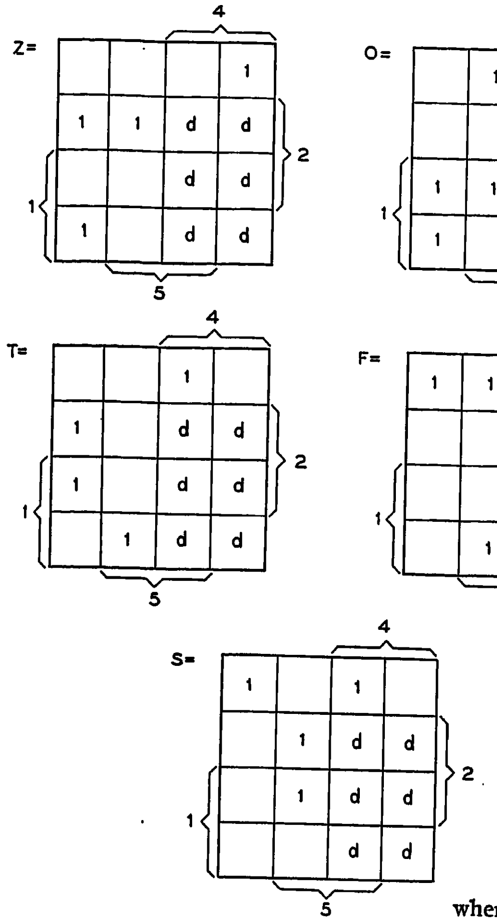

Fig. 13. A translator problem

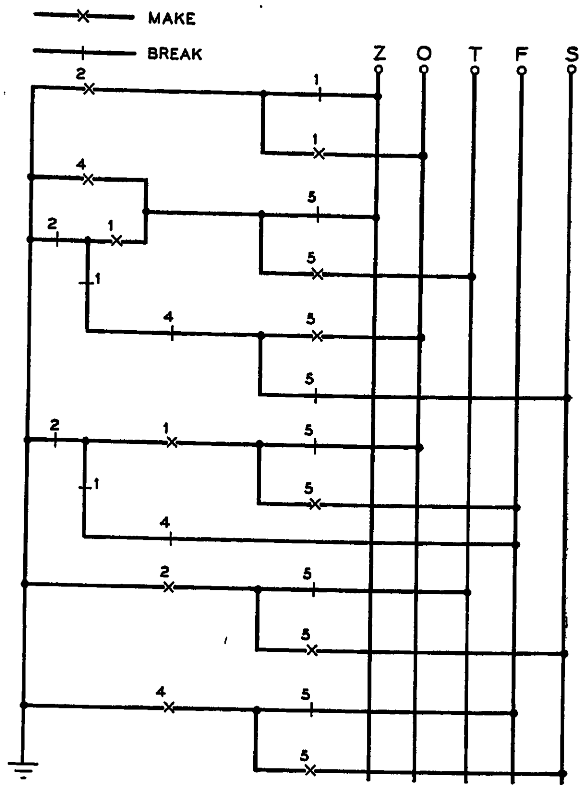

Fig. 15. The finished translator network

contact network will not contain make-contacts, or break-contacts, on some of the relays.

For example, the functions in Fig. 11 are shown on four-variable maps, but they may be realized in terms of only three variables, as in Fig. 12. Neither D nor D' is necessary.

In this case, it can be seen at a glance that the patterns appearing in the D and D' subcubes in both maps are identical. Therefore the output is independent of the value assigned to D. This is a case wherein both the following rules hold:

1. A function may be represented without the appearance of an unprimed variable, say D if, and only if, to each p-square in subcube D there corresponds an adjacent p-square in subcube D'.
2. A function may be represented without the appearance of D' if, and only if, to each p-square in subcube D' there corresponds an adjacent p-square in D.

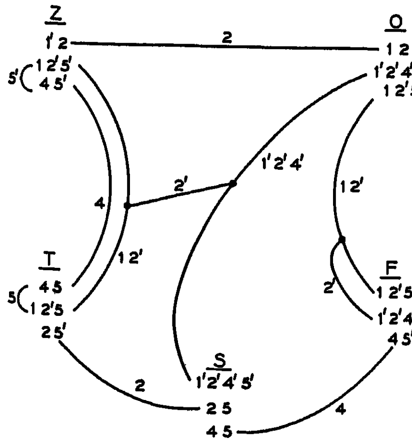

Fig. 14. Work sheet for synthesis of the translator

Illustrative Example: A Relay Translator

Suppose it is desired to find a relay contact network to translate coded decimal digits from a 1-2-4-5 code to 2-out-of-5 code. The five outputs will operate the relays Z (zero), O (one), T (two), F (four), and S (seven). The required translation properties are listed in Table I. The unarithmetic representation for zero is standard in the 2-out-of-5 code.

The remaining six input conditions for the 1-2-4-5 relays are unused or don't-care conditions. However, it is required that none of these conditions results in operation of zero or two of the five output relays. From these specifications, one obtains the five maps in Fig. 13.

At this point, p-subcubes must be selected, and the desirability kept in mind of factoring and disjunctive combinations. The chosen p-subcubes are listed in Table II, where the numbers in parenthesis indicate the order in which they were selected. This should be followed on the maps in order to see how the terms will combine.

A check on the six d-squares now shows that each of them has been taken = 1 on at least three of the maps. Hence the restriction on unused conditions has been satisfied, and no changes need be made in Table II.

The worksheet on which the network is planned is shown in Fig. 14. The lines drawn between terms designate disjunctive combinations or factoring; and the symbols adjacent to the lines indicate which contacts are shared in each case. A careful comparison of this worksheet with the resulting network, shown in Fig. 15, will enable the reader to understand both.

Three-Dimensional Maps

Up to this point, we have discussed functions of no more than four variables. If it is desired to increase the number of variables on a map, two possibilities suggest themselves:

1. Increase the number of variables plotted on each axis.
2. Use three mutually perpendicular axes instead of two.

Both methods are feasible. If method 2 is employed, then for (even) n variables, we will have $n/2$ on each axis. This means an array of $2^{n/2}$ by $2^{n/2}$ squares. However, with more than two variables on an axis, the definition of adjacence must be extended rather tenuously and subcubes become more difficult to recognize. This scheme is like the one originally suggested by Veitch.[3]

We have chosen method 2, which allows a 50-per-cent increase in the number of variables without any extension of the rules. Thus, for six variables, the methods we have described still apply, but in three dimensions.

A suitable framework is shown in Fig. 16. It consists of four 6-inch square plexiglass sheets supported at 1-1/2-inch intervals by rods of the same material. The rods and sheets are glued together. The author has been told that the 3-dimensional ticktacktoe boards sold at some toy shops under various names are satisfactory.

Each sheet is ruled at 1-1/2-inch intervals parallel to both pairs of edges. Thus we have a 4-by-4 array of squares on every sheet. The plexiglass framework enables us to do away with the writing and erasing which would be necessary when dealing with similar problems by other methods. In using it, we employ movable markers, such as 7/8-inch plastic roulette chips. The following scheme is suggested:

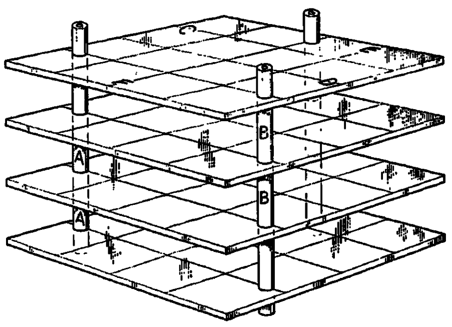

Fig. 16. The cube: a 3-dimensional plastic framework for maps

1. Mark all p-squares with white chips.
2. Mark all d-squares with black chips.
3. As subcubes are selected, mark each one with a set of distinctively colored chips.

Chips of eight or nine different colors are usually sufficient to make all the selected subcubes easily distinguishable. The corresponding products are then found by means of labels on the edges of the plastic cube.

One satisfactory labeling scheme is shown in Fig. 16. The two bottom planes are A, while the middle two are B. The variables C, D, E, and F are arranged on each plane as on the top, each letter serving to label two rows or columns. Opposite ends of any row, column, or vertical on the cube must be considered adjacent. Then every subcube may be thought of as a rectangular parallelepiped with edges 1, 2, or 4 units long. For multioutput problems, it is best to have a set of cubes, one per output.

The extension to seven variables is probably best accomplished by placing two cubes side by side. Corresponding squares in the two cubes must be considered adjacent when looking for p-subcubes. Eight variables can be handled with a set of four cubes, and nine variables require eight cubes. In the latter case, it is convenient to make them so as to stack easily into two layers of four each. Beyond nine variables, the mental gymnastics required for synthesis will, in general, be formidable. Other methods are even more limited in this respect. Outstanding exceptions to this limitation are the symmetric and positional circuits, discussed by Keister, Ritchie, and Washburn.[4]

Conclusions

Employment of the map method seems to be profitable when nontrivial problems in combinational circuit synthesis arise. Its most important advantages appear to be flexibility and speed. Further, if such problems arise frequently, it is advantageous to have a method, such as this, which can be learned and used effectively in a short time by designers new to the field.

Discussion

S. H. Caldwell (Massachusetts Institute of Technology, Cambridge, Mass.): When Shannon published his classic paper on analyzing relay and switching circuits,[1] the engineer was given a powerful method for the solution of many problems in the field of switching circuits. Unfortunately, when one attempted to use the method, there arose a peculiar sort of frustration. Given a circuit which had been designed by the methods of trial and error prevalent at the time, it was readily possible to use Shannon's techniques to investigate alternative forms. In particular, the switching algebra could be used directly for the simplification of contact networks. But the situation was different with respect to the synthesis of a network (unless it could be described by a symmetric function). In the general case, it was necessary to resort to a word statement of the required circuit characteristics and then convert this to an algebraic statement.

For simple problems, and especially those which involved a small number of variables, no difficulty was encountered, but because of their very simplicity such problems rarely needed the algebraic approach. When problems of any magnitude were attempted, the method broke down both because of the difficulty of writing word statements and because of the difficulty of converting bulky word statements into algebraic expressions.

These difficulties were resolved by the adaptation of the logical truth table into the familiar table of combinations (see ref. 1 of the paper). This mechanism enabled the designer to state his requirements in an orderly manner, and gave him a systematic means for checking the completeness of his reasoning. Moreover, the transition from the table of combinations to an equivalent algebraic statement became almost a matter of routine, depending on individual preference for simplifying the algebraic expression by inspection of the table or by algebraic manipulation.

The arrays described by Veitch (see ref. 3 of the paper) and by Mr. Karnaugh represent further development of the table of combinations into forms which are more compact, and which also have the property of making more evident the ways in which the algebraic expression of a switching function can be simplified. Of course, the end result desired in all cases is a minimization of the required circuit, whatever we mean by the word "minimization."

The problem of manipulating functions of many variables is much like the problem the physicist had in his development of mathematical models of atomic structure. Over a period of years he succeeded in getting better and better mathematical solutions for the hydrogen atom, but none of his methods really worked when he tried to add just one more electron. Similarly, in these various methods for reducing switching functions to minimal forms we seem to be producing better and better ways for reducing functions of four variables, but we are still rather unhappy about five and six variables. The author's plastic cube for the treatment of six variables is an ingenious extension of his four-variable array, and it certainly has the reduction properties he ascribes to it. It does not, however, have the neatness of display which is a feature of the plane map; groupings of variables are not as immediately evident, and alternative groupings are even less apparent.

Mr. Karnaugh rightly points out that the search represented by this paper is in its early stages. It should be added that the need for better methods for handling the problem in more than four variables will become acute, and it is a problem worthy of the best thinking. Recent developments in the synthesis of sequential circuits show that the end result of a sequential synthesis is a combinational problem. It is a multiple-output problem in many variables, and has ramifications which will tax the best efforts of the circuit designer. Among the possibilities for meeting this problem is that of mechanizing the process involved in the map method.

Incidentally, I am not impressed by the drawbacks attributed to the Harvard Computation Laboratory minimizing chart. The large number of entries involved is no drawback in these days of cheap duplication processes. Keeping track of the entries is really a simple routine. In using the chart for the realization of six-variable functions with don't-care conditions, I find that one rarely has to complete the vertical ruling of the entire chart because the required conditions are usually satisfied with terms at the left-hand side of the chart. In some cases one finds a condition which is satisfied by only one possible minimal term, where the acceptance of that term in turn specifies the nature of one or more don't-care conditions. Of course, the six-variable cube inherently contains the same information, but it is doubtful that its display gives the designer quite as much immediate guidance as he gets from the minimizing chart.

M. Karnaugh: In view of Professor Caldwell's remarks about mechanization, it appears to be desirable to restate the reasons for presenting this paper.

The map method, in its present form, is likely to be useful in two ways: as a pedagogic device, for the introduction of ideas about logic circuits and their synthesis, and also as a desk-top aid to the working engineer.

In making full use of the human faculty for recognizing geometric patterns at a glance, the map method supplies a number of short cuts to synthesis that are not as easily found by other methods. On the other hand, the development of machine which can recognize such relationships has only begun. If one mechanizes the map method in a more conventional way, using a repetitive scanning technique, then the result is similar to a mechanization of the Harvard minimizing charts and no special advantages are expected.

The minimizing charts, which represent one of the first significant advances over purely algebraic manipulation, have proven their usefulness in practice and will undoubtedly do so even more convincingly when machines are programmed to work along the same lines. However, it has been the author's experience that maps present the specifications for a logic circuit in a form more easily used by the human operator. Here, habit and taste enter the picture and it would be unwise to dwell on this point.

For those who are relatively new to the problem under discussion, it is suggested that a number of problems be worked by both methods. It is of interest to see how they are related, and each will throw some light on the operation of the other.

The Use of Steel Sheet for the Construction of Shielded Rooms

A. M. INTRATOR
ASSOCIATE MEMBER AIEE

LOW-LEVEL electronic or electrical measurements are particularly susceptible to errors introduced by external electromagnetic influences. The coupling of spurious electromagnetic energy into a measuring system not only may result in the receipt of false information but also can sometimes cause the complete masking of the desired data as well. For these reasons, many low-level measurements, such as the determination of crystal characteristics, filter insertion loss, noise measurements, and the like, must be made in a location as free as possible from such interference. In a laboratory, such isolation from interference is usually achieved by completely enclosing an area in copper or bronze screening. By shielding off a region relatively free of external interference in this way, a working area is provided within which sensitive electronic measurements can be made.

Certain instrumentation requires a much higher degree of freedom from extraneous influences than can be obtained in screened enclosures. A reduction in the shielding efficiency of screened booths occurs at the lower frequencies because of practical limitations in wire size and at higher frequencies because the wave lengths begin to approach the dimensions of the mesh openings. Fig. 1 shows a typical attenuation curve of a screened room. Because sheet metal presents neither of these difficulties, it is often used instead of screening, to enclose those areas in which a high degree of shielding is required.

Copper sheet has ordinarily been used for this purpose, although copper-clad steel has been used in some cases. Such rooms are usually double-walled; the inner and outer sheet-metal walls are spaced about 4 inches apart and are insulated from each other except at the point where the power line enters the room. Ordinarily the walls are hung upon a kiln-dried, wax-impregnated wood frame and all seams and mounting nails or bolts are completely soldered over to reduce the possibility of energy leakage into the room. Special seals are used to insure continuous metal-to-metal contact around the periphery of the door. Air is introduced through "wave guide below cutoff" vents, the cutoff frequency being determined by the expected top operating frequencies in the room. All power lines entering the room are filtered.

These rooms are very expensive, having ranged in cost from about $10,000 for small rooms to $100,000 for much larger

ones. Much of the expense results from the extensive use of copper. Copper not only is an expensive metal but also requires tedious and correspondingly costly assembling techniques when being used for a shielded room. In addition, copper is at present a critical defense material in short supply. Four thousand pounds of 16-ounce copper sheet was required in the construction of one 12-foot by 16-foot by 8-foot double-walled room. For these reasons, a study was initiated to explore the possibility of using less critical and less expensive materials in the construction of high-performance rooms. A review of the theory of shielding, together with an economic comparison of the use of various metals for shielded rooms, pointed to the possible use of standard structural steel sheet.

Principles of Shielding

A shield is a physical barrier introduced between two regions to prevent the leakage of energy from one region into the other. Although no shield can be perfect, a shield can be so made that the ratio of energy levels of the two regions is very large. This shielding is accomplished in two ways: through the reflection of energy from the surface of the barrier, and through the absorption of energy within the barrier.

To illustrate this, consider the shield as an infinite plane of finite thickness and assume that the energy incident upon the shield is in the form of plane waves. In this case, for an electrically thick shield in which the absorption is of such magnitude (of the order of 10 decibels or more) that the effect of reflections at one surface does not appreciably affect the conditions at the other surface, it can be shown that the total shielding effectiveness is[1]

$$S=8.686\sigma R_s d+10\log_{10}\frac{(\eta+Z_s)^4}{16\eta^2 Z_s^2}\text{decibels} \quad (1)$$

where

the first term in the expression represents the absorption loss
the second represents the reflection loss
σ = conductivity of the shield, mhos per meter
d = thickness of the shield, meters
η = impedance of plane waves in free space, 377 ohms
Z_s = impedance of the wave in the metal = $(1+j)\sqrt{\pi f\mu/\sigma}$
f = wave frequency, cycles per second
μ = absolute permeability of the metal, henrys per meter
$R_s=\sqrt{\pi f\mu/\sigma}$
S = shielding attenuation, decibels

For nonferrous metals, the permeability is relatively independent of frequency and is equal to μ_0, the permeability of free space. However, for ferrous metals, μ is a function of frequency, as well as of the magnetic field strength and the previous magnetic history of the material. The permeability of steel decreases with increasing frequency, in a manner illustrated by Fig. 2.[2] If we assume this to be the permeability of the steel for computation purposes, Fig. 3 represents the variation of reflection loss and absorption loss with frequency of 24-gauge sheet copper and 24-gauge sheet steel.

Except at frequencies of the order of 10^{10} cycles per second or higher, the absorption loss in the steel is greater than that in copper. On the other hand, the reflection loss for the incident plane waves is higher at the copper surface than at the steel. In both cases, these theoretical attenuation values are much larger than would necessarily be required in practice. Most electronic equipment is not ordinarily sensitive to signals of field strengths of less than 0.01 microvolt per

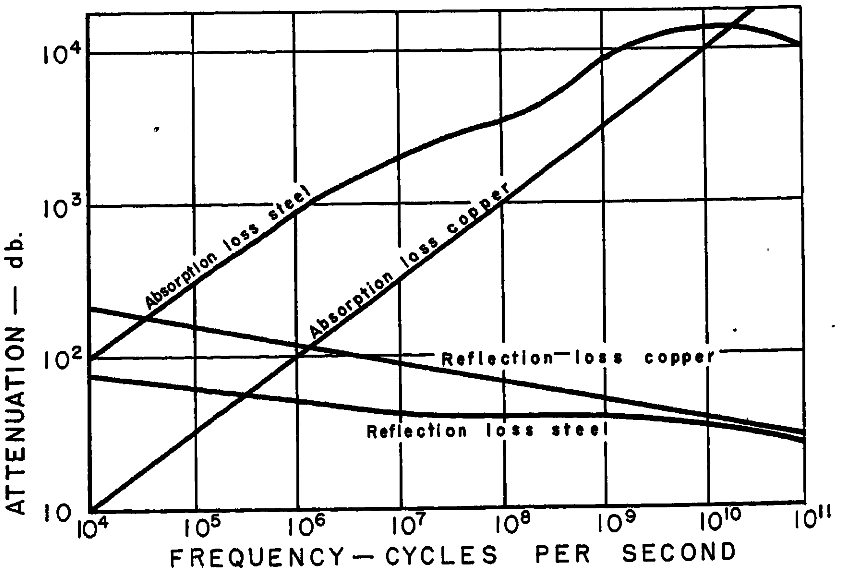

Fig. 3. Absorption and reflection loss of copper and steel as a function of frequency

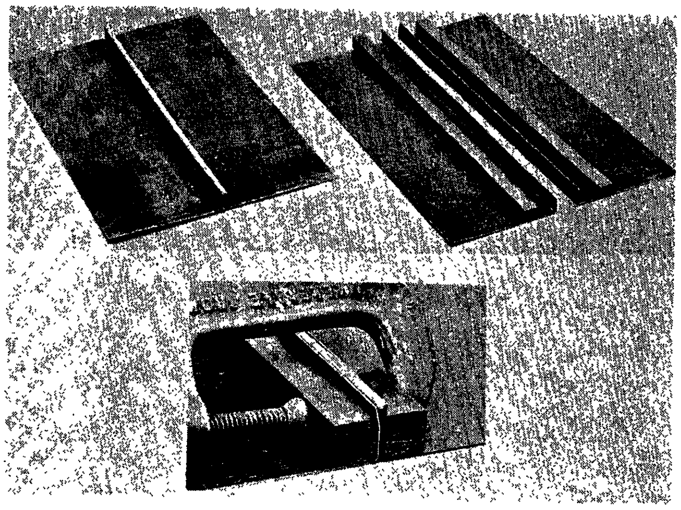

Fig. 4. Procedure used in brazing steel panels to form wall of room

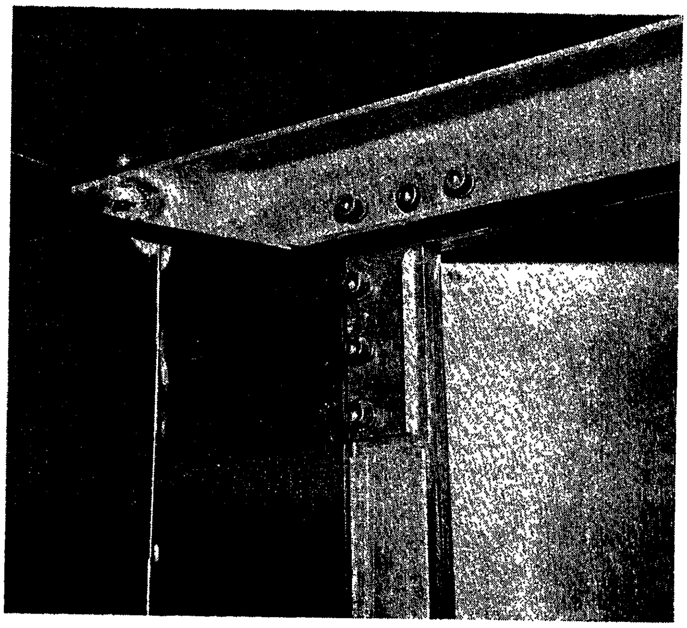

Fig. 5. Door jamb corner construction

meter. The dielectric breakdown strength of air at normal temperatures and pressures is in the order of 10^6 volts per meter for a sphere gap.[3] The maximum attenuation that could possibly be attained under these conditions is 280 decibels.

Generally, however, the shield is not a plane and the incident energy is not in form of a plane wave. Inasmuch as the reflection loss is a function of the shape of the shield and the type of impinging wave, while the absorption loss within the metal is relatively independent of these characteristics (provided the radius of curvature of the surface of the shield is ten times the skin depth), the attenuation loss within the shield is often used to determine the thickness of metal needed for a specific shielding performance. This thickness is given by

$$d=0.114\frac{S}{\sqrt{\pi f \mu \sigma}} \text{ meters} \qquad (2)$$

Thus it is seen, from equation 2 and Fig. 3, that the thickness of metal necessary to achieve a given attenuation decreases with increasing frequency. It would therefore appear sufficient to make calculations only at the lowest frequency in selecting the thickness of metal required to give a specific attenuation over some frequency range.

Design and Construction

The possibility of using ferrous metals for the construction of high-performance shielded rooms is clearly implied in the theory. Except at very high frequencies, the greater permeability of ferrous metals make these metals superior to copper in shielding effectiveness, for the same thickness of metal.

To verify these conclusions and also to study economical construction methods of constructing rooms made of steel, an all-steel shielded room was constructed. Because it happened to be available at the time, Tran-Cor *72*, no. 24-gauge sheet steel was used for the construction. The manufacturer's data indicated that this steel has an initial relative permeability of 1,000 at 15 kc and a resistivity of 54 microhm-centimeters. Tran-Cor *72* has the advantage of a high initial permeability with satisfactory ductility and workability for easy bending during fabrication. According to the analysis presented earlier in the paper, steel with these characteristics should offer an absorption loss of 57 decibels at 15 kc and higher attenuations at higher frequencies.

Other commercial steels can be used; and a low carbon steel, such as SAE *1010*, which is usually available from warehouse stock throughout the country, would perhaps be more satisfactory.

The size of the available sheet stock was 28 inches by 8 feet. In order to use these sheets most efficiently in building the room, an 8-foot by 8-foot by 9-foot room was designed.

The joints used in fastening the sheets together are shown in Fig. 4. The edges of the sheets were braked into 2-inch 90-degree bends; the sheets were then joined by clamping the edges together in 2- or 4-foot sections, as shown. To fuse the joint, 0.062-inch brass or Tobin bronze wire was laid in the groove, brazing flux was applied, and an acetylene torch was moved along the joint. The clamping fixture protected the panel from the flame and, by holding the joint rigidly, minimized distortion. It was found that about 6 feet of joint could be welded an hour.

Each wall, the ceiling, and the floor were assembled horizontally in this manner; the brazed units were then set up and assembled in the same way; short sections were successively clamped together and the joints brazed. For the most part, the brass wire was fed into the joint by hand as brazing progressed. Because the panels had been carefully made of sheets of standard size, no difficulty was encountered in matching sections or in the warping of sections. Because the braked edges at the joints provided enough rigidity and structural strength for a room of this size, no supporting framework was required except that necessary to compensate for the weight of the door.

The door jamb consisted of 2-inch by 1-inch steel-bar stock, into which a 1/4-inch by 3/8-inch groove was milled. A light 3/8-inch by 3/4-inch by 1/8-inch bar was spot-welded to the door jamb, as shown in Fig. 5, to provide additional support. Horizontal support for the framework of the jamb was obtained by a 3-inch by 1-inch by 1/4-inch channel and a light 1-inch by 1/2-inch angle iron was fitted along each of the corners for increased rigidity. This was securely attached to the door by brazing and bolting. Care was taken to braze and sweat solder around the bolts and to tack weld at other points.

The door was made of the same sheet steel as that used in the construction of the room, spot-welded to a welded steel frame of 1-inch by 1/2-inch steel channel reinforced by 1/4-inch by 3-inch steel spreaders. Its over-all dimensions were 3 feet by $6^{1}/_{2}$ feet. To secure a continuous firm contact between the door and the jamb upon closure, hinges and clamps were spaced at $8^{1}/_{2}$-inch intervals to provide equal pressure. Turnbuckles and braces were used at the top and bottom of the door so that adjustments could be made to offset any door warpage that might occur. A 3/8-inch diameter solid rubber strip was fitted into the groove in the jamb bar to cushion the bronze contact strip which was soldered to the inner surface of the door around the periphery at the contact area. The slight flexing of the metal as the rubber tubing was compressed upon the closing of the door introduced a little wiping action that aided in keeping the contacting surfaces clean.

During the tests, it was found that an iron-to-iron pressure connection was inadequate for shielding purposes. The contact resistance at such a closure was high enough to allow considerable energy leakage through the door closure even when the iron surfaces were newly polished. Although the single bronze strip on the door appeared adequate for the purposes of the short-term test, bronze stripping should be used on both the door and the jamb for more permanent installations.

In the experimental room, the latching mechanism could be operated only from within the room. To permit, for safety purposes, entry from the outside when the mechanism was secured, an emergency entry port was provided. This port consisted of a hole 6 inches in diameter cut near the latch handle, over which a $6^{3}/_{8}$-inch diameter cover of the same sheet steel was sweat-soldered with a soft lead solder. A tab and handle were fastened to the cover so that the solder joint could be pulled apart easily. On a more permanent installation, a simpler means of opening the door, from both inside and outside the room, is necessary. It has been the experience of the author that little energy leakage occurs at the door latch handle if the latching mechanism and handle is securely grounded to the door. Such a mechanism is shown in Fig. 6. The contact strip is fastened to the handle and rides on the brass plate as the handle is turned.

To use such a shielded room as a test chamber, auxiliary services must be provided. Such services are especially necessary when the room is constructed of solid sheet walls rather than screening, because with such walls lighting and ventilation are absolutely required. Of course, these services must be provided in such a manner that they decrease in no great way the over-all shielding performance of the room.

Ventilation

Ventilation does not present any serious problems. The ventilator can consist of "wave guide below cutoff" ducts arrayed in a honeycomb fashion to form the inlet or outlet port. The maximum cross-sectional dimension of the individual ducts should be smaller than 1/2 wave length of the highest frequency to be shielded against. Automobile radiators have often been satisfactorily used for this purpose.

Power and Lighting

The major energy leakage into shielded rooms is usually that resulting from interference carried on the power lines; for this reason, it is necessary to filter the incoming electric power properly. Each line should be individually filtered. The basic circuit of the filter designed for use with the test room is shown in Fig. 7. To improve the performance of the fiber at higher frequencies, additional sections were added. These consisted of four inductors, each composed of six turns of no. 14 wire wound on a 1-inch arbor and spaced six turns to the inch. The inductors were by-passed by 1,000-micromicrofarad "feed-through" type capacitors. The performance curve of this filter is given in Fig. 8. The filter was encased in a shielded container, the separate sections of the network being compartmented by sheet-metal separators to eliminate mutual coupling between one part of the circuit and another. A bare copper wire, soldered at each point where it passed through the separators, was used as a common ground. The filter box was connected electrically to the shielded room at only one point through a section of steel tubing soldered tightly to box and the wall. This precaution was taken to minimize the circulating currents in the room's walls that would arise if multiple contact was made. A number of filters are now available commercially that have been specifically designed to be used with shielded rooms.

The filtered power lines entering the room should be enclosed in rigid steel conduit, the conduit being soldered or brazed to the wall at intervals not greater than 1/4 wave length of the highest frequency at which the room is to be used.

Illumination is provided only by incandescent lamps since fluorescent lights have been found to be a serious source of radio interference.

Test

The problem of obtaining reliable data on the performance of high-attenuation shielded rooms has been a difficult one. Ideally, the room should be isolated in space and immersed in a uniform high-intensity electromagnetic field of known magnitude. The field strength should then be measured and integrated over the interior of the room by sensing devices and instruments too small to perturb the distribution. The reduction in the strength of the field as measured throughout the volume of the room would be an indication of the shielding effectiveness of the room.

However, in the practical case, shielded rooms are used under a large variety of circumstances but never in the ideal one. They are situated near masses of dielectric and conducting media which give rise to many secondary electromagnetic effects that disturb the fields to which the room is subjected. Further, these fields are rarely plane and include low-impedance distributions as well as high-impedance ones.

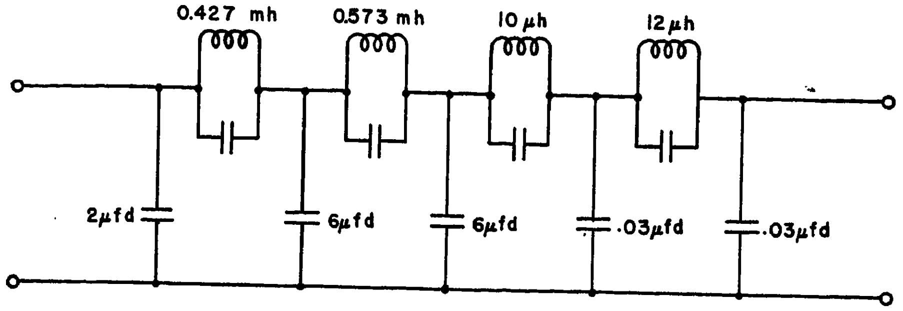

Fig. 7. Shielded-room power-line filter circuit

These limitations have generally been recognized by engineers and consequently many qualitative, though practical, methods have been devised for determining the adequacy of the particular shield under the conditions in which it will be used. Such methods usually consist of placing a transmitter within the room and a sensitive receiver outside of the room and then measuring the variation in attenuation of the transmitter's field when the door to the shielded room is opened and closed. Most shielded-room evaluation has been made in this manner although for more abstract studies some have put rooms on trucks and taken them to regions of high-intensity fields, such as those near a transmitter tower, in order to measure the degree of shielding achieved by the room.

Inasmuch as the primary objective of this study was to verify those theoretical observations that pointed to the use of steel for the construction of shielded rooms it was felt that a practical test method that would allow the performance of the room to be evaluated as quantitatively as possible in its operating location should be sufficient. It was decided to produce the test field by a source within the room and a magnetic dipole radiator was chosen for this purpose. Magnetic radiators offer two main advantages: their fields in the near region are of the low-impedance type most effective in coupling to a low-impedance conducting sheet, such as steel, and magnetic loops are easy to monitor. An ammeter can measure loop current. Knowledge of the current in the loop and its relative position in the room is sufficient to calibrate and reproduce its performance.

It was realized that this technique might be difficult to use at very high frequencies because the increased driving impedance of the loop would demand an extremely high-powered transmitter to reproduce the loop currents and corresponding fields used at the lower test frequencies. Limitations in the funds available prevented further exploration at these higher frequencies. However, the results obtained with the loop radiator can be reasonably expected to give the minimum effectiveness of the steel as a shielding medium, inasmuch as the difficulty with which the energy penetrates the shield decreases as the frequency is lowered. These measurements, therefore, should check the performance under theoretically the most stringent conditions.

Measurements were made in two frequency regions, 2 to 15 megacycles, and 10 to 30 kc. At the maximum frequency of 15 megacycles, the transmitter loop consisted of a copper rod 3/8 inch in diameter, formed into a single-turn 20-inch diameter circle and having a measured inductance of 1.23 microhenrys and an unloaded Q at 10 megacycles of 255. A 0 to 15-ampere radio-frequency ammeter was used to measure the loop current and a 150-watt transmitter was used to drive the loop.

Within the 2-to-15-megacycle range, a standard high-sensitivity radio receiver utilizing an unresonated receiver loop identical to the transmitting loop was used as the field detecting device. Because the built-in shielding of the receiver was inadequate, the receiver was always operated inside the shielded room.

The general test procedure involved substitution techniques. The transmitting and receiving loops were mounted on a table coaxially and spaced 8 inches apart. The transmitting loop was fed by a short, parallel-wire transmission line, and the receiving loop was connected to the receiver through a 6-foot coaxial cable. A calibrated 170-decibel variable attenuator was placed in the receiver transmission line. The receiver which was located inside the shielded room, was connected to the loop through a coaxial fitting in the wall. A 10-decibel attenuating pad was placed between the receiver and the loop transmission line to isolate the loop from the receiver. This pad was within the room, but the larger range of attenuators was left outside. There was no evidence of radiated leakage into the attenuators.

The transmitter was then adjusted to maintain almost 4 amperes of loop current. At this excitation, nearly the full 170 decibels were required of the receiving loop attenuator to give a low sensitive voltage indication on the automatic volume control of the receiver. Readings were taken of the transmitting loop current and the automatic volume control voltage. The receiver loop was then placed inside the room, the transmitting loop being kept outside. The loops were moved to coaxial positions, parallel to and equidistant from the wall of the room and separated by the same total distance previously used. The transmitting loop current was adjusted to 4 amperes, and the receiving-loop attenuators were adjusted so that the receiver indicated the same automatic volume control voltage as that used during the calibration procedure. The difference in the attenuator settings required to obtain the same

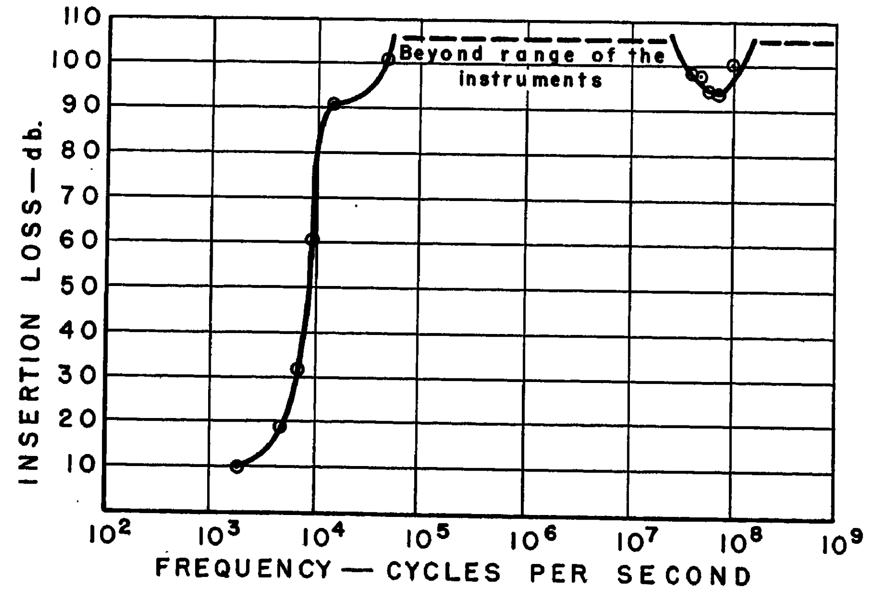

Fig. 8. Power-line filter performance curve

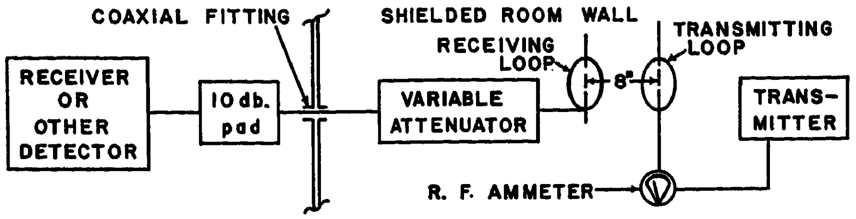

a) ARRANGEMENT FOR CALIBRATING INSTRUMENT

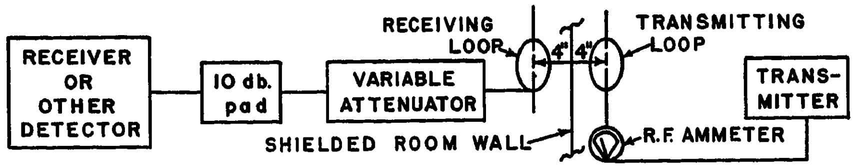

Fig. 9. Block diagram of test setup used for evaluating the performance of the shielded room

receiver automatic volume control voltage in the two setups was taken as the attenuation introduced by the room. A block diagram of the test procedure is shown in Fig. 9.

Because it was possible that some of the received energy may have been introduced through the power-line filter, a battery power source was installed inside the room and the measurements were repeated. No change was noticed.

A similar substitution procedure was used to obtain the attenuation at 15 kc. For this frequency, a receiving loop with a diameter of 20 inches was made up of 100 turns of no. 28 enameled copper wire. This loop had a measured inductance of 13.38 millihenrys and an unloaded Q of 33 at 15 kc. A harmonic analyzer was used to measure the loop voltage.

Results

Employing this method, the measured attenuation of the room was found to be 46 decibels at 15 kc and greater than 160 decibels between 1 and 10 megacycles. These values are somewhat less than those which had been calculated for the thickness of steel used. However, the calculated results were based upon the value of the permeability of the steel which had been furnished by the supplier—a relative permeability of 1,000 at 15 kc. Subsequent measurements of the permeability indicated that the actual value was closer to 500. When the corrected value is used in the equation, a calculated attenuation of 41 decibels is obtained, which value agrees fairly closely with the experimental results. The permeability difference may have resulted from the mechanical working of the metal when it was being assembled.

Checks made of the attenuation between 10 and 30 kc showed that the measured shielding in decibels was proportional to the square root of the frequency. This fact indicates that the attenuation through the metal evidenced by skin-effect losses in the walls was the principal mechanism by which the shielding was accomplished under the test conditions. Such conclusions are in accord with the theory presented earlier in the paper, and, therefore, it must be expected that attenuations of greater than 46 decibels at 15 kc can be achieved by the appropriate selection of type and thickness of steel, through the use of equation 2.

The test setup employed represents the most stringent conditions that might be encountered in practice: that of shielding against the near field of a partially or completely closed loop carrying a large current. The near field of a current loop is a low-impedance field. Such a field undergoes little reflection loss at metal-air boundaries; and consequently, the results represent the minimum attenuations that could be secured under the worst conditions.

Conclusions

High-performance shielded rooms may be built of sheet steel. By the appropriate selection of the thickness and type of steel, a single-walled room may be built to achieve the degree of shielding required. The modified skin-depth equation as given by equation 2, serves as a good criterion for selecting the proper type and thickness of steel.

Discussion

Harry R. Meahl (General Electric Company, Schenectady, N. Y.): Although I agree with the author's conclusion that high performance-shielded rooms may be built of sheet steel, I cannot agree that the paper proves it.

In the results, a measured value of 46 decibels at 15 kc is given, together with a statement that this is less than the calculated value, but that using measured permeability gave a calculated value of 41 decibels. I found the calculated value of absorption loss for a permeability of 500 and a conductivity of 0.185×10 to be 32 decibels at 15 kc, and the reflection loss to be 90 decibels, or a total shield effect of 122 decibels. This is a large difference, which, if true, shows the calculation to be useless. However, it seems more likely that the measured data is in error. I suspect the power line filter, because it appears that the filtering action was tested by substituting batteries when operating in the 2-to-15-megacycle range where it is good, rather than at 10 or 15 kc where its filtering action is questionable.

My experience with shielding has been that an extremely small opening can allow serious leakage. Consequently, I favor the use of radiation absorbing shielding, so that the unwanted electromagnetic energy is converted to heat as soon as possible instead of being reflected from one shield to another until it finally leaks out of the usually available cracks.

A. M. Intrator: I appreciate Mr. Meahl's comments on my paper. However, there are certain points in his discussion which are in error. Mr. Meahl calculated the absorption loss in the steel to be 32 decibels using a conductivity of 0.185×10. I presume this is in units of mho per meter. If so, since the resistivity of the steel was 54 microhm-centimeters, Mr. Meahl's value is incorrect. The correct conductivity is 1.85×10^6 mho per meter. Substitution of this value into equation 2, and using a relative permeability of 500 for the steel still results in a calculated absorption loss of 41 decibels, as shown

$$\text{Absorption loss}=\frac{0.635\times10^{-3}}{0.114}\times\sqrt{\pi(500\times1.257\times10^{-6})(1.85\times10^{4})\times(1.5\times10^{4})}=41\text{ decibels}$$

where

0.635×10^{-3} = thickness of 24-gauge sheet steel, meters

$500\times1.257\times10^{-6}$ = absolute permeability of the steel, henrys per meter

1.85×10^{6} = conductivity of the steel, mho per meter

1.5×10^{4} = frequency, cycles per second

I believe that Mr. Meahl may have made his error in calculating 32 decibels for the absorption loss by using the incorrect value for the conductivity and by using the relative permeability, 500, instead of the absolute permeability, $500\times1.257\times10^{-6}$, in the equation.

Consideration of the reflection loss in the calculations by Mr. Meahl is not warranted for the type of measurements made. The measurements were made using loops for both the pickup and the field source. The field near a current loop is a low impedance field and suffers little reflection loss at the metal-air boundaries. This procedure was used intentionally to avoid, as much as possible, contribution by reflection losses to the experimentally determined results. Inasmuch as the reflection loss was minimized as a factor in the experiment, the results represent the most rigorous type of shielding performance obtainable, since little or no additional shielding was provided by reflection losses.

The tests to determine whether or not some of the received energy was coming in through the power line filter, by substituting batteries for the power source, was made at 15 kc as well as in the 2-to-15-megacycle range.

I fully agree with Mr. Meahl that extremely small openings can cause severe leakage. However, the purpose of this paper was to point out that steel can be used as a substitute for copper in constructing high-performance shielded rooms.

The Control of Noise and Crosstalk on N1 Carrier Systems

A. J. AIKENS
NONMEMBER AIEE

C. S. THAELER
ASSOCIATE MEMBER AIEE

THE 12-channel *N1* carrier system is designed primarily for short- and medium-haul service and to make use of existing, and new, cable plant with a minimum of special treatment. As compared to other types of carriers, the lower transmission levels of the *N1* system tend to make it more susceptive to interference from external sources. The use of higher line frequencies with the corresponding decrease in coupling loss between line conductors tends to increase the amount of crosstalk between carrier systems. While the technical features of the *N1* system have already been described,[1] it may be well to review some of the characteristics that are of interest in connection with the control of noise and crosstalk on message circuits. These include:

1. Transmission of both side bands and the carrier.
2. A compandor per channel. At the transmitting end, a compressor raises the average talker volume by about 10 decibels (db) and reduces by one-half the normal range of talker volumes. At the receiving end, a complementary expandor restores the talker volumes to their normal range.
3. Transmission in the two directions in different frequency ranges on separate pairs in the same cable. Low-group frequency range, 44 to 140 kc; high-group range, 164 to 260 kc; frequency inversion at each repeater by modulating the signal with a 304-kc carrier.
4. In each repeater section the carriers at the high-frequency end of the band are transmitted at higher level than those at the low-frequency end. Because of the increase in attenuation with frequency, the relative levels at the receiving end are reversed.

Control of Noise

Noise Objective

In general, the effective noise on an *N1* channel should not exceed 31 decibels adjusted (dba) referred to the zero level point. Under the Bell System general toll switching plan for dial operation, the terminal net loss of a single circuit will vary from about 4.5 db up, depending upon the type of facility and the length of the circuit. If this objective is met, the maximum noise on even the lowest loss circuit will be about 5 db below the level at which the average subscriber would become conscious of its presence. Since the expandor in each *N1* channel terminal is designed to have a hangover time of about 40 milliseconds to avoid clipping the trailing ends of syllables, the noise present at the end of a high level signal is not as fully attenuated as during the silent interval. To achieve the equivalent of 31 dba of noise on a noncompandored system, it has been found that the silent interval noise, as measured with a Bell System 2-type noise set, should not exceed 26 dba.

Sources of Noise

The principal sources of noise encountered in the operation of *N1* systems are as follows:

1. System noise.
2. Secondary induction from telephone plant.
3. Secondary induction from external sources.
4. Nonsoldered cable pair joints.

Discussion of Noise Sources and Mitigation

System Noise

By design, the noise contributed by the repeaters and terminal equipment has been held to about −38 dba of equivalent input noise for a 200-mile circuit. This noise consists of the usual first-circuit *sh-sh* (thermal-type noise) and interchannel modulation due to the nonlinearity of the modulators and demodulators. The noise from these sources is so low as to be masked by noise from other sources.

The *N1* system uses "out-of-band" signaling employing both side bands of a 3,700-cycle tone, transmitted 15 db below the carrier level. Since the channel filters do not entirely suppress these signaling tones, a small amount of noise leaks into the message channel. This noise is not generally significant since the signaling tone is usually removed during the talking period, and it is transmitted at a low level.

A thermal noise generator is provided in the transmitting terminal of the *N1* system to furnish a controllable amount of steady hiss-type of noise that may be used to mask low level crosstalk or cross-modulation. Even with the maximum output of the generator, the thermal noise produces a negligible impairment to message circuit transmission while masking the crosstalk by about 5 db. So far, no use has been made of this technique although it is quite possible that it will be employed as the number of *N1* systems in nonquadded cables is increased.

Paper 53-226, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 18, 1953; made available for printing May 14, 1953.

The authors wish to acknowledge the efforts of the many persons who made this study possible, especially the work of S. E. Church, S. G. Hale, H. A. Stone, Jr., R. S. Tucker, and M. A. Weaver, all of Bell Telephone Laboratories.

Secondary Induction from Telephone Plant

The operation of relays and switches in a telephone office puts noise voltages between the office wiring and ground. While the office wiring associated with the *N1* systems consists of shielded pairs, this noise is picked up by noncarrier wiring over which it travels longitudinally to pairs in the same cable sheath as the *N1* pairs. Due to the high longitudinal coupling between all pairs under the same sheath, noise voltages appear on the *N1* pairs, and depending upon their longitudinal-to-metallic balance, part of the noise appears in the metallic circuit. When installing *N* carrier on existing cables, it is not generally feasible to improve the cable balance although it is possible to exclude from *N* operation pairs having particularly poor balance. The path by which noise from internal sources enters the *N* system is shown in Fig. 1.

Since little can be done to reduce the noise after it has entered the *N* cable, it is desirable to suppress it before it reaches the carrier pairs. This might be done by introducing a high impedance into the longitudinal circuit of the noncarrier pairs without appreciably increasing their metallic circuit loss in the useful frequency range. With *K* carrier systems this was accomplished by means of series retardation coils in the noncarrier circuits. This treatment proved to be expensive, and a cheaper way of suppressing the noise on *N* carrier systems is still being sought.

One measure that has been used is to keep the carrier and noncarrier pairs in separate sheaths or shielded compartments for a limited distance from the office. As the length of the twin cable section is increased, the received signal level on the *N1* pairs at the point of exposure to the noise is increased and the noise itself is reduced, thus greatly improving the signal-to-noise ratio.

Noise arising from the operation of telegraph equipment may be effectively suppressed at the source. In many cases the telegraph equipment already includes noise killers to control the noise in the audio-frequency range. These may be supplemented by suppression that is more effective at carrier frequencies. Not all types of telegraph systems cause serious interference. With metallic operation, the currents are so small as to create negligible disturbance. However, the large currents used with grounded simplex operation have proved bothersome. Experience has shown that a simple filter consisting of a 0.5-microfarad capacitor connected between ground and the mid-point of the simplex-deriving repeating coil will provide adequate suppression.

One of the more commonly used measures to control dial office noise is to limit the length of the repeater section adjacent to the noise source and thus restrict the amount of noise gain. The amount of metallic noise on a cable pair at the main distributing frame in a dial office will vary widely but it has been found under typical conditions to be in the order of 100 decibels below 1 milliwatt in a 3-kc band in the *N1* frequency range. This compares with a side-band level at the input of a high-low repeater which may drop to 75 decibels below 1 milliwatt for a full 8-mile repeater section. At a high-low repeater the 304-kc carrier modulates noise components in the frequency range between 348 and 444 kc, the lower side band of this modulation also falling within the 44- to 140-kc low-frequency group. This image frequency noise is excluded from low-high repeaters and low-group receiving terminals by the low-pass filter, and is no problem at high-group receiving terminals since the 304-kc group carrier is not present.

Secondary Induction from External Sources

The most important path for induction from sources external to the telephone plant is by secondary induction from noncarrier pairs in the *N1* cable which have extensions or taps to open-wire lines or to branch cables of short length connected to open wires or subscriber drops. Noise from atmospheric static or radio-frequency transmitters which is present on the open wire or drops is carried into the cable longitudinally where it appears as metallic noise on the *N1* pairs, as previously discussed. Several different measures have been used to suppress this type of noise, depending upon its magnitude, frequency, and nature.

Where suppression is desired over a wide range extending through the transmitted *N1* frequencies and the image frequency band, the most effective suppression is provided by longitudinal retardation coils which insert loss in the ground return circuit. Existing coils which were developed for use with the *K* and *J* carrier systems have been used to a limited extent but they are expensive and do not have adequate loss in the image band. New coils are under development and some prototypes have been tested with satisfactory results. It appears that they will afford about 25 db of suppression throughout the entire *N1* transmitted and image frequency bands. In developing the new coil every effort is being made to keep its metallic circuit loss at a minimum. Fig. 2 shows a longitudinal retardation coil connected at the junction of open wire and cable.

The experience with *N1* systems in the vicinity of Annapolis, Md., will serve to illustrate the application of this type of suppression. On many systems in this area, channels 3 and 7 were turned down because of interference from nearby radio transmitters. The noise was introduced into vulnerable points of the *N1* circuits by way of open-wire and drop-wire extensions of non-*N* cable pairs. The interference had been anticipated when engineering the carrier systems, and as a result the two or three repeater sections nearest the radio transmitters were reduced in length to facilitate its suppression.

After placing the initial systems in service, experiments were begun to see what could be done to reduce to tolerable levels the noise on the affected channels. Between Annapolis and Hyattsville there were 354 different open-wire and drop-wire extensions of non-*N* pairs, of which 106 required treatment to acceptably reduce the *N1* channel noise. The only major group of extensions requiring no suppression were in the 3½-mile-long repeater section at the Annapolis end of the system. The suppression finally

selected consisted of toroidal coils such as shown in Fig. 2, wound so as to insert a relatively high impedance in the longitudinal circuit of the offending antenna-like pairs but not in the metallic circuit of these pairs. A design including high core loss gave a large resistive component to the impedance to aid in preventing resonance.

Table I shows how the noise in the affected channels was reduced by the installation of the 106 separate suppressors.

An interesting aspect of the tests was that subsequent removal of suppression from a single open-wire extension 1,500 feet long, connected to the cable at a point about 12 miles from the radio transmitters, raised the noise nearly to the level existing before any extensions were suppressed.

In some cases noise has been experienced on systems operating on cables without open-wire taps or drop loops. Here the longitudinal noise currents present on the sheath encountered a high impedance due to the presence of an insulating joint and the noise was thereby transferred to the longitudinal circuit of the pairs. Certain capacitors used to by-pass insulating joints in voice frequency cables do not effectively by-pass carrier frequency currents. Where the need for the insulating joint no longer exists, it has been permanently removed.

Table I. Reduction of Radio Interference into N1 Systems

Channel	Noise at Zero Transmission Level at Annapolis	
	Without Suppression	With Suppression
Worst No. 3	67 dba	27 dba
Average No. 3	50	23
Worst No. 7	59	28
Average No. 7	50	22
	Noise at Zero Transmission Level at Hyattsville or Washington	
	Without Suppression	With Suppression
Worst No. 3	68	30
Average No. 3	52	27
Worst No. 7	49	25
Average No. 7	37	21

In other cases the joint has also been bridged by a 4-microfarad capacitor.

Some use has been made of slot rejection filters as a stopgap measure until the installation of suppression which does not impair the *N1* message circuit. To minimize the impairment to speech transmission, only narrow-band slot filters are employed and this means, of course, that the method is satisfactory only when the interference is a single frequency tone. It is admittedly not a desirable measure since the effectiveness of the suppression is reduced by variations in the interfering frequency. It is obviously undesirable to use slot rejection filters on circuits which may be operated in tandem with other circuits which may also contain filters tuned to a different frequency.

Nonsoldered Cable Pair Joints

Occasionally *N1* systems are operated in part or entirely over cable pairs with nonsoldered joints. This usually occurs only in the case of older exchange cables since it is now common practice to solder new cables which are candidates for *N1* operation. The defect in nonsoldered joints is due primarily to a barrier of oxides and possibly sulfides. The joint resistance may be variable, because of temperature changes or vibration, and may produce a noise sounding like thermal noise with superimposed irregular clicks and pops. Where a cable on which *N1* carrier is to be installed is known to have a bad history from the standpoint of variable resistance, it is possible to make a series of tests over a period of time to determine which pairs are properly suitable for carrier use.

The presence of d-c supplying repeaters with power is thought to help minimize noise production in the nonsoldered joints. Where such power is not supplied over the cable pairs, it is possible to supply up to 20 mils of bleeder current to aid in stabilizing the joint resistance.

Control of Crosstalk

The solution to a number of crosstalk problems present in other open-wire and cable carrier systems has been facilitated by the design of the *N1* system. For example, frequency frogging has solved the runaround crosstalk problem at repeaters without requiring the introduction of loss in the longitudinal path as in open-wire systems, or the use of separate cables which permit pair frogging as in the case of type-*K* cable carrier. Also, the compandor per channel helps to control far-end and other types of crosstalk without the use of frequency staggering as applied in 3- and 12-channel open-wire systems or the provision of the intersystem crosstalk balancing associated with type-*K* carrier.

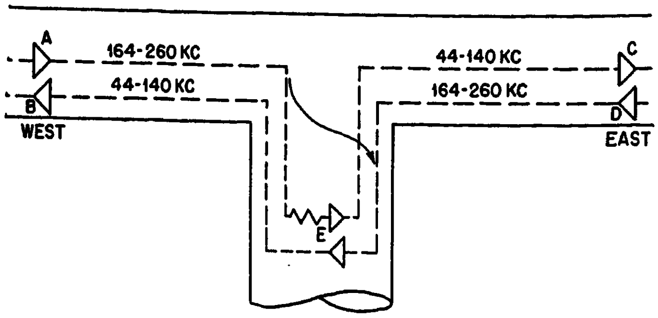

Fig. 4. Crosstalk in lateral cables

It is possible to operate a large number of *N1* carrier systems in most of the cables now in telephone plant. In quadded cables it is expected that carrier may be operated on substantially every quad. In nonquadded cables, where the coupling losses are somewhat lower, crosstalk poses more of a problem. Anticipating this, the thermal noise generator was provided in each transmitting group unit. However, as previously noted, it has not yet been necessary to introduce this crosstalk masking noise.

CROSSTALK DESIGN OBJECTIVE

The Bell System has developed a system for rating performance as controlled by crosstalk which takes into account the distribution of talker volumes at the originating toll switchboard, the number of disturbing circuits, the rms value of the current ratios in each group of similar crosstalk couplings, and the masking effect of various types of noise, including babble or the crosstalk from multiple disturbers. The crosstalk couplings between the combinations of quads or pairs in a cable vary over a considerable range. It is evident therefore that, if a limited number of the conductors in a cable is employed for carrier operation, the probability of hearing crosstalk from other systems is reduced. Without elaborating further on the fine points of crosstalk index, as this criterion of performance is known, we may note that good performance will be achieved if the coupling loss between the toll switchboard at the transmitting end of a disturbing circuit and the toll switchboard at the receiving end of the disturbed circuit is about 35 db. This assumes that no noise is present on the disturbed circuit. With the masking noise, comparable performance will be realized with a coupling loss of about 30 db.

Crosstalk Advantage of the Compandor

The expandor at the receiving terminal of the *N1* channel introduces a loss of 28 db as long as the total side-band power at its input is below the level at which the expandor begins to open up. This is always true in the case of the crosstalk encountered in commercial practice. The 28-db loss effectively attenuates the crosstalk during the silent interval when it is most objectionable. If the disturbing circuit is not compandored we may take full credit for this attenuation, but if it is equipped with a compandor we must recognize the effect of its compressor on raising the average talker volume at the transmitting terminal. Under present-day conditions, the *N1* compressor increases the crosstalk potentialities by about 7 db and hence the net compandor advantage for crosstalk between *N1* systems is 28–7, or 21 db.

Transverse Far-end Crosstalk

Fig. 3 shows the path of transverse crosstalk in which *AB* is the disturbing circuit and *CD* is the disturbed circuit. Since the crosstalk loss per unit length varies inversely with frequency, it is evident that the coupling loss between *AB* and *CD* will be less in the first repeater section than in the second. It may also be noted that in the first section the crosstalk loss for channel 12 using a 256-kc carrier will be less than for channel 1, which uses a 168-kc carrier. However, in the second repeater section channel 12 operates on a 48-kc carrier at which frequency the coupling loss is greater than for channel 1 with its carrier at 136 kc. It has been found that with an even number of repeater sections the amount of far-end crosstalk is substantially the same on all channels and that the coupling loss is about the same as would apply between channels using a carrier frequency of 165 kc in every repeater section. Since the far-end coupling loss versus frequency characteristic for cable pairs is usually free of peaks and valleys, it is possible to estimate crosstalk for all channels on the basis of 165-kc couplings.

The coupling losses between pairs in the same quad are relatively low unless intraquad balancing is employed. However, by utilizing the two pairs of a quad for the same *N1* system, the effect of this low coupling loss is not significant since different bands of frequencies are transmitted over the two pairs. The coupling loss between equal level points on the pairs in different quads is considerably higher, the rms loss being in the order of 75 db per mile at 165 kc, and the 1 per cent minimum roughly 10 db less. These losses may vary ±5 db depending upon the size of cable and type of construction, (that is, long-pair twist or short-pair twist) but are typical of present-day cables in the 30-quad size. With couplings such as this, the transverse crosstalk in quadded cables is not serious even on systems up to 200 miles or more in length, and no cable balancing is required. When placing new quadded cables primarily for *N1* carrier use certain splicing precautions may pay dividends in lower crosstalk, particularly when the cable is of small size. This effect of splicing will be discussed later.

The situation with nonquadded cables is different, particularly in the case of older types in which the same length of pair twist was used for all pairs in the cable. For example, the rms losses in nonstaggered twist cables run about 55 db per mile at 165 kc. With improved manufacturing methods and more rates of twist, it has been possible to raise the rms coupling loss in a present-day 25- or 26-pair unit of pulp-insulated 19-gauge cable to about 68 db per mile at 165 kc with the rms coupling loss between units about 9 db higher. Even better performance has been achieved in some experimental cables utilizing polyethylene insulation and ten different rates of pair twist.

Control of Transverse Crosstalk

When *N1* systems are placed in existing quadded cables, little is done other than to remove any loading that is present on the carrier pairs and whatever voice frequency crosstalk balancing capacitors have been installed in the loading splices. The crosstalk balancing units in other splices are removed only if the cable is opened for some other reason. Building-out stubs which were placed to provide uniform loading section length are removed since these no longer serve a useful purpose and may introduce considerable crosstalk.

When new quadded cables are placed for *N1* use they are frequently of small size since even a 27-quad cable is capable of providing 300 message channels if fully developed for carrier use. As the size of a cable is reduced, it is obvious that the chance for any two quads to occupy adjacent positions is increased. The coupling between adjacent quads is much greater than between alternate or more widely separated quads so the rms coupling loss decreases with size. To achieve the least crosstalk, therefore, it is desirable to splice the cable so as to equalize as nearly as possible the number of adjacencies between all *N1* carrier quads. Rather than leave the splicing plan entirely in the hands of chance, splices in small cables are sometimes planned using the so-called number-splicing technique. This procedure insures as thorough a mixing of the quads at each splice as is theoretically possible. With larger cables, simplified random splicing techniques are generally adequate.

More care is desirable when engineering carrier on nonquadded cables, since the over-all coupling losses are somewhat lower than in quadded cables and the couplings vary over a wider range. If the cables are in place, the amount of crosstalk is estimated, taking into account the length and coupling loss in each cable section and the number of possible disturbing channels. Should the expected performance fail to meet the desired objective, the use of cables with higher coupling losses is the first consideration. If this is not feasible, it is possible to select pairs in each repeater section so as

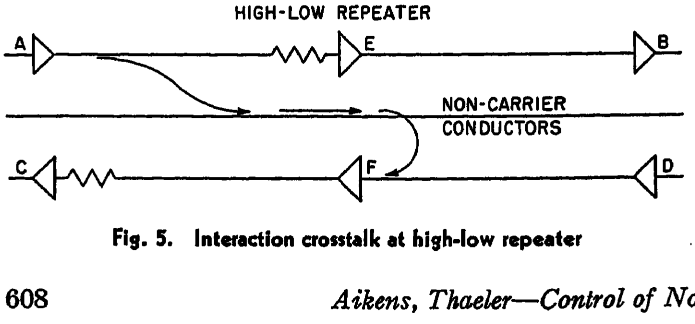

Fig. 5. Interaction crosstalk at high-low repeater

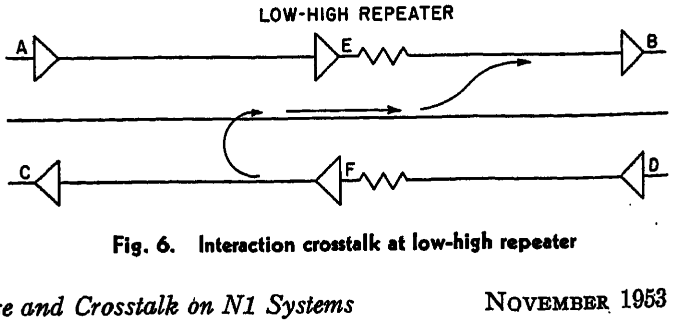

Fig. 6. Interaction crosstalk at low-high repeater

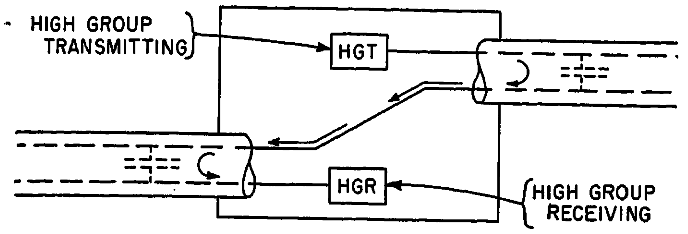

Fig. 7. Interaction crosstalk at terminal

to minimize the effects of bad coupling. This is accomplished by assigning to the same frequency group only those pairs between which the coupling losses are relatively high. In some cables there may be a few bad actors which do not lend themselves even to this treatment, and they must therefore be discarded from carrier use. The possibilities for improving performance by pair selection are great but so are the costs of the coupling measurements. Practical application of the technique is therefore expected to be rather limited.

When placing new nonquadded cables, the approach is similar to that for existing cables except for the opportunity to increase the coupling loss by controlling the splicing.

CROSSTALK IN LATERAL CABLES

Fig. 4 illustrates a situation where it has been desirable to locate a high-low repeater at the end of a lateral cable. The repeater section to the west has been assumed to require the use of a pad at the input to the repeater at *E*. The repeater section to the east requires no such pad and there is, therefore, in the lateral cable a level difference between pairs in the same frequency group. If the level difference at 256 kc is greater than about 27 db with a lateral cable length of about 200 feet, the resulting near-end crosstalk from *A* to *B* may add significantly to the crosstalk already present at terminal *B*. The remedy is to reduce the level difference in the lateral cable either by equalizing the length of the repeater sections or by moving part or all of the span pad from the input of the repeater at *E* to the output of the repeater at *A*.

As the length of the branch cable is increased, the coupling loss is decreased and the corresponding level difference at 256 kc must be reduced. When more than one lateral cable is used on the same system, it is necessary to evaluate the effects of all such cables in contributing to the near-end crosstalk.

Consideration of lateral cable crosstalk between low-frequency groups is not generally required since the coupling losses in the cable are higher. At low-high repeaters, however, differences in high-frequency levels because of the use of pads at the repeater outputs are subject to the same restrictions as just outlined.

INTERACTION CROSSTALK AT A REPEATER

Fig. 5 shows the interaction crosstalk path at a repeater by way of paralleling noncarrier conductors. If the length of the repeater section from *A* to *E* is shorter than from *D* to *F*, requiring the use of span pads as shown, there will be a level difference between channels operating at the same carrier frequency. When the 256-kc level difference at a single repeater exceeds about 27 db, the amount of crosstalk through the interaction path represented by the arrows may contribute significantly to the crosstalk at *C*. Again, since the loss in this coupling path is higher at the low frequencies, the interaction crosstalk is not generally a problem at low-high repeaters.

This type of interaction crosstalk may occur wherever successive repeater sections differ in length. It is necessary, therefore, to be sure that the combined crosstalk from all high-low repeaters does not become excessive. In general this will be the case if the 256-kc level difference between the inputs from east and west at each high-low repeater is limited to 16 db or less.

Occasionally it is desired to place a span pad or artificial line at the output of a low-high repeater as shown at *E* in Fig. 6. Since the levels at the repeater outputs are the same, the level on the cable pair at the output of the repeater at *F* will be higher than on the pair at the output of the pad at *E*. Again there is an interaction path through the noncarrier pairs, and the same 27-db level difference objective applies.

INTERACTION CROSSTALK AT TERMINALS

At the beginning of the discussion of crosstalk, reference was made to the frequency frogging at each repeater, which facilitates the control of crosstalk between high-level and low-level pairs in the same cable. In most cases, this frequency segregation of high- and low-level signals is also maintained at the carrier system terminals by specifying either "high-group transmitting—low-group receiving" terminals or "low-group transmitting—high-group receiving" terminals in a given office.

There are instances, however, in which the operation of high-group transmitting and high-group receiving terminals in the same office is desired. Fig. 7 illustrates how crosstalk from the high-group transmitting terminal can appear as near-end crosstalk on noncarrier pairs in the same cable, then travel longitudinally through the office to noncarrier pairs in another cable containing *N1* systems using high-group receiving terminals. When there is no equipment on the noncarrier pairs the longitudinal loss of the office wiring may be substantially 0 db. In quadded cables the total coupling loss may be as low as 100 db at 256 kc at which frequency the level difference between the two carrier terminals may be over 60 db.

The longitudinal loss through the office is increased by the presence of repeating coils and voice frequency repeaters on the noncarrier pairs, and also varies with the degree of interconnection between the noncarrier facilities in the two cables. While the metallic circuit and phantom circuit losses may be in the order of 50 to 100 db, the ground return loss will generally be in the order of 10 to 20 db. If the total loss in the interaction path is inadequate, it may be increased by inserting longitudinal suppression coils in the noncarrier pairs. Care must also be taken to insure adequate physical separation of the carrier terminals and the associated wiring. At present it is believed that this will be achieved by using separate, even though adjacent, bays for the two groups of terminals and by separating the wiring by the width of at least one bay.

CONCLUSION

Most of the *N1* carrier noise problems were anticipated in connection with the original development and the engineering of the specific projects. However, in some instances the solutions have been learned from experience, the best teacher of all. *N1* circuits are now operating under conditions considerably more severe than originally expected and the trend will doubtless continue. As for the effectiveness of the control measures, it may be noted that in a recent survey embracing over 4,000 channels, only 8 per cent of the channels exceeded the noise objective and on half the circuits the noise conditions were at least 8 db better than the objective. In a number of cases, certain channels are being kept out of service until one or another of the measures outlined can be applied. As further noise suppression is installed, many of the working channels will also be benefited. The noise survey includes the effect of dial office noise but probably does not fully reflect atmospheric static noise since the measurements were made at random times throughout the year.

No comparable surveys of the amount of crosstalk are available, but discussion with the operating companies, and measurements on some long systems operating in nonquadded cables, indicate that adequate control of crosstalk has also been achieved.

Discussion

W. C. Farrell (Chesapeake and Potomac Telephone Company of Baltimore City, Baltimore, Md.): We should like to commend the authors for the excellent job they have done in preparing and presenting their paper. The points included are both thoroughly and clearly covered. The following comments on the noise aspects of their presentation which may be of value to interested parties are observations that the Toll Transmission Engineering Section of the General Engineering Department of The Chesapeake and Potomac Telephone Company of Baltimore City has made through the experience of applying the *N-1* systems to the telephone plant in Maryland.

It is suggested that the pairs selected for use for *N-1* systems be those which have good longitudinal-to-metallic balance. This characteristic can be evaluated only by measuring the pairs at the system terminals and at intermediate repeater points prior to their assignment. While this is a straightforward process on nonloaded pairs in a new cable, it can become both involved and expensive in cables working at full capacity with loaded voice-frequency circuits.

This latter situation is the one most frequently encountered in practice. It is often necessary to take circuits out of service to permit unloading and rearranging conductors to make them suitable for carrier use. Obviously, in cases of this type, the selection of pairs by measurement may become quite costly and, unless the testing work is carefully performed, the work operations may have serious effects upon service.

Although our experience to date on interference in *N-1* carrier systems from sources external to the telephone plant has been confined to static and radio transmitters, it is the belief of our organization that the possibility of other carrier systems being originators of future trouble should not be overlooked. As in the cases already outlined, the longitudinal path to ground via taps from cables would afford this source an entrance path to the *N-1* cable. This belief is based on the fact that the frequency band utilized for the *N-1* system is also used by right-of-way companies. For instance, the power companies are using frequencies from 7 kc to 245 kc. It seems advisable to keep in mind this fact in laying out new carrier systems or investigating existing interference problems in the telephone plant.

Administration of suppression methods that have not been standardized, and consequently are not included in formal instructions, has proved to be a problem where large numbers of people from various groups have jobs to perform on the *N-1* cables. This has been the case along the Annapolis-Hyattsville route in our territory. We believe that a large part of this is the result of the limited number of suppression units available during the experiments which necessitated leaving taps untreated that were not important offenders, even though they were in a zone known to include the troublesome exposures. As a result, as these locations are visited and changes are made which may affect the interference level, suppression is seldom added. Also the omission of suppression on some taps tempts the man without a background in inductive interference to be lax in observing informal instructions on the subject. We believe, however, that when the new retardation coil is available in sufficient quantities to meet our needs along with instructions for its use, this problem will be alleviated.

Mention was made of a possible stop-gap measure referred to as a slot rejection filter. To date this has not been used in our territory for the reasons stated in the paper. Within recent weeks, an additional anticipated objection to the slot filter was justified. This is simply the fact that there is nothing to prevent the originator of the radio-frequency interference from shifting his frequency.

For this reason, the interference that was formerly on channel 7 of the system in the Annapolis area now appears on channel 10 at a different voice frequency. This obviously means that the investment in the slot filter has been lost. The suppressors, on the other hand, will be effective at the new frequency.

W. F. Potter (New England Telephone and Telegraph Company, Boston, Mass.): In view of the extensive application of *N* carrier systems, this paper, discussing the control of noise and crosstalk in these systems, is important and most timely. It may be of interest to review briefly some specific experiences encountered in the New England area which illustrate various points covered by the paper.

Secondary induction from telephone plant, particularly noise in the carrier frequency range caused by operation of switching equipment, has been a major problem, being particularly severe where high-low repeaters are located in step-by-step dial offices. On one of our first *N* systems where the *N* carrier base circuits to a high-low repeater were in the same nonquadded cable as the dial exchange lines, a severe noise condition was eliminated by removing the *N* pairs from the exchange cable and placing them in the quadded core of a relieving toll cable for a distance of 700 feet from the office.

In another case, involving an 8-mile repeater section to a high-group receiving terminal, 3,000 feet of compartmented entrance cable was installed in which a quadded core for the *N* carrier pairs is shielded from the dial exchange pairs by layers of steel and copper tape. In another case, where the repeater spacing was slightly over 7 miles, segregation for a distance of 1,300 feet at a high-low repeater point was accomplished by providing a cable with a small quadded core to which the *N* pairs were assigned, using the surrounding nonquadded pairs for dial exchange lines and trunks. Because of the shorter repeater spacing, giving higher carrier levels at the input to the high-low repeaters, no shielding was required around the core.

In laying out *N* systems every effort is made to make dial offices low-high repeater points. Where this arrangement is not economically feasible, repeater spacings adjacent to high-low repeaters have been shortened.

On Cape Cod, two *N-1* systems were installed between Hyannis and Provincetown, a distance of about 50 miles. This cable has about 1,000 drop wires and 400 open-wire leads between these two points. Three channels in each system were adversely affected by the signals from three different radio stations. Suppression of the open-wire and drop-wire leads was not felt to be practicable, and other mitigative measures were sought.

One of these radio stations, approximately 30 miles from Hyannis, and operating on 194 kc with 1,000-cycle tone telegraph signals, interfered with channel 4 of each system. A steady tone of 2,000 cycles was received on channel 4 as a result of beating of the 194-kc carrier of the radio station with the channel frequency of 192 kc. In addition, the telegraph signal at 1,000 cycles was also present on the channel but at a much lower level. By inserting a 2,000-cycle slot filter in the voice-frequency path from the carrier channel to the switchboard at each end of the circuit, the following results were obtained.

On one system at Hyannis the over-all noise without suppression was 55 decibels adjusted (dba) at the zero level point. With the 2,000-cycle slot filter this was reduced to 34 dba. The 1,000-cycle tone was reduced from 39 to 33 dba. The 2,000-cycle noise without suppression was 54 dba. With the 2,000-cycle slot filter this was reduced to a negligible value which could not be measured. Similar results were obtained on the second system at Hyannis and on both systems at the Provincetown end.

A second radio station about halfway between the ends of the carrier systems operating on 406 kc, with continuous-wave code transmission, interfered with channel 5 of each system. Since this frequency lies outside the channel frequencies, a different approach was used to mitigate the noise conditions. The 406-kc radio carrier beating with the 304-kc oscillator in the high-low repeaters produced telegraph code signals at 2 kc. Trial insertion of a 2-kc slot filter at the Hyannis switchboard reduced the 2,000-cycle code signal from 77 dba to 48 dba. This value of 48 dba was not of course satisfactory, so a radio frequency filter tuned to 406 kc consisting of two antiresonant series elements and a shunt series-resonant element with the midpoint grounded, was tried at a high-low repeater.

This was not effective until the filter was isolated from the line by longitudinal chokes at the input and carrier frequency repeating coils at the input and output of the filter. The simplexed d-c path supplying power to the repeater was by-passed around this filter through a retard coil.

This filter arrangement was used at the two high-low repeater points nearest the radio station, and the following results were obtained at the switchboards.

At Hyannis, without the filter, the noise was 75 dba on both systems. This filter reduced the noise to 25 dba on one system and to 12 dba on the other. At Provincetown, noise of 64 dba on both systems was reduced to 31 dba on one system and to 32 dba on the other.

The third radio station transmitting on 137 kc produced a telegraph code signal of 1,000 cycles on channel 1 of each system, the frequency of channel 1 being 136 kc. No suppression of this interference was attempted with slot filters because of the high level of the code interference with only 30-decibel suppression expected from the slot filter.

The interference to channel 1 and channel 5 has now been eliminated by a change in the transmitting frequency of the two radio stations. The 137-kc transmitter was changed to 147.5 kc which is 7.5 kc above the channel 1 frequency band. Channel 5 is no longer affected by radio interference, since the 406-kc radio station has been changed to 436 kc, and the beat frequency with the 304-kc oscillator now lies between channel 1 and channel 2.

The recently developed optional channel 13 operating at 40 kc and 264 kc will be substituted for channel 4 on all systems in this area so that we will be able to operate all 12 channels of all systems without radio interference.

Crosstalk has not been a problem on any *N-1* systems in the New England company's area.

One problem yet to be solved is that of impulse noise of a few milliseconds' duration, which, although of such short duration and low amplitude as not to interfere with speech transmission, is of such a character as to interfere with carrier telegraph systems and some subscriber special service lines.

A-C Null-Type Recorder with Balancing Amplifier Which Provides Damping and Suppresses the Quadrature Component

A. J. WILLIAMS, JR.

J. F. PAYNE, JR.
ASSOCIATE MEMBER AIEE

ELECTROLYTIC conductivity is a good example of a measurement which can be made most satisfactorily by using an a-c null-type instrument. The use of alternating current instead of direct current reduces polarization at the electrodes. The use of a null-type recorder permits the measurement of conductivity directly by means of a Wheatstone bridge, thus avoiding the need for voltage regulation. This paper describes difficulties encountered when an unimproved electronic balancing amplifier is tried for this type of instrument. Theory and performance of an improved amplifier are given.

Electrolytic conductivity measurements are widely used in industry to determine chemical concentration. This measurement of concentration may be used to control the product strength (as in the production of sulphuric acid) or to determine the leakage or carry over of a solution of one concentration into a solution of different concentration (as in the contamination of condensed steam from a steam turbine).

Fig. 1 shows a Wheatstone bridge arranged for the measurement of electrolytic conductivity. If the filled electrolytic conductivity cell behaves as a pure resistance R, the bridge may be completely balanced by adjustment of the opposite arm R_1. The bridge equations show that

$$1/R = R_1\frac{1}{R_2R_3}$$

hence the conductance of the cell $1/R$ is directly proportional to R_1.

Actually a filled electrolytic conductivity cell may not behave as a pure resistance, and its equivalent circuit may include a series capacitive reactance, as shown in Fig. 2. In this case, adjustment of R_1 cannot completely balance the bridge and the phasor diagram of Fig. 2 is an attempt to explain this pictorially. The voltage remaining across the detector E_{ab} has a phase in quadrature with the desired component of detector voltage. The desired component is that component of detector voltage produced by a change in electrolytic conductivity.

This quadrature component does not interfere with the balancing of a-c null-type recorders of the form which use an a-c galvanometer and a mechanical balancing system. For this form of recorder the field of the a-c galvanometer is phased so that the quadrature voltage produces a torque on the moving coil which averages to zero.[1,2] Otherwise stated, the effect of the quadrature component is suppressed.

In 1933, a d-c null-type recorder was produced commercially, in which a reversing motor and an electronic balancing amplifier was used.[3,4] Through the years the electronic balancing system has been simplified[5] and refined[6] but when modified for a-c measurement its performance has been inferior to that of the a-c galvanometer and the mechanical balancing system, when used where a quadrature component of bridge output exists, as in the measurement of electrolytic conductivity. An electronic balancing amplifier which is improved to be free of this inferiority is the basis for this paper.

The idea for the improved amplifier evolved from a study of difficulties with the unimproved electronic balancing amplifier, and from a comparison with the galvanometer form of balancing system. The latter system suppresses the quadrature component prior to amplification, whereas the unimproved electronic system amplifies the quadrature component and relies upon its suppression by the characteristics of the 2-phase balancing motor at the amplifier output. This motor has no rotating field and hence no starting torque, if the voltage applied to the amplifier winding is in time phase with the voltage applied to the other winding normally energized from the line. In practice, two difficulties are encountered:

1. Because of the change in characteristics of the several tubes and other elements in the amplifier with time, temperature, signal

Paper 53-244, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 17, 1953; made available for printing April 16, 1953.

A. J. WILLIAMS, JR., and J. F. PAYNE, JR., are with the Leeds and Northrup Company, Philadelphia, Pa.

The dual vibrator was developed by R. E. Tarpley and W. H. Packer. Experimental work during the early stages of the amplifier development was done by W. R. Clark and the late F. F. Dern, Jr.

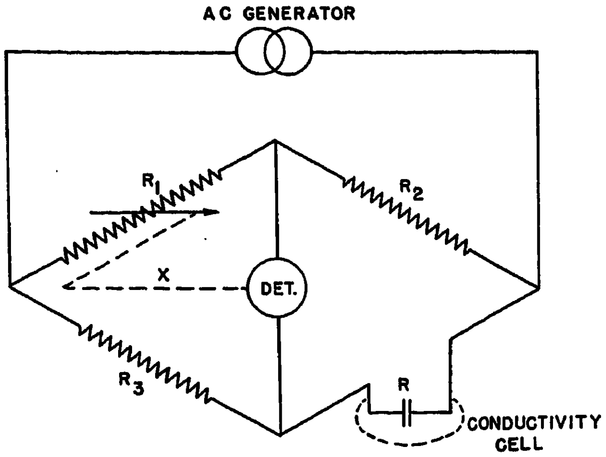

Fig. 1. Wheatstone bridge for the measurement of electrolytic conductivity

If the bridge is completely balanced by adjustment of R_1, its value is then a measure of the conductance $1/R$, since R_2 and R_3 are held constant

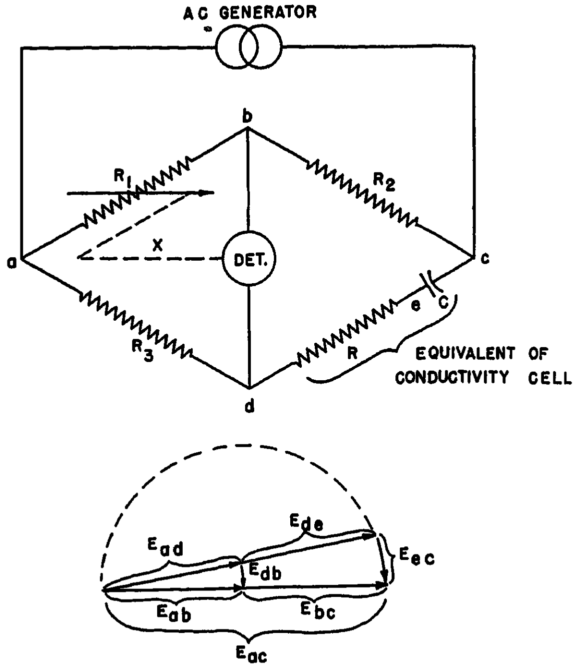
$$\frac{R_3}{R_1}=\frac{R}{R_2}$$

$$R_2R_3=RR_1$$

$$1/R=R_1\frac{1}{R_2R_3}$$

Fig. 2. Source of quadrature component

The equivalent circuit of an actual filled electrolytic conductivity cell may include a series capacitive reactance; hence adjustment of R_1 cannot completely balance the bridge. The voltage remaining across the detector has a phase in quadrature with the component which would be produced by a change in electrolytic conductivity



amplitude, and line voltage, the quadrature component generally applies a voltage to the motor which is not in phase with the voltage applied from the line. A torque results which can only be balanced by a shift of the slidewire and pen away from the correct position. The recorder reading is thus in error.

2. Because it is amplified, the quadrature component causes useless heating in the motor, and loads the later stages of the amplifier so that the desired signal finds an amplifier with reduced power-handling capacity and with modified gain. The result is generally a slower and less sensitive recorder.

The idea for improving the balancing amplifier was basically to suppress the quadrature component prior to amplification.

Systems analogous to the a-c galvanometer were considered. In the a-c galvanometer, the quadrature component produces a torque of double frequency but its average value is zero.[3] The mechanical filtering action of the system suppresses the effect of the double-frequency torque. Analogous systems may be nonmechanical, but they still require a filter (which may also be nonmechanical) to suppress the double-frequency effect resulting from the quadrature component. Filtering introduces delay, which is undesirable in a balancing amplifier for a fast recorder, hence all systems analogous to the a-c galvanometer were classified as undesirable.

The virtue of the a-c galvanometer seems to reside in the single-valued nature of its output. To be more exact, it is the single-valued nature of the output from the periodic pointer-sensing mechanism[7,8] on the galvanometer. Even if there is a quadrature component and even if the magnetic field is not phased to bring the average resulting torque to zero, there is still only one value of output. Therefore the mechanical balancing system has only one input which, by balancing the slidewire, it can reduce to zero or nearly to zero.

In the improved electronic balancing amplifier, the input to the first stage tube is reduced to a single valued function by sampling the unbalance at preferred times on each cycle. The preferred times are at the maximum and minimum of the desired component, and hence at the zeros of the quadrature component. When successive samples are equal, no signal is fed into the first stage tube. When they are unequal, an a-c voltage is fed into the first stage, the polarity of this voltage indicating the sense of the unbalance.

Fig. 3 shows the arrangement of circuit elements used to accomplish this result. The bridge to be balanced is at the left, and at the right is the first stage of the amplifier whose output feeds one winding of a 2-phase motor (not shown) which can drive the slidewire R_1 toward the balance point. The moving contact on R_1 carries along with it a pen for recording (not shown).

The bridge output is sampled by disconnecting capacitor C_{t1} from the bridge by the break of connection between con-

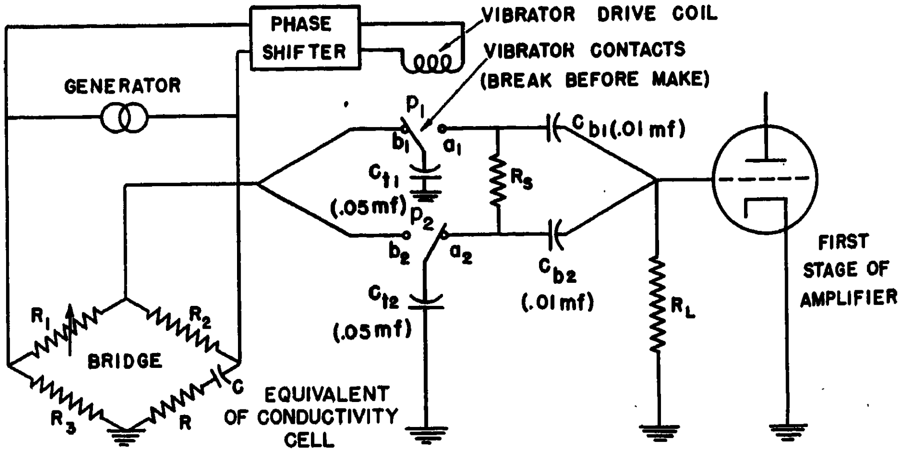


Fig. 3. Simplified circuit

C_{t1} and C_{t2} sample the bridge output at the instant of contact break, thus giving a single valued input to first stage of amplifier. The phase shifter is set to suppress quadrature component. C_{b1}, C_{b2}, R_L and R_S provide damping

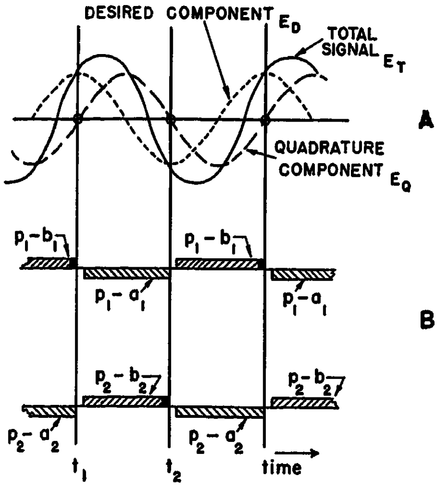

Fig. 4. Timing of contacts

The upper part of the figure shows the total signal and the two components into which it may be resolved

The critical contact times are at t_1 when p_1-b_1 opens, and at t_2 when p_2-b_2 opens. t_1 and t_2 are at the zeros of the quadrature component

tacts p_1 and b_1. These contacts are parts of a switch driven in synchronism with the bridge supply, marked generator in Fig. 3. The phase shifter is set so that the break occurs when the quadrature component of voltage is passing through zero. Shortly after this break, connection is made between contact p_1 and contact a_1. The sample of voltage, retained by capacitor C_{t1}, is impressed upon the amplifier input through capacitor C_{b1}. After the completion of a half cycle, the bridge output is again sampled, this time by disconnecting capacitor C_{t2} by a break between the contacts p_2 and b_2. These contacts had made connection at or about the same time that p_1 made connection with a_1. Since just 1/2 cycle was allowed to elapse, the second sample is taken when the quadrature component of voltage is again passing through zero.

This sequence of events is presented pictorially in Fig. 4. Time is the abscissa, with later times toward the right. The shaded areas at the bottom of the figure indicate contact connections as labeled. The critical times (emphasized with short heavy lines) are when p_1—b_1 opens at time t_1 and when p_2—b_2 opens at time t_2. Preferably, these openings should occur as the quadrature component passes through zero (emphasized by small circles), and Fig. 4 is so drawn. (The total signal will generally contain both components, the desired component and the quadrature component). This sampling technique passes along a signal in which the desired component is enhanced (since the sampling is taken at its peaks) and in which the quadrature component is suppressed (since the sample is taken at its zeros).

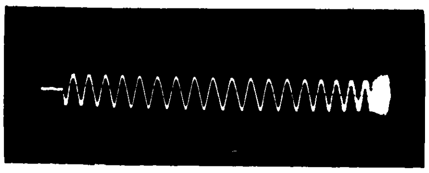

Fig. 5. Input signal to balancing amplifier

This is a cathode-ray oscillogram of a 60-cycle-per-second signal, manually initiated about 4 cycles after manually triggering the single sweep

Demonstration of Quadrature Suppression

The suppression of the quadrature component can also be presented pictorially by cathode-ray oscillograms made with a balancing amplifier including the circuit of Fig. 3. For experimental purposes, the bridge of Fig. 3 was replaced by a simple resistive voltage divider and a manually operated key was added, so the signal to the amplifier could be abruptly initiated. A cathode-ray oscillograph, arranged with d-c amplification, a manually triggered sweep, and a camera, was connected across the input to the balancing amplifier. The two manual operations were coordinated into a single manually operated tap key, so that the sweep was started when the moving arm left its top position and the signal was initiated when the arm arrived at its bottom position. Fig. 5 is the oscillogram. There is no significant signal for a time corresponding to about 4 cycles; then the 60-cycle signal starts abruptly and continues at constant amplitude. The wave length is constant until the spot slows down near to the right hand limit of its travel. This is the type of signal used for the input to the balancing amplifier for the several oscillograms which follow.

Fig. 6 is intended to show the effectiveness of quadrature suppression. To the improved balancing amplifier, including the sampling circuit of Fig. 3, there was applied an input signal of the form shown in Fig. 5. The four oscillograms were all taken at the grid of the output tube of the amplifier. The input signal for all four oscillograms had the same amplitude, but its phase was 90, 30, 10, and 3 degrees, from quadrature, reading from the top trace down. The successive reduction in amplitude from the top oscillogram down shows that the signal amplitude (at this point in the amplifier) approaches zero as the phase of the amplifier input approaches true quadrature. At true quadrature, the zeros of the input signal voltage occur just as the samples are taken, as shown in Fig. 4.

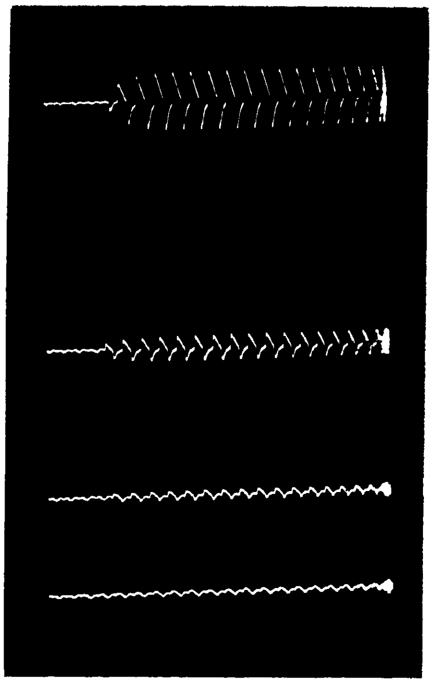

Fig. 6. Quadrature suppression

The input to the amplifier had the same amplitude for all four oscillograms. Its phase was 90, 30, 10, and 3 degrees, reading from the top trace down. The oscillograms (taken at the grid of the output tube of the amplifier) show that the signal amplitude approaches zero as the phase of the input approaches quadrature

Damping

The effectiveness of quadrature suppression is independent of the values of the circuit elements C_{t1}, C_{t2}, C_{b1}, C_{b2}, R_S, and R_L, shown in Fig. 3. For simplicity, the oscillograms of Fig. 6 were made with R_S at zero ohms. This parallels C_{b1} and C_{b2}, so a single capacitor could have been used. The oscillograms would have been essentially the same if C_{b1} and C_{b2} had been short circuited and R_L had been open circuited. In brief, the circuit elements between the synchronous switch and the first-stage tube are not needed for quadrature suppression.

Fig. 7 shows the response of the recorder to an abrupt change of input with the balancing amplifier improved only for quadrature suppression. The top record made on a fast moving chart shows overshoot and oscillation. Although overshoot is tolerable on many feedback-control systems, it is intolerable on recorders because it may erroneously be interpreted as overshoot of the measured quantity, especially with a slow chart as shown at the bottom of Fig. 7. Alarms might erroneously be triggered regardless of

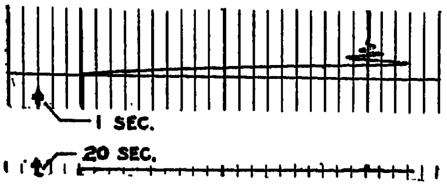

Fig. 7. Underdamped recorder

A fast chart was used for the top record to show overshoot and oscillation. With a slow chart, as in the bottom record, the overshoot of the recorder might erroneously be interpreted as overshoot of the measured quantity, $R_S=0$, $R_L=1$ megohm. Each division is 1 per cent of full scale

chart speed, because of overshoot. For Fig. 7 the circuit values (not already given in the circuit of Fig. 3) were $R_S=0$ and $R_L=1$ megohm. These were the values used for the oscillograms of Fig. 6.

A study of Fig. 6 by someone skilled in the art of feedback-control systems would lead to the prediction of overshoot, since there is nothing in the amplifier characteristic to offset the adverse effect of inertia in the balancing motor.

The circuit of Fig. 3 was devised to give to the balancing amplifier a characteristic which provides damping for the recorder. With R_S infinite (and R_L still 1 megohm) the response of the amplifier at the grid of the power tube is shown in Fig. 8. The input to the amplifier was a modulated step input, as already shown on Fig. 5. The response has an abrupt rise and then decays rapidly toward zero, the time constant (of the envelope) being about $1^1/_2$ cycles or 0.025 second.

In evaluating this response, the ideal response for pure "rate action" should be considered. Since the change in input is a step, its rate initially is infinite but of infinitesimal duration; in brief, it is an impulse of finite value. A measure of the amount of the actual response may be taken as its area; for Fig. 8 this is finite, as it should be. A measure of the quality of the actual response may be taken as its compactness in time, or more exactly the reciprocal of its time constant when the form (of the envelope) is that of Fig. 8.

The form of the response may be explained by referring to Fig. 3. When C_{t1} first connects to C_{b1}, the voltage of C_{t1} is impressed upon the first-stage grid. Immediately, current flows through R_L and C_{t1} developing a voltage across C_{b1} and thus reducing the voltage on the grid. The same action takes place between C_{t2}, C_{b2}, and R_L. The action is cumulative, since there is no way for the charge to leak off of C_{b1} or C_{b2}. As the voltage of C_{b1} approaches that transferred by C_{t1}, the signal to the first grid diminishes toward zero. The time constant of C_{b1} and R_L is 0.01 second, but since charging takes place slightly less than half the time, the effective time constant may be slightly over 0.02 second. This is close to the observed time constant of 0.025 second.

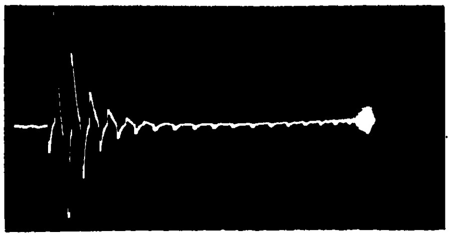

Fig. 8. Amplifier with damping only

In response to a modulated step input, the balancing amplifier gives an output which rises abruptly and then decays to zero, when R_S is infinite

An amplifier with the response of Fig. 8 would have no sensitivity to bridge unbalance and hence would not be generally useful. Fig. 9 shows the amplifier response when $R_S=33$ megohms and $R_L=1$ megohm. The final or steady-state response is not zero but about 20 per cent of the maximum value; hence, the amplifier is useful for balancing a null-type recorder. The damping characteristic is retained, as indicated by the large amplitude in the early part of the response.

The steady-state amplitude is explained by the discharge path through R_S of the capacitors C_{b1} and C_{b2} in series. Even in the steady state, they cannot be charged to the voltage on C_{t1} (and C_{t2}), and hence a voltage equal to the difference is transmitted to the grid of the first stage.

A balancing amplifier with the response of Fig. 9 gives a recorder response as shown at the top of Fig. 10. Overshoot is prevented and there is no oscillation. Balance is not completed in minimum time, since faster balancing is shown at the bottom of Fig. 10, for which R_S was 22 megohms. The amplifier response for this condition was taken but is not shown, since it is very similar to Fig. 9, the steady state amplitude being about 30 per cent of the peak amplitude.

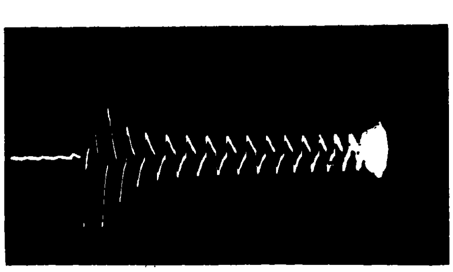

Fig. 9. Amplifier with damping and with sensitivity

In response to a modulated step input, the balancing amplifier gives an output which rises abruptly and then decays to about 20 per cent of the maximum value, when $R_S=33$ megohms and $R_L=1$ megohm

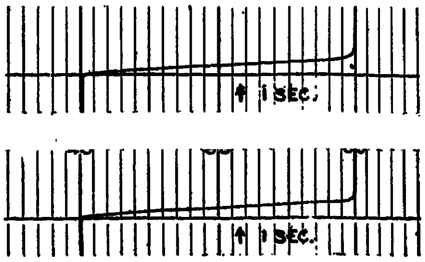

Fig. 10. Damped recorder

With $R_S=33$ megohms, overshoot is prevented but balance is not completed in minimum time, as shown in the top record. With $R_S=22$ megohms, balancing is faster, as shown in the bottom record. Each division is 1 per cent of full scale

When R_L is increased to 4 megohms and R_S is put back at 33 megohms, the steady-state amplitude is about 35 per cent of the peak amplitude and the quality of the damping has been reduced as expected. The recorder with this amplifier does not overshoot but there is a greater tendency toward oscillation, apparently because of the reduced quality of the damping.

GENERAL

The appearance of the recorder is very similar to that of a recorder shown in a previous paper[5]; hence, there is no need for a picture. Fig. 11 shows the balancing amplifier, the appearance of which is essentially the same as that of the balancing amplifier used for the d-c null-type recorder.[6] The rectangular plate at the left covers the hole used by the capacitor for the input filter of the d-c amplifier.[6] The dual vibrator which makes possible the improved performance is shown with its cylindrical case in Fig. 11, and without its case in Fig. 12. It is designed so that the extra mechanical load imposed by the extra set of contacts does not result in poor timing.

Besides electrolytic conductivity, there are other measurements which can be made advantageously with an a-c null-type recorder with the improved balancing amplifier. Power-line frequency measurement by means of a Wheatstone bridge using fixed capacitors, fixed resistors, and variable resistors[9] is one example. Another example is the measurement of the position of a magnetic core in relation to a coil. This device, sometimes referred to as a differential transformer, has found use in the measurement of level, pressure,[10] flow, etc.

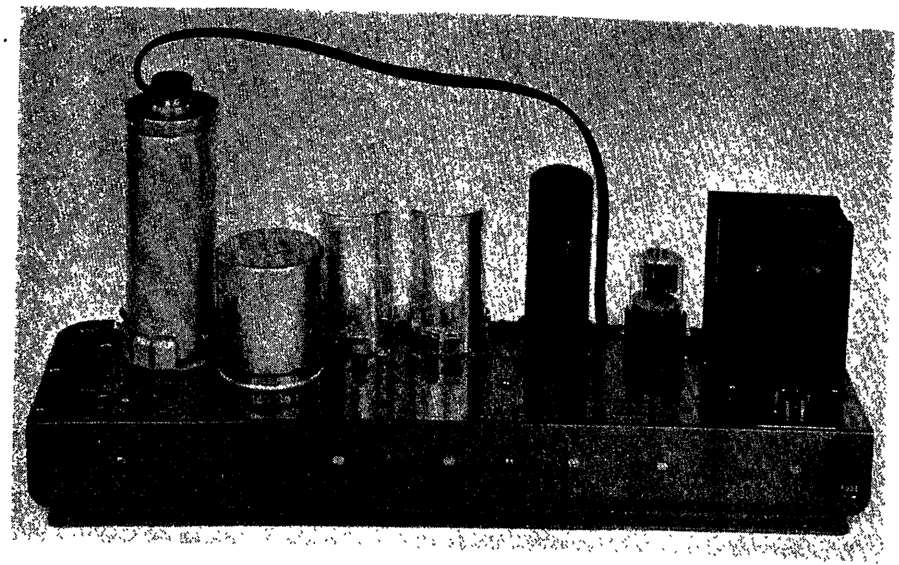

Fig. 11. Balancing amplifier

Appearance resembles that of the more commonly used balancing amplifier for d-c null-type recorder. The vibrator (converter) used for sampling receives its driving power through the cord connection at its top

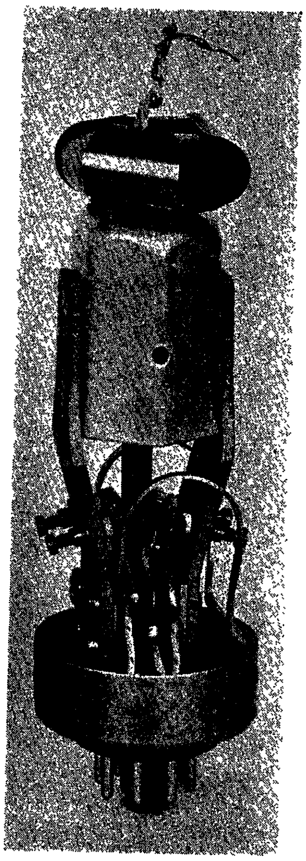

Fig. 12. Dual vibrator

The case has been removed to show the arrangement of contacts and the four adjusting screws. Only three of the six connecting wires show in this view

Although the simple theory for these circuits indicates that the voltage across the detector can be reduced to zero at balance, actual experience shows that there is generally a residual voltage which cannot be eliminated by adjustment of the circuit elements under the control of the balancing system. One component of this residual voltage is the quadrature component, already mentioned in connection with the electrolytic conductivity recorder. A second such component is direct current, but this feeds no signal to the first-stage tube, since successive samples are equal. For the same reason all even harmonics are suppressed regardless of phase. Odd harmonics are suppressed if they have zeros at the sampling times. If odd harmonics are present and their zeros are not at the sampling times, a signal is sent which runs the balancing motor until successive samples are equal, and the input to the first stage is again reduced essentially to zero.

Summary

An attempt has been made to describe the need for and the means used to achieve improvements in the electronic balancing amplifier for the a-c null-type recorder, as applied to difficult measuring problems such as electrolytic conductivity.

By the use of a sampling technique, involving a vibrator type of synchronous switch, the quadrature component of bridge unbalance is suppressed along with other undesired components. The sampling technique is effective because of the single valued nature of the derived output.

Recorder damping is accomplished by an unconventional use of resistive and capacitive elements in conjunction with the switching action of the vibrator.

Response curves, experimentally obtained, are given for the balancing amplifier alone and for the complete recorder. The curves are an attempt to explain pictorially the damping action, as well as quadrature suppression.

◆

Discussion

Thomas J. Higgins (University of Wisconsin, Madison, Wis.): This well-written and well-integrated paper comprises an excellent account of the difficulties besetting solution of the particular problem in a-c measurements outlined therein and of the means employed for solving it. The use of appropriate sampling to eliminate, in the large, the undesired quadrature component is an ingenious approach to obviation of this "intruding" component. In the discusser's opinion, this paper encompasses a very useful and widely applicable contribution to the domain of a-c measurement techniques.

William G. Amey (Leeds and Northrup Company, Philadelphia, Pa.): Phase discrimination usually is obtained by means of a modulation process which converts the input signal of fundamental frequency into an output signal containing two or more frequency components. If the modulation process is suitable, the amplitude of at least one of those components is determined by

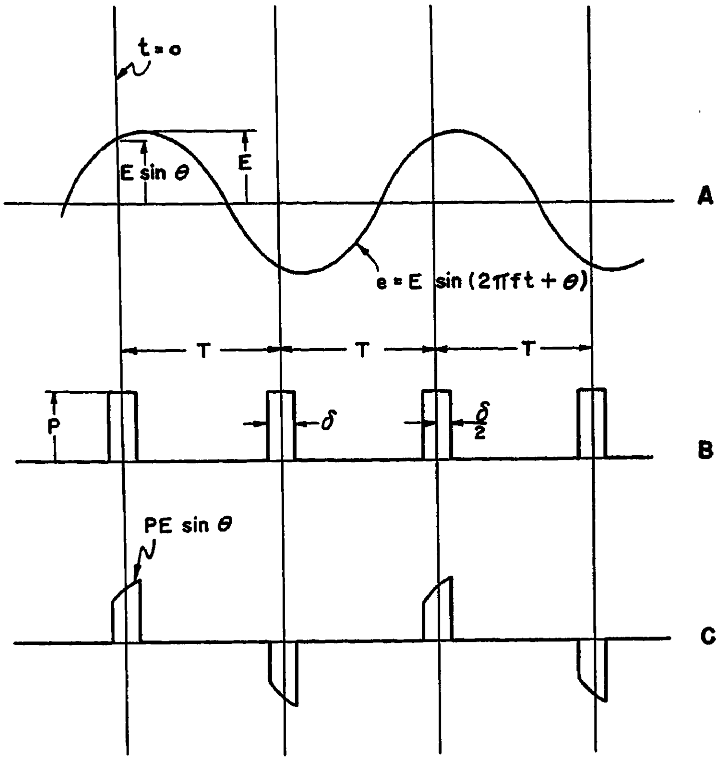

Fig. 13. Simple pulse sampling for phase discrimination

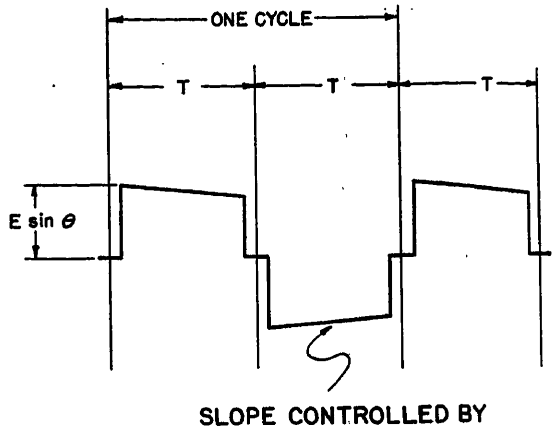

Fig. 14. Amplifier grid voltage resulting from the use of sampling capacitor

Note: Wave shape is independent of signal sampled

the relative phase of the input and modulating signals, and thereby provides phase discrimination. For that purpose, the authors have used an interesting scheme of pulse sampling which avoids one of the shortcomings of most pulse-modulation techniques.

Fig. 13(A) shows a generalized signal component having a phase angle θ, such that the instantaneous magnitude is $E \sin \theta$ at time $t=0$. For purposes of phase discrimination, this component can be modulated by sampling pulses of the type shown in Fig. 13(B) to give a resultant modulated output signal like that of Fig. 13(C).

If the sampling time δ is made sufficiently small compared to the fixed repetition time T (that is, δ/T having a value of 0.01 or less), the resultant output pulses can be considered to be flat-topped with a pulse height of $PE \sin \theta$. The instantaneous values S of this wave form are given quite accurately by the Fourier series

$$S \cong 2EP\frac{\delta}{T}\sin\theta\sum_{k=1}^{\infty}\cos 2\pi(2k-1)ft \qquad (1)$$

where f is the fundamental signal frequency $=1/2T$, and t is the time measured from the time reference.

According to equation 1, this output signal consists of a component of fundamental frequency f, and other components which are odd harmonics of f. All components have the same amplitude, but only the fundamental is useful for the authors' purposes. As expected, the amplitude varies with the relative phase of the sampling pulse and the input signal component. An in-phase component corresponds to $\theta=90$ degrees and gives the maximum signal output, as shown in Fig. 6. As the quadrature condition is approached, θ decreases; at true quadrature, the output is zero and phase discrimination is complete.

Such phase discrimination is purchased, however, at an intolerable price. The quantity E represents the smallest input signal amplitude with which the authors would like to deal. P is the sampling-pulse amplitude, which has a fixed value of unity when the sampling is done by switching, as in this case. Consequently, as δ is reduced to provide better phase discrimination, the useful output signal amplitude decreases proportionately. Some compensation is afforded by the use of an amplifier of higher gain and lower noise level than normal. In general, however, this simple method of sampling leads to excellent phase discrimination, with virtually no output signal to prove it.

Recognizing this difficulty, the authors used a more suitable approach to the problem. Instead of merely connecting the amplifier briefly to the bridge output, they used the energy stored in a sampling capacitor. The capacitor was connected to the bridge until the desired instant for sampling was reached. The capacitance was so related to the bridge impedance that the capacitor voltage followed that of the in-phase component very closely. With exactly the right phasing, the capacitor was disconnected when it was charged to the peak voltage of the in-phase component. This provided excellent phase discrimination, since the sampling time was effectively only that required to disconnect the capacitor from the bridge.

The capacitor, with its charge proportional to the peak value of the in-phase component, was shortly thereafter connected to a network on the input grid of the amplifier. It was left in this connection as long as practicable before being switched back to the bridge connection. A duplicate capacitor and switch were so connected and phased that effective sampling of the other half cycle of the in-phase component was also accomplished. With a suitably high impedance of the grid network, the voltage on the input grid was then approximately that shown in Fig. 14. Fourier analysis of this waveform reveals that the desirable fundamental component has essentially the same magnitude as the original in-phase signal component which was sampled. The reason is that the energy stored in the intermediate sampling capacitor is made available to spread the short-duration pulses of Fig. 13(C) into those of longer duration in Fig. 14.

This desirable result is obtained at the cost of somewhat greater loading of the bridge by the sampling capacitor than would have been true in the simple sampling arrangement first discussed. There appears to be no adequate means of compensating the difficulties of the simple scheme, however, while the effects of the authors' sampling capacitor can be compensated by suitable bridge design or by means of impedance-matching transformers.

George B. Hoadley (North Carolina State College, Raleigh, N. C.): Dr. Amey has emphasized how the authors' use of the two capacitors C_{t1} and C_{t2} has allowed them to use a sampling technique without losing amplitude of the fundamental signal input to the amplifier. I wish to point out that the price paid for this is a reduced input impedance to the amplifier, which comes about because the bridge must supply charging current to the capacitors. This lowered input impedance is not objectionable at all in the use of the amplifier with the conductivity bridge, and the authors are to be congratulated for their ingenuity in developing this system.

A. J. Williams, Jr., and J. F. Payne, Jr.: The authors appreciate the discussion of Professor Higgins. The word "intruding," which he uses with reference to the quadrature component, expresses very well our sentiments concerning this undesired component.

Dr. Amey shows mathematically how the amplitude of the fundamental is reduced by the sampling technique when sampling is accomplished by simply connecting the first stage of the amplifier to the bridge for brief periods during each cycle. Sampling by the use of recurrent but brief periods of connection through a metallic switch was used by Rosa[1] in an instrument for the analysis of recurrent wave forms prior to the development of the cathode-ray oscillograph. This approach was considered for the recorder problem, but was discarded because of the complexity of the vibrator which would be required to provide damping as well as quadrature suppression.

Professor Hoadley points to the loading of the bridge by connection of capacitors C_{t1} and C_{t2} alternately across the bridge output terminals. This is unquestionably true. Two comments appear to be appropriate.

Because the input impedance to the electron tube is high, the value of the capacitors can be small and the input impedance to the amplifier need not be low. It is about 50,000 ohms for the values shown in Fig. 3.

If one or more of the amplifier tubes were moved to a position ahead of the vibrator, a higher impedance would be presented to the bridge. This arrangement would introduce phase shift and the possibility of phase-shift variations which might not be tolerated.

Basic Concepts in the Analysis of Stationary Electric Circuits

D. W. SPENCE
ASSOCIATE MEMBER AIEE

C. R. CAHN
ASSOCIATE MEMBER AIEE

THE NEED FOR and part of the purpose of this paper is demonstrated by the following example: Fig. 1 shows a conducting ring linked by magnetic flux ϕ. Three identical voltmeters are connected symmetrically around the ring as shown. What will be the readings of the voltmeters in terms of the rate of change of the flux $d\phi/dt$ and the ring resistance R?

It is the experience of the authors that many capable and experienced engineers will analyze this device by constructing the incorrect equivalent circuit of Fig. 2. From it they will conclude that the voltages between the nodes are zero and, consequently, that the voltmeters indicate zero. This error is usually due to the engineers not having given sufficient thought to:

1. What—precisely—do they mean by voltage?
2. What—precisely—does a voltmeter indicate about a circuit?
3. How—precisely—does such a circuit work?

Another contributing factor is that the usual electrical engineering fundamentals course, in connection with stationary circuit analysis, is nothing but electrostatics and magnetostatics with Faraday's law tacked on. The analysis of all electromagnetic apparatus operating at any frequency above d-c requires, however, electrodynamic fundamentals, including some field concepts, but avoids dependence on electromagnetic field theory.

Many engineers can, of course, correctly solve the problem of Fig. 1. In most cases this is done by superimposing a supplementary procedure onto their commonly used network analysis. The authors believe, on the other hand, that a circuit theory based on the fundamentals presented in this paper leads directly to the routine solution of all stationary circuits.

The specific objectives of this paper are as follows:

1. To review the circumstances under which a potential function may be defined and the usefulness thereof;
2. To provide definitions of potential difference, electromotance (emf), and what we call the Ri (resistance-current) product, which are of sufficient generality and precision to be useful in near-zone circuit analysis at all frequencies and which differentiate between these quantities;
3. To emphasize the importance of the $q(-\partial \mathbf{A}/\partial t)$ force in electric circuits at all frequencies at which transformer action is significant;
4. To maintain that Kirchhoff's second law is legitimately expressed in two different forms, and to show how and under what circumstances each form is applied.

The present development is restricted to stationary circuits in the near zone.

Conservative and Nonconservative Force Fields

In the analysis of electric circuits, the distribution of currents, the work done, and the energy interchanged in the process of charge flow are of interest. Hence, we are concerned with forces and line integrals of forces and, since most electric forces are experienced through regions of macroscopic dimensions, with fields of force. Of great importance is whether or not a force field or a given component of a force field is conservative. Mathematically speaking, if $\mathbf{f}$ constitutes the force field under consideration, the field is conservative in a given region if and only if

Paper 53-268, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15-19, 1953. Manuscript submitted Jan. 19, 1953; made available for printing April 30, 1953.

D. W. SPENCE is with Syracuse University, Syracuse, N. Y., and C. R. CAHN is with Syracuse University and the Niagara Mohawk Power Corporation, Buffalo, N. Y.

The writers wish to record their appreciation to members of the Electrical Engineering Department, Syracuse University, Syracuse, N. Y., and in particular to Dr. W. R. LePage and Dean R. A. Galbraith, for many discussions over the last 3 years concerning the concepts in this paper.

$$\oint \mathbf{f}\cdot d\mathbf{l}=0 \qquad (1)$$

around any and all conceivable closed paths in the region. If, however, the field is not conservative, a conservative component of the field may be defined; that is, equation 1 is satisfied for the component. Physically speaking, a force field is conservative in a region if a body on which the force acts would experience no net interchange of energy with the field if it were to pass around any arbitrary closed path in the region back to the point from which it started, in negligible time.

For a conservative force field, it is possible to define a scalar potential function, as is commonly done for electrostatic fields. Such potential functions are extremely useful because of two properties they possess:

1. There is a unique potential associated with each point in the region of the field;
2. The potential difference between two points is a measure of the energy interchange associated with motion from one point to the other, by any path whatever, of a body on which the force acts.

For a conservative component of a nonconservative field, it again is possible to define a unique potential function. The corresponding potential difference in general is not a measure of total energy interchange in such a case. If, on the other hand, an attempt were made to define potential difference in terms of the total energy interchange, the "potential difference" between two points in a nonconservative force field would not be independent of path, and the "potentials" would not be unique. In the latter two cases the usefulness of the potential function largely vanishes.

The electrical engineer must consider nonconservative force fields, since a current flowing around a closed path in a conservative electric force field, by definition (equation 1), cannot be the agent for the continuous nonreversing coupling of energy from the force field to a nonelectrical (mechanical, chemical, etc.) system, or vice versa. Hence, any analysis made of the inner workings of an electric energy conversion device, such as a motor, generator, or battery, will be involved with nonconservative fields, and potential concepts may prove to be unsuitable to the analysis.

Let us examine now the forces on the charged particles whose flow constitutes electric current. (The $q(\mathbf{V}\times\mathbf{B})$ force acting when charged particles move around a stationary circuit in a magnetic field are ignored in this discussion, since they necessarily are always normal to the filamentary conductors to be considered and hence are of negligible effect in connection with work and energy.) It is convenient to speak not of the force itself, but of the force per unit charge experienced by charged particles in an electric force field, and this ratio with its associated direction is called the electric intensity $\mathbf{E}$. Thus

$$\mathbf{E}=\frac{\mathbf{f}}{q} \qquad (2)$$

This definition is made generally for time-varying as well as magnetostatic situations.

The total electric intensity $\mathbf{E}$ must be resolved into two components, which we will call the electrostatic component $\mathbf{E}_s$ and the electromotive component $\mathbf{E}_m$.

The electrostatic component $\mathbf{E}_s$ is equal to the total electric intensity which would be calculated considering only charges and their positions. The most suitable definition for present purposes is in terms of sources, as follows

$$\mathbf{E}_s=\frac{1}{4\pi\epsilon_0}\left[\iiint\frac{\rho\mathbf{r}d\tau}{r^3}+\iint\frac{\sigma\mathbf{r}ds}{r^3}+\int\frac{\lambda\mathbf{r}dl}{r^3}\right] \qquad (3)$$

where

$\mathbf{r}$ = the vector radius from the element of volume $d\tau$, surface ds, or length dl to the point at which $\mathbf{E}_s$ is being evaluated

ρ = the volume density

σ = the surface density

λ = line density of charge, including all separated or simulated charges in polarized electric media in the region under consideration

The integration is through all volumes, over all surfaces, and along all lines making up the apparatus being analyzed. The extensive information on the evaluation of $\mathbf{E}_s$ in the literature is all applicable, of course. Equation 3 and the literature pertaining to $\mathbf{E}_s$ are mainly of theoretical interest here, however, since in circuits our concern with $\mathbf{E}_s$ is in connection with potential difference, the magnitude of which is usually evaluated indirectly.

The reason for the name of $\mathbf{E}_s$, electrostatic component, is clear; it is equal to the total electric intensity in electrostatic cases. Note, however, that there is no requirement here that the charges contributing to $\mathbf{E}_s$ be stationary or of unvarying magnitude, and consequently $\mathbf{E}_s$ will in general be a function of time. The importance of the electrostatic component of the total electric intensity lies in the fact that it is always conservative. Furthermore, in many important cases it is the total electric intensity in the region of interest even when the field varies with time.

Where the vector difference between $\mathbf{E}$ and $\mathbf{E}_s$ is not zero, we make the following definition of the electromotive component $\mathbf{E}_m$

$$\mathbf{E}_m=\mathbf{E}-\mathbf{E}_s \qquad (4)$$

so that by definition the two components $\mathbf{E}_s$ and $\mathbf{E}_m$ alone comprise the total electric intensity $\mathbf{E}$.

Investigation of physical devices discloses that in practically all regions where an electromotive component exists, it is nonconservative and consequently can furnish energy to or extract energy from an electric circuit carrying a current; hence the name. The forces represented by the electromotive component (that is, the $q\mathbf{E}_m$ forces) are present in all devices which can act as energy sources or as energy sinks (except those which dissipate energy directly as heat); for example rotating machinery, transformers, batteries, thermocouples, and piezoelectric crystals.

In connection with stationary circuits, the nonconservative force or intensity component with which electrical engineers are most concerned is that found in inductors, transformers, and coupled circuits. This intensity component is a fundamental quantity, but it is not encountered in either electrostatics or magnetostatics, where most fundamental forces and intensities are studied. Briefly, whenever the currents in electric apparatus change with time, charged particles in the region of the apparatus experience a force in addition to those they experience under magnetostatic conditions. This force is described at each point by an electric intensity component which we shall call the induced electromotive component. It is a function of the time-rate of change of currents and current densities and is given by an equation analogous to equation 3, as follows

$$\text{Induced } \mathbf{E}_m=-\frac{\mu_0}{4\pi}\left\{\iiint\frac{\left(\frac{\partial\mathbf{J}}{\partial t}\right)d\tau}{r}+\iint\frac{\left(\frac{\partial\mathbf{K}}{\partial t}\right)ds}{r}+\int\frac{\left(\frac{\partial\mathbf{i}}{\partial t}\right)dl}{r}\right\} \qquad (5)$$

where

r = the distance from the element of volume $d\tau$, surface ds, or length dl to the point at which $\mathbf{E}_m$ is being evaluated

$\mathbf{J}$ = the vector current density

$\mathbf{K}$ = the vector surface-current density

$\mathbf{i}$ = the vector filamentary current, including all simulated currents and current densities in magnetized media in the region under consideration

The integration is through all volumes, over all surfaces, and along all filaments making up the apparatus being analyzed. It follows from equation 5 that the induced electromotive component is simply related to the magnetic vector potential **A** as follows

$$\text{Induced } \mathbf{E}_m = -\frac{\partial \mathbf{A}}{\partial t} \qquad (6)$$

where again the literature on the evaluation of **A** is applicable.

This induced electromotive component of electric intensity usually is not easy to evaluate directly, and if evaluated, may still be difficult to integrate as required for the solution of circuit problems. It consequently is little studied in connection with circuits. For purposes of understanding, it is worth more study of a semiquantitative nature; it indicates, for instance, the amount of the electromotance, or emf, of self-induction developed in any section of a closed loop, and it permits a nice insight into the effect of irregular conductor size around an inductive loop. It is essential to the study of the behavior of conductors which are not part of closed loops. For strictly quantitative purposes, however, the effect of the induced electromotive component is nearly always determined in an indirect manner.

The Essential Circuit Variables

In addition to current, there are three electric variables which are essential to the analysis of electric circuits, and these quantities we define as follows

Potential decrease from a to b

$$= v_{ab} \equiv \int_a^b \mathbf{E}_s \cdot d\mathbf{l} \qquad (7)$$

Electromotance, or emf, from a to b

$$= e_{ab} \equiv \int_a^b \mathbf{E}_m \cdot d\mathbf{l} \qquad (8)$$

$$Ri \text{ product from } a \text{ to } b = (Ri)_{ab} \equiv \int_a^b \mathbf{E} \cdot d\mathbf{l} \qquad (9)$$

All of these quantities are measurable in volts. The potential decrease from one point to another is independent of the path of integration. This is not true of the electromotance and the *Ri* product, however, and the paths of integration must be specified in these cases if they are not obvious.

The term "*Ri* product" and the compound symbol $(Ri)_{ab}$ used in the definition of the line integral of the total electric intensity **E** obviously are not as simple and are more specialized in origin than is desirable in such a fundamental definition. They become a little ridiculous in the limiting case of capacitors and open circuits, where R approaches infinity and i approaches zero with the product continuing to have a finite value not zero. But the introduction of a new term and a new symbol is also somewhat undesirable, and the fact is that in circuit work with filamentary conductors the line integral of **E** is practically always represented by an *Ri* product. **E** itself is proportional to the total force, the vector sum of the forces of the electrostatic and electromotive components, and results in a current flow great enough so that the energy an electron, say, gains from E along a particular segment of the path is exactly absorbed by interelectron collisions. This work per unit charge is nearly always proportional to current, and we call the proportionality factor resistance. Better terminology and symbols definitely are needed however.

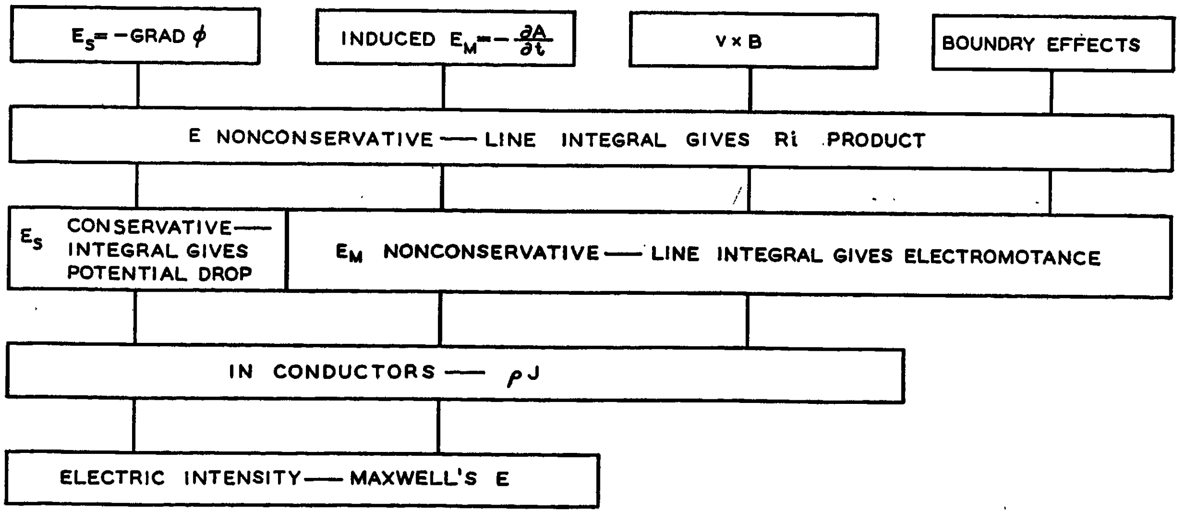
The avoidance of the terms "increase," "decrease," "rise," and "drop" in the general definitions of the electromotance and the *Ri* product is necessary because such terms have meaning only in connection with potential, and the line integrals of $\mathbf{E}_m$ and **E** cannot be described by potential functions. The very important special case wherein it is meaningful to talk of an "*Ri* drop" will be discussed in the following.

The three definitions, equations 7, 8, and 9, are made more meaningful by the following considerations. In electric conduction processes, three distinct types of energy phenomena are possible. They are:

1. Potential energy may be stored in or withdrawn from the electrostatic component of the electric intensity. The measure of this interchange is the potential difference.
2. Energy may be reversably transferred into or out of the circuit from or to mechanical form, chemical form, magnetic form, thermal form, etc. The measure of this interchange is the electromotance.
3. Energy may be irreversibly dissipated as heat in the conducting medium. The measure of this interchange is the *Ri* product.

Fig. 3 compares the current-producing components of electric force per unit charge which are utilized in this paper. For completeness, the **V**×**B** term, which can be considered as a component of the total force per unit charge as far as conduction effects are concerned, is included in the table. However, because of the complications involved in evaluating the various components in reference frames other than one which is stationary with respect to all media and apparatus under consideration, the present discussion is limited to stationary cases.

The breakdown of **E** utilized in Fig. 3 is presented on the basis not of uniqueness but of usefulness. The concepts to be used in circuit analysis are developed with the assumption that the charge and current distributions throughout the apparatus being analyzed are known. From this assumption, useful circuit definitions are formulated, and practical methods of evaluating the defined quantities are derived as indicated in the following.



$E_S = -\text{GRAD } \phi$
INDUCED $E_M = -\frac{\partial A}{\partial t}$
V × B
BOUNDRY EFFECTS
E NONCONSERVATIVE —— LINE INTEGRAL GIVES Ri PRODUCT
E_S CONSERVATIVE—— INTEGRAL GIVES POTENTIAL DROP
E_M NONCONSERVATIVE —— LINE INTEGRAL GIVES ELECTROMOTANCE
IN CONDUCTORS —— ρJ
ELECTRIC INTENSITY —— MAXWELL'S E

Fig. 3. Forces on charged particles

The three quantities defined by equations 7, 8, and 9 usually are not evaluated by means of these defining equations, but by other methods derived from the definitions. Except in capacitors, the potential difference, when it can be evaluated at all, is evaluated by means of well-known equations derived as follows

$$v_{ab}=\int_a^b(\mathbf{E}_s\cdot d\mathbf{l})=\int_a^b(\mathbf{E}\cdot d\mathbf{l})-\int_a^b(\mathbf{E}_m\cdot d\mathbf{l})=(Ri)_{ab}-e_{ab} \quad (10)$$

More customarily

$$v_{ba}=e_{ab}-(Ri)_{ab} \quad (11)$$

In the case of capacitors, of course, $v=q/C$. Equations 10 or 11 may be used to evaluate v_{ba} after e_{ab} and $(Ri)_{ab}$ are evaluated, although it may not always be possible to evaluate all the quantities in the equations, as will be demonstrated below.

The fact that the value of potential difference is equal to the difference between the values of the electromotance and the *Ri* product does not, of course, mean that the electromotance and the *Ri* product are themselves potential differences. But there seems to be a powerful, if illogical, tendency to feel that they do mean just that. A somewhat analogous situation arises in mechanics. Consider a body, initially at rest, which is propelled vertically upward from a reference plane in simple translation. Then at any instant the energy relation for the body is

$$\text{potential energy} = \text{work input} - \text{kinetic energy}$$

In spite of this relationship, no one holds that work input and kinetic energy are forms of potential energy, or that it is possible adequately to describe the energy relationships of mechanics by reference to potential energy alone, except in special cases. As a matter of fact, the representation of the special case of a battery by a simple potential rise equal to and in the direction of the electromotance, and a simple potential drop in the direction of i equal to the *Ri* product is a very useful procedure quite justified by equation 11. In such cases, and in cases where there is no electromotive component, so that $v_{ab}=(Ri)_{ab}$, it appears meaningful to speak of the "*Ri* potential drop" or the "*Ri* drop." The danger lies in reasoning from equation 11 that potential difference is the only quantity needed.

It falls within the province of the electrical engineer to evaluate analytically only those electromotances which are of magnetic origin. All other electromotances, such as those in batteries, thermocouples, crystal transducers, etc., are evaluated experimentally in accordance with equation 11; that is, with a high-resistance voltmeter. This is possible since they are nearly always practically independent of current within their operating range. The evaluation of electromotances of magnetic origin is very especially the concern of the electrical engineer, however. In such cases, we have from equations 5 and 8

$$e_{ab}=\int_a^b\left(-\frac{\partial\mathbf{A}}{\partial t}\right)\cdot d\mathbf{l} \quad (12)$$

Although equation 12 is a usable equation, in most cases it is easier to evaluate the time rates of change of the magnetic fluxes linking the circuit loops of which branch *ab* is a component. This information can be utilized analytically as follows.

Although specifically not the definition, for our purposes, of either quantity, the following relation between **B** and **A** can be derived

$$\mathbf{B}=\text{curl }\mathbf{A}$$

Then, with the aid of Stokes's theorem, given a stationary surface S bounded by a stationary closed curve Γ, the electromotance acting around the path Γ is

$$e_\Gamma=\oint_\Gamma\left(-\frac{\partial\mathbf{A}}{\partial t}\right)\cdot d\mathbf{l}=\iint_S\left(-\frac{\partial}{\partial t}\text{curl }\mathbf{A}\right)\cdot d\mathbf{s}=\iint_S\left(-\frac{\partial\mathbf{B}}{\partial t}\right)\cdot d\mathbf{s}$$

$$e_\Gamma=-\frac{d\phi_S}{dt} \quad (13)$$

where ϕ_S is the total flux of **B** across S, e_Γ acting clockwise as viewed in the reference direction of the flux ϕ_S. (It should be noted here that the method of extension of these concepts to nonstationary circuits is indicated by Cohn's work.[1])

Equation 13, which can be derived from our definitions and from experimental information about the magnetic induction vector **B**, is also available experimentally as Faraday's law, of course. For purposes of understanding, though, it is felt that the approach to equation 13 should still be through equations 5 and 8, with Faraday's experimental work being used to justify the last step to equation 13 if the Stokes's theorem approach is unsuitable.

The *Ri* product usually is evaluated by measuring or calculating both R and i. In the case of some types of sources, however, it is necessary to determine R by application of equation 11 with two different loads. In the case of capacitors, if there is no significant electromotive component of electric intensity present in the capacitor, we have, integrating through the capacitor

$$\int\mathbf{E}\cdot d\mathbf{l}=\int\mathbf{E}_s\cdot d\mathbf{l}$$

$$Ri=v=\frac{q}{C}$$

If the electromotive component is not negligible, but is known, it may still be possible to evaluate *Ri* through use of the complete expression

$$\int\mathbf{E}\cdot d\mathbf{l}=\int\mathbf{E}_s\cdot d\mathbf{l}+\int\mathbf{E}_m\cdot d\mathbf{l}$$

The question might be asked, in connection with this section: What is voltage? It appears in the literature that "voltage" is used to describe all three quantities defined above. In a majority of the cases, it refers to potential difference, except when used in the phrase "induced voltage," when it refers to electromotance. In the future it is suggested that "voltage" be used synonymously with potential difference.

The question might also be asked: What does a voltmeter indicate? A nonelectronic voltmeter, of course, responds to the current through it, and is calibrated to indicate the product of the current and the internal resistance between the voltmeter terminals—in other words, the *Ri* product through itself. An electronic voltmeter responds to and indicates the integral of total **E** between grid and cathode of the input tube, which, again, is defined as the *Ri* product.

The question of the designation of the reference, or positive, direction of the various electric quantities defined above may well be considered in the light of the definitions. The reference direction of the *Ri* product is just the reference direction of the current i. The general practice of using double subscripts or else an arrow to indicate this direction seems entirely satisfactory.

In the case of the electromotance, the reference direction indicates, as a mathematical consideration, the direction in which the line integration is performed, and, as a physical consideration, the direction along the path in which the electromotive component is acting when positive. This indication also is given quite satisfactorily by double subscripts or by an arrow. There is no prohibiting reason why the reference direction cannot also be indicated by a + polarity mark or by + and − marks, the + mark being placed at the terminal which becomes positive on open circuit and hence toward which the electromotive component is directed. This designation does not seem to be as logical as the double subscripts or arrow, however, and it probably tends to increase the confusion between electromotance and potential difference.

Polarity marks are very well suited to the indication of the reference direction of a potential difference, on the other hand. A potential decrease from one point to another in a circuit arises only from an excess of charge at the first point, and the principle use of polarity marks is to indicate just such a situation. The use of an arrow to indicate the reference direction of a potential difference is also quite possible if subject to careful definition, but it seems to be little more than an unfortunate carry-over from the electromotance convention. The confusion in the literature arising from the use of arrows to indicate both potential increases and potential decreases seems to emphasize the unsuitability of the arrow for this purpose. As a demonstration of one convention felt to be more satisfactory, the examples in this paper use the single + and brace notation of LePage and Seely.[2,3]

Kirchhoff's Laws

Kirchhoff's first law is not subject to consideration here. Kirchhoff's second law in both forms is a consequence of the conservative nature of the electrostatic component of electric intensity $\mathbf{E}_s$, as expressed in the equation

$$\oint \mathbf{E}_s \cdot d\mathbf{l} = 0 \qquad (14)$$

Consider first the electromotance form of the law. It is derived as follows

$$\oint \mathbf{E} \cdot d\mathbf{l} = \oint \mathbf{E}_s \cdot d\mathbf{l} + \oint \mathbf{E}_m \cdot d\mathbf{l}$$

$$\oint \mathbf{E} \cdot d\mathbf{l} = \oint \mathbf{E}_m \cdot d\mathbf{l}$$

$$\Sigma Ri = \Sigma e \qquad (15)$$

where all integrations and summations are in the same direction around the same closed path. It can be expressed in words as follows:

> "Around any circuit loop the algebraic sum of the *Ri* products, a given direction being taken as the reference or positive direction of current, is equal to the algebraic sum of the electromotances acting in the current reference direction."

This form is required in circuits which are everywhere linked by magnetic flux, as in the analysis of electric machinery. It embodies the terminology originally used by Kirchhoff,[4,5] although from his proofs it appears that he actually had potential concepts in mind.

The second, or potential difference, form of the law is simply equation 14 in circuit terms, that is

$$\Sigma v = 0 \qquad (16)$$

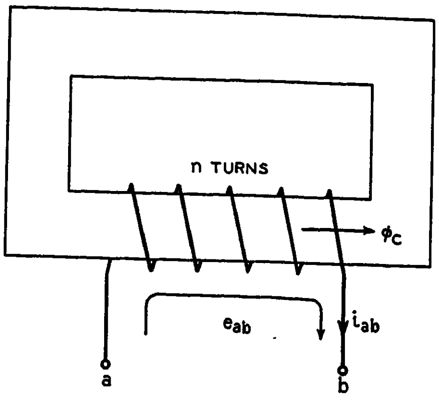


Fig. 4. An inductor with a large number of turns

It can be expressed in words as follows:

> "Around any circuit loop, the algebraic sum of the potential differences is zero."

This form is applicable in circuits composed of lumped circuit elements, including coils and transformers, but with no distributed fluxes linking the circuit loops. It is essential to modern network analysis.

In those many cases where the electromotance in each branch can be evaluated and represented as a simple potential difference, equation 16 is usually simpler and more error-proof to apply. In cases of magnetically induced electromotance, however, it may or may not be possible to evaluate the electromotance in each branch, and so may or may not be possible to evaluate the potential difference between junctions, and to use equation 16. In such cases equation 15 may be required.

Examples

The application of the concepts presented in this paper to the solution of electric circuits is demonstrated in the following three examples. They are also intended to illustrate the mechanics of the circuit action, the energy phenomena, and the obtaining of the potential-difference equivalent circuit.

Example 1

In Fig. 4 is an *n* turn coil wound on an iron core (with *n* large), connected in a circuit whose elements are not close to the core. The changing current in the winding and the simulated currents in the core produce an induced electromotive component, $\mathbf{E}_m = -\partial\mathbf{A}/\partial t$, tending to cause charges to move from one terminal of the inductor to the other. Thus, a potential difference is set up between the terminals, and an electrostatic component is produced both inside and outside the inductor. Within the winding, the electrostatic component of intensity opposes the electromotive component, the resultant of the two being just sufficient to maintain the current through the conducting medium. Because of the large number of turns on the inductor, acting to build up the charge separation, the electromotive component of intensity is negligible in comparison with the electrostatic component outside of the immediate vicinity of the core. Therefore, as far as the external circuit is concerned, the potential difference between the terminals is the agency by which external currents are made to flow and by which energy is coupled in or out of the inductor, and it is the measure of energy per unit charge passing the terminals of the inductor. The electromotive component inside the inductor serves the necessary purpose of maintaining the potential difference between the terminals, but it does not directly couple energy to the outside circuit.

The analysis of the inductor uses the concepts in equations 7, 8, 9, and 11. The magnetic vector potential **A** and the flux in the core ϕ_c are assumed to be functions of the current in the inductor winding, with sources of **A** external to the inductor neglected. The flux is assumed concentrated in the core with no leakage. Each turn has the same $-\partial\mathbf{A}/\partial t$ along it, and each turn is effectively a closed loop. Integrating in the direction from *a* to *b* around one turn, the electromotance acting around one turn is found by equation 8 to be

$$e = \oint \left(-\frac{\partial\mathbf{A}}{\partial t}\right) \cdot d\mathbf{l} = -\frac{d\phi_c}{dt}$$

The electromotance from *a* to *b* is the electromotance of the *n* turns in series and is

$$e_{ab} = ne = -n\frac{d\phi_c}{dt}$$

The *Ri* product from *a* to *b* obviously is the resistance of the winding from *a* to *b*, times the current in the winding, or

$$(Ri)_{ab} = R_{ab}i_{ab}$$

Equation 11 shows that the potential decrease from terminal *b* to terminal *a* is

$$v_{ba} = e_{ab} - (Ri)_{ab} = -n\frac{d\phi_c}{dt} - R_{ab}i_{ab} \qquad (17)$$

Equation 17 is a relation between the terminal potential difference and the current in the winding, since ϕ_c is a function of i_{ab}.

Although neither term on the right of equation 17 is a potential difference, the potential difference of the terminals is correctly obtained from the equivalent

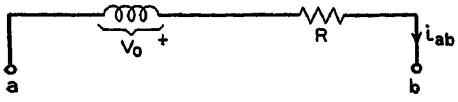

Fig. 5. Equivalent circuit of the inductor of Fig. 3

$$v_0 = e_{ab} = -n\frac{d\phi_0}{dt}$$

$$v_{ba} = v_0 - Ri_{ab}$$

circuit of Fig. 5, in which the terms of equation 17 are represented by potential differences. This circuit is useful in connection with the potential difference form of Kirchhoff's voltage law, equation 16, in the analyses of circuits containing the inductor, since the effect of the inductor on the external circuit is completely determined by the terminal potential difference.

An equation similar to equation 17 for the inductor may be obtained for circuits where any type of electromotive component is localized. In every circuit of this type the action of the electromotive component is to produce an electrostatic component which acts on the portion of the circuit outside of the region of the electromotive component.

The concept of power flow and energy interchange is enhanced by the writing of equation 17 in the form

$$e_{ab}i_{ab} = R_{ab}i_{ab}^2 + v_{ba}i_{ab} \qquad (18)$$

Equation 18 shows that the electromotance e_{ab} may be considered as a measure of the power per unit of current passing from the magnetic field to the circuit. This concept is of importance in electric machinery, where the product of electromotance and current in a d-c motor gives the power being converted to mechanical form.

EXAMPLE 2

The problem discussed in the introduction may now be solved without hesitation with the aid of the concepts presented above. No information is given concerning the distribution of the sources of the magnetic field, so that the electromotive component cannot be evaluated, equation 11 cannot be solved for v, and so the potential difference form of Kirchhoff's second law, equation 16, cannot be used. However, the induced electromotance around a closed loop is expressed by equation 13 in terms of the magnetic flux linking the loop and may be used in the electromotance form of Kirchhoff's second law, equation 15. For a closed path in the conducting ring, equation 15 gives

$$Ri = -\frac{d\phi}{dt}$$

Equation 15 for the loop composed of segment ab of the conducting ring and the adjacent voltmeter leads is

$$R_{ab}i - R_{m1}i_{m1} = 0; \quad i_{m1} << i$$

since no flux links this loop. The discussion of voltmeter readings above has shown that $R_{m1}i_{m1}$ is the indication M_1 of the voltmeter. Since R_{ab} is one-third of the total resistance R, the voltmeter indication is

$$M_1 = \frac{1}{3}Ri = -\frac{1}{3}\frac{d\phi}{dt}$$

Thus the analysis of this problem requires no consideration at all of potential differences. Indeed, if the sources of the magnetic field are axially symmetrical with respect to the ring, and if the voltmeters are removed, there will be no separation of charge at all, no potential difference, and no electrostatic component. The electromotive component is uniformly distributed around the ring. In this case, energy from the sources of the magnetic field is applied to the heating of the conducting ring by the electromotive component directly, and the intermediate process of setting up a potential difference, as in the first example, does not exist.

The fact that no investigation of the electrostatic component is necessary does not mean that the electrostatic component plays an unimportant part in the mechanism of electromagnetic induction. Indeed, a complete understanding of the induction process is impossible without considering the role of the electrostatic component.

In general, the circuit illustrated in Fig. 1 will have a conducting ring that is nonuniform along its length, and the sources of the magnetic field will be unsymmetrically placed. The total electric intensity in the conducting ring must satisfy Ohm's law, $\mathbf{J} = \sigma\mathbf{E}$, and the current density $\mathbf{J}$ must vary so that the current in every cross section of the conductor is the same. On the other hand, the distribution of the electromotive component is determined by the positions of the sources of the magnetic field. The function of the electrostatic component, then, is to make up the difference between the total electric intensity and the electromotive component. If at any time the electrostatic component does not have the proper value everywhere, there will be a temporary flow of current in such a manner as to redistribute the charge on the surface of the conducting ring until the proper $\mathbf{E}_s$ is obtained. In a good conductor, this readjustment of the charges occurs so rapidly[6] that it may be considered instantaneous in near-zone circuit analysis.

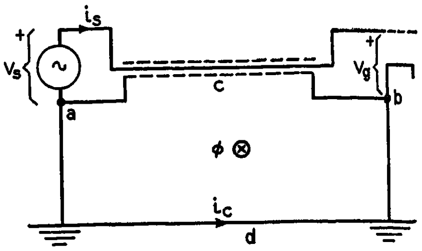

Fig. 6. A ground-loop circuit

EXAMPLE 3

The necessity of using the electromotance form rather than the potential difference form of Kirchhoff's second law arises in a minority of situations, and the preceding problem is a rather artificial example of such a situation. There are, however, important problems the preferred analysis of which requires the use of the electromotance form of the law, equation 15. The analysis of the squirrel-cage rotor is one. Another, from the medical electronics field, where microvolt signals in the power-frequency band are encountered, is presented in the following.

In Fig. 6 is shown a circuit carrying a circulating current i_c in a ground loop, $acbd$, caused by excessive chassis grounding. The ground loop is linked by 60-cycle magnetic flux from the power transformer and heater leads. It is desired to know what effect the circulating current will have on the circuit.

The electromotive component of electric intensity existing in the various individual parts of the ground loop being practically impossible to determine, the electromotance form of Kirchhoff's second law, which is applicable to closed loops, is used. The Ri products at the tube terminals and the generator are assumed to be effectively equal to the potential differences v_g and v_s at those points. The area of the loop formed by the signal generator, the coaxial cable, and the tube is effectively zero, and so there is no flux linkage in that loop. Using equation 15 clockwise around that loop

$$\Sigma Ri = \Sigma e$$

$$-v_s + v_g + R_{acb}(i_c + i_s) = 0$$

or, assuming $i_s << i_c$

$$v_g = v_s - R_{acb}i_c$$

Going clockwise around the ground loop, $acbd$

$$-(R_{acb} + R_{adb})i_c = -\frac{d\phi_c}{dt}$$

Then

$$v_g = v_s - \frac{R_{acb}}{R_{acb}+R_{adb}}\frac{d\phi_c}{dt}$$

This equation indicates the effects of ground loop orientation and area and of the resistances of the various branches that make up the ground loop.

◆

Discussion

D. R. Mack (General Electric Company, Pittsfield, Mass.): The authors emphasized correctly that electromotance and *Ri* product are not potential differences. Equally important is the fact that the corresponding components of field intensity, $\mathbf{E}_m$ and $\mathbf{E}$, are not gradients of potentials. The electromotive component $\mathbf{E}_m$ is produced by a time-varying magnetic field which is nonconservative. Therefore, the electromotance (emf) between two points in the field depends upon the path of integration taken between the points.

Consequently, the value of $\mathbf{E}_m$ at any point is not unique, but depends upon which of the paths of integration through the point is being taken. An example is the field in the gap of an electromagnet, shown in Fig. 1 of the discussion.

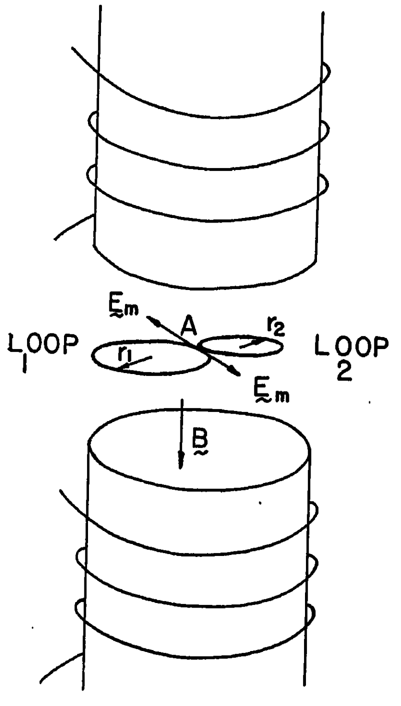

Fig. 1. Field in the gap of an electromagnet

Assume that the flux density $\mathbf{B}$ is uniform in the gap. If a conducting loop of wire, such as loop 1, is inserted in the gap, the voltage induced in it will be

$$v = \frac{d\phi}{dt} = \pi r_1^2 \frac{d\mathbf{B}}{dt} \tag{1}$$

The electric intensity at any point, such as *A*, around the loop will be

$$\mathbf{E}_m = \mathbf{E} = \frac{v}{2\pi r_1} = \frac{r_1}{2}\frac{d\mathbf{B}}{dt} \tag{2}$$

If loop 1 is replaced by loop 2 (tangent at point *A*, where loop 1 was), the electric intensity at point *A* is

$$\mathbf{E}_m = \frac{r_2}{2}\frac{d\mathbf{B}}{dt} \tag{3}$$

which is different in magnitude and opposite in direction from the value at the same point when computed in loop 1. The value of $\mathbf{E}_m$ at any point depends upon the path it is in.

For this reason, equation 5 of the paper must be interpreted with caution. This equation, and the text just preceding it, indicate that $\mathbf{E}_m$, the force on a unit charge due to nearby changing currents, has at any point a unique value given by equation 5. This implication is not true; equation 5 is meaningful only when it is integrated to find the emf, as the authors have done in equations 8 and 13.

Note in equation 13 that after Stoke's theorem is applied, the curl of $\partial\mathbf{A}/\partial t$, not $\partial\mathbf{A}/\partial t$ itself, is integrated over a surface to obtain the emf. That is

$$\begin{aligned} e_\Gamma &= \iint \left(-\nabla\times\frac{\partial\mathbf{A}}{\partial t}\right)\cdot d\mathbf{s} \\ &= \iint -\frac{\partial}{\partial t}(\nabla\times\mathbf{A})\cdot d\mathbf{s} \\ &= \iint -\frac{\partial\mathbf{B}}{\partial t}\cdot d\mathbf{s} = -\frac{d\phi_S}{dt} \end{aligned} \tag{4}$$

The value of $\mathbf{E}_m$ given by equation 5 of the paper is not the only one which will satisfy equation 4 of the discussion. If any gradient $\mathbf{E}_1$ is added to $-\partial\mathbf{A}/\partial t$ we have

$$\nabla\times\mathbf{E}_m = \nabla\times\left(\mathbf{E}_1 - \frac{\partial\mathbf{A}}{\partial t}\right) = \nabla\times\mathbf{E}_1 - \nabla\times\frac{\partial\mathbf{A}}{\partial t} = -\nabla\times\frac{\partial\mathbf{A}}{\partial t}$$

Thus an $\mathbf{E}_m$ consisting of $-\partial\mathbf{A}/\partial t$ and any gradient $\mathbf{E}_1$ will integrate to the correct value of emf. The potential having the gradient $\mathbf{E}_1$ may be caused by the time-varying magnetic field, and not be present at all under magnetostatic conditions. H. K. Farr (General Electric Company, Pittsfield, Mass.) has suggested that such a potential might explain the anomaly of Fig. 1 of the paper. Charges on the surface of the conductor may cause a potential whose gradient $\mathbf{E}_1$ reconciles the difference between $\mathbf{E}_m$ given by equation 5 of the paper, and the values obtained in equations 2 and 3 of this discussion.

J. J. Smith (General Electric Company, Schenectady, N. Y.): It may be helpful to point out that in some cases it is possible to measure directly the voltages considered by the authors. For instance, in example 1, Fig. 4, of the paper, if another winding of *n* turns is wound over the present exciting winding, the voltage at the terminals of this winding is their electromotance. The voltage across the present exciting winding might be called the "total voltage," which would appear to be a more suitable name than the term "*Ri* product," used by the authors. If these two windings are connected together at one end, then the voltage across the other end is the authors' "potential difference." This latter is usually called the "*Ri* drop." Such an additional coil is used in the Epstein frame for testing magnetic-core loss. Its use allows the value of the magnetic flux density *B* in the sample to be measured directly, and no allowance has to be made for the *Ri* drop, which would have to be done if the total voltage, or voltage across the exciting winding, were the only one measured.

Example 2, Fig. 1, of the paper may be similarly handled. Let another conductor *a'b'* be laid as close as possible to *ab*. If *a* and *a'* are connected together, then the voltage measured between *b* and *b'* when these points are close together is the authors' potential difference v_{ab} between *a* and *b*, which again is usually called the *Ri* drop. The important point in making this measurement is that the area of the loop *baa'b'* should approach zero, so that no voltage can be induced in it due to changing magnetic flux. These measurements can be made as the points *a* and *b* approach each other, and thus $\mathbf{E}_s$ can be defined to be v_{ab}/ab, as *ab* approaches zero. The change of flux in the ring may be measured by placing a second ring as close as possible to the present ring. If this second ring is open at one point, then the voltage across its terminals is their electromotance. However, a complete circuit is always needed for such a measurement and thus it is not easy to go from this measurement to a value of $\mathbf{E}_m$. It can be done by introducing the concept of vector potential along lines previously outlined by the writer,[1] but this is too lengthy to go into here. A simpler procedure is given in the following.

The authors give the well-known definition for electric field strength $\mathbf{E}$ in equation 2 of the paper as the force on a unit charge. In equations 3 and 5 of the paper, they define $\mathbf{E}_s$ and $\mathbf{E}_m$ by mathematical formula. It would seem preferable to define either $\mathbf{E}_s$ or $\mathbf{E}_m$ in terms of a measurement which can be made similar to the one in equation 2, if possible. We shall do this here, using a definition of electric displacement density. This definition is a slight modification of one being developed by the American Standards Association Committee *C61* on Electrical and Magnetic Units and Magnitudes. Take two small plates close together and connect them together with a wire. Then if they are brought up from a location where the electric field is zero to a point at which there is an electrostatic field, a current will flow in the wire corresponding to the separation of charge on the plates. Call the integral of this current, with respect to time, the total charge Q on the plates; then the electric displacement density **D** is given by

$$\mathbf{D}=\underset{A\rightarrow 0}{\text{limit}}\frac{Q}{A}=\underset{A\rightarrow 0}{\text{limit}}\frac{1}{A}\int_0^t I dt \qquad (1)$$

when the direction of the plates is such as to make the integral a maximum.

If there is a changing magnetic field present, this will also produce a separation of charge, and thus an additional current in the wire. To separate this current due to the magnetic field from the current due to the electric field, connect the plates together by two wires on opposite edges of the plates. Then the current in these wires due to the electric field will be in the same direction, while the current due to the magnetic field will be in opposite directions. Thus by using a current transformer or oscillograph, or other suitable measuring device, we can measure the integral of the sum of these currents I_1 and I_2 with respect to time. From this, a value of D can be obtained which is independent of the effect of the magnetic field as

$$\mathbf{D}=\underset{A\rightarrow 0}{\text{limit}}\frac{1}{A}\int_0^t (I_1+I_2)dt \qquad (2)$$

Thus two separate measurements can be made at any point:

1. The force per unit charge given by equation 2 of the paper;
2. The charge separation per unit area of the two plates given by equation 2 of the discussion.

In general, it is not to be expected that these two measurements should even have the same direction. However, we note that in the measurement of **D** any effect due to a changing magnetic field has been excluded. Thus if the $\mathbf{E}_m$ of the paper is the contribution due to the changing magnetic field, we might expect that **D** would be proportional to $\mathbf{E}_s$ of the paper and write

$$\mathbf{D}=\epsilon\mathbf{E}_s \qquad (3)$$

where ϵ is the permittivity, which is a known quantity for a given medium. The use of **D** in equation 2 of the discussion will also be found very helpful in the more general case involving capacitors, which the authors refer to only briefly.

The objection may be raised that equation 3 of the discussion is generally written $\mathbf{D}=\epsilon\mathbf{E}$, where **E** is the total electric field intensity. There are other reasons for believing that this equation should be revised, but they cannot be gone into here; it is the one given in the older definitions, such as the American Standard Definitions of Electrical Terms.[2] For those who prefer to use the older definitions unchanged, the foregoing discussion would still hold, by changing the name electric displacement density to another name, and giving it a new symbol. The reason for not doing this in the present discussion is that the terminology used here follows some of the newer definitions, such as the American Standards Association *C61* Committee, and the electrical definitions proposed by the International Standards Organization.

Applying the foregoing reasoning to the example 2, Fig. 1, of the paper, the value of $\mathbf{E}_s=\mathbf{D}/\epsilon$ can be measured with two plates at any point along any path from a to b. If the path is a circle close to the ring, it is found that **D** is in the same direction as the ring itself at all points, and its magnitude is also the same at all points. Thus, from such measurements, the integral of $\mathbf{E}_s$ along the path ab can be formed to give the potential difference between these points. The value of the integral is found to be independent of the path in going from a to b. If the integration is around any complete path starting at a and ending at the same point a, then the value of the integral is zero, and thus $\mathbf{E}_s$ is a conservative field.

The total electric field strength $\mathbf{E}_t$ at any point can be measured by the force on a unit charge placed at the point. Subtracting $\mathbf{E}_s$ from $\mathbf{E}_t$ we obtain $\mathbf{E}_m$. However, it is found the integral of $\mathbf{E}_m$ around any closed path starting from b, and passing through a and returning to b, is equal to the change of the flux linking this path. From this it follows that the integral of $\mathbf{E}_m$ from a to b depends on the path. Thus, it does not have a unique value until the path of integration is specified, and hence $\mathbf{E}_m$ is a nonconservative field.

The following suggestion is made with reference to the terminology used by the authors. The integral of $\mathbf{E}_s=\mathbf{D}/\epsilon$ will be called the potential difference; the integral of $\mathbf{E}_t=\mathbf{F}/Q$ will be called the total voltage. The use of "*Ri* product," suggested by the authors for this would produce confusion with existing practice. Call the integral of $\mathbf{E}_m=\mathbf{E}_t-\mathbf{E}_s$ the electromotance. Then all these quantities are measured in volts. Or, it might be said that they are "voltages," as an overall term. It would seem better to reserve the terms "potential difference" and "electromotance" for the two components, conservative and nonconservative, of the total voltage, as discussed in the foregoing. An advantage of this terminology is that it would still hold when capacitors are considered.

D. W. Spence and C. R. Cahn: Mr. Mack raises the timely question of uniqueness in connection with our definitions. Slepian and Cullwick debated this matter somewhat inconclusively[1–6] in *Electrical Engineering* a few years ago. Certainly there are, for instance, several definitions of **A** which satisfy curl **A** = **B**. And if the sources of an **E** field are not known, the authors are aware of no tests which will uniquely separate the $\mathbf{E}_s$ and $\mathbf{E}_m$ components. Making such a separation by test is not the objective, however. Generally speaking, the charge and current distributions, or at least the nature of the charge and current distributions, are known in the apparatus being analyzed. Under such circumstances, it is the authors' experience that the definitions presented, based on an assumed knowledge of charge and current distributions, are powerful aids in the solution of engineering problems and are the most reasonable quantitative definitions of some important electric quantities.

Mr. Mack claims, however, that our admittedly arbitrary definitions do not give unique values of the defined quantities. With this we must disagree. Using the concepts of electromagnetic field theory, our definitions of $\mathbf{E}_s$ and induced $\mathbf{E}_m$ are equivalent to

$$\mathbf{E}_s=-\text{grad } v \qquad (1)$$

$$\text{Induced } \mathbf{E}_m=-\partial\mathbf{A}/\partial t \qquad (2)$$

where v, the scalar electric potential, and **A**, the vector magnetic potential, are defined as follows

$$\text{curl } \mathbf{A}=\mathbf{B} \qquad (3)$$

$$\text{div } \mathbf{A}=-\mu_0\epsilon_0\partial v/\partial t \qquad (4)$$

$$-\text{grad } v=\mathbf{E}+\partial\mathbf{A}/\partial t \qquad (5)$$

These equations, though arbitrarily chosen, are sufficient to determine uniquely the two components of **E**.

They result in **A** being a function only of currents and v a function only of charges.

Concerning his example, it is one of the points of the paper that it usually is difficult or impossible to evaluate $\mathbf{E}_m$ and $\mathbf{E}_s$, and consequently e and v in individual sections of flux-linked loops, necessitating solutions in terms of the electromotances and *Ri* products around the complete loops. Certainly we see no justification in assuming the component of $\mathbf{E}_m$ along the conductors to be uniform around any arbitrarily located loop, as indicated in Mr. Mack's equation 2.

As a matter of fact, in Mr. Mack's example, the assumption of uniform **B** in the gap and the circular symmetry indicated in his Fig. 1 indicate that, neglecting the currents in his exploring loops, $\mathbf{A}=\theta_1 krf(t)$ is a possible expression for **A** in the air gap, giving $\mathbf{B}=\text{curl }\mathbf{A}=\mathbf{z}_1 2kf(t)$. With this value for **A**, the solution of Mr. Mack's

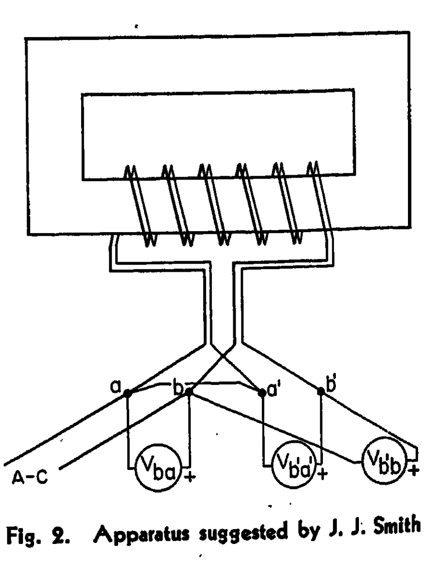

Fig. 2. Apparatus suggested by J. J. Smith

example will be undertaken. The authors are aware that the assumption of an exactly uniform, time-varying **B** field is barred by Maxwell's equations. It is assumed, however, that the frequency is low enough that the assumption of uniformity of **B** is a good approximation.

Mr. Mack's term "voltage" and symbol v are not defined and apparently differ from the definitions presented in our paper. In our terminology, his equation 1 becomes

$$e=-\frac{d\phi}{dt}=-\pi r_1^2\frac{\partial \mathbf{B}}{\partial t}=-2\pi r_1^2 k\frac{df(t)}{dt} \tag{6}$$

where e is the emf acting around loop 1. His equation 2 is replaced by two equations

$$\mathbf{E}_m=-\frac{\partial \mathbf{A}}{\partial t}=-\theta_1 kr\frac{df(t)}{dt} \tag{7}$$

$$\begin{aligned}\mathbf{E}=\rho\mathbf{J}&=\mathbf{l}_1\frac{RS}{l}\frac{i}{S}=\mathbf{l}_1\frac{Ri}{2\pi r_1}=\mathbf{l}_1\frac{e}{2\pi r_1}\\&=\mathbf{l}_1\left(-\frac{r_1}{2}\frac{\partial \mathbf{B}}{\partial t}\right)=\mathbf{l}_1\left(-r_1 k\frac{df(t)}{dt}\right)\end{aligned} \tag{8}$$

where Ri is the Ri product around the loop and is equal to e by equation 15 of the paper, and $\mathbf{l}_1$ is a unit vector tangential to the loop at each point on the loop. $\mathbf{E}_m$ is independent of what loop is under consideration, so that we do not get Mr. Mack's equation 3.

As Mr. Farr and Mr. Mack suggest, there is an electrostatic component $\mathbf{E}_s$ arising from charge separation on any loop not coaxially placed within the gap. Its value along or within one of the loops, where **E** is known, is

$$\mathbf{E}_s=\mathbf{E}-\mathbf{E}_m=k\frac{df(t)}{dt}\{\theta_1 r-\mathbf{l}_1 r_1\} \tag{9}$$

This value of $\mathbf{E}_s$ can be integrated around the loop to find the potential drop v from one point on the loop to another.

Like Mr. Mack, Dr. Smith presents examples which are helpful in bringing out the points in our paper. Unlike many electrical engineering problems, these are such that it is not intuitively obvious what "voltages" are present. The values of current present are uniquely determinable, but what voltage exists depends on what "voltage" is defined to be. From this standpoint, it is unfortunate that Dr. Smith also uses the word "voltage" without defining it.

More seriously, as nearly as the authors can ascertain Dr. Smith's meaning, he seems to have misinterpreted two of our definitions and consequently to have come to some incorrect conclusions.

In Fig. 2 of the discussion, the leads are brought out to a region remote from the core where the $\mathbf{E}_m$ component is negligible, so that $\mathbf{E}=\mathbf{E}_s$. As discussed in the paper, the voltmeters read the Ri product through themselves, that is, the integral of **E** through themselves. But since $\mathbf{E}=\mathbf{E}_s$, this is the same as the potential difference, so the voltmeters also read the potential difference between the terminals to which they are connected. This is usually the case in electric apparatus, though not always. It will now be assumed that the readings of these voltmeters are what Dr. Smith refers to when he speaks of "voltage."

If e_{ab} is the electromotance acting in winding a^1, $(Ri)_{ab}$ the Ri product through winding ab, and $e_{a'b'}$ and $(Ri)_{a'b'}$ are the corresponding quantities in winding $a'b'$, then, by equation 11 of the paper

$$v_{b'a'}=e_{a'b'}-R_{a'b'}i_{a'b'} \tag{10}$$

$$v_{ba}=e_{ab}-R_{ab}i_{ab} \tag{11}$$

$$v_{b'b}=e_{a'b'}-R_{a'b'}i_{a'b'}-e_{ab}+R_{ab}i_{ab} \tag{12}$$

The windings are such that $e_{a'b'}=e_{ab}$, and it is assumed that the voltmeters are high resistance so that $i_{a'b'}=0$. Then the voltage referred to in Dr. Smith's second sentence is $V_{b'a'}=e_{a'b'}=e_{ab}$, the electromotance, just as he says. The voltage of his third sentence is $v_{ba}=e_{ab}-R_{ab}i_{ab}$, which cannot be described by one term except as the potential drop from b to a, v_{ba}. The authors had no intention of indicating that this quantity is the Ri product. The voltage of Dr. Smith's fourth sentence is $v_{b'b}=e_{ab}-R_{a'b'}(0)-e_{ab}+R_{ab}i_{ab}=R_{ab}i_{ab}$, the Ri product in the exciting winding, and is not the potential difference across either winding. Dr. Smith's term "total voltage," if substituted for the authors' "Ri product," is logical in that it is the integral of total, or net, **E**. There is some question whether it is desirable from a standpoint of connotation, however.

The same reasoning applied to Dr. Smith's second paragraph seems to invalidate his determination of $\mathbf{E}_s$. His limit v_{ab}/ab gives **E**, where his v_{ab} refers to voltmeter reading, not potential difference.

Dr. Smith's "D-Measurer" is very interesting. Dr. Slepian argues,[2] however, that there is no test which will separate the $\mathbf{E}_s$ and $\mathbf{E}_m$ components of **E**, and we cannot see where the **D** Dr. Smith measures will be other than $\epsilon\mathbf{E}$ ($=\epsilon\mathbf{E}_s-\epsilon\partial\mathbf{A}/\partial t$, in electromagnetic fields). The $-\partial\mathbf{A}/\partial t$ component of electric intensity should charge the test capacitor just as well as the $\mathbf{E}_s$ component does. True, any rotational component of the $-\partial\mathbf{A}/\partial t$ field, as measured by $-d\mathbf{B}/dt$, and as evidenced by an increase or decrease of $-\partial\mathbf{A}/\partial t$ from one side of the capacitor to the other, is averaged out, but $-d\phi/dt$ is not the only way that changing currents, that is, magnetic effects, affect apparatus such as Dr. Smith's search capacitor. The authors suggest in the paper that $-\partial\mathbf{A}/\partial i$ is a more productive place to start the analysis of such out-of-the-ordinary apparatus than is $-d\phi/dt$.

In summary, the authors feel that the concepts presented in the paper are very useful in reasoning about the operation of much typical electric apparatus. They provide a common method of analyzing electrochemical, electrothermal, and perhaps piezoelectric, as well as electromagnetic, apparatus. But in purely electromagnetic situations, the resolutions of the **E** field has conceptual significance only, and is not subject to unique experimental verification.

A Commutatorless D-C Tachometer

A. R. ECKELS
ASSOCIATE MEMBER AIEE

W. R. PECK
NONMEMBER AIEE

IN MANY applications the commutator noise produced by conventional tachometers presents great problems. This is particularly true in cases where it is desirable to measure speed variations which have the same frequency components as the commutator noise. It is also true in some servomechanism systems where the commutator noise will saturate the amplifiers or will introduce a spurious response.

Several devices have been developed to avoid these difficulties and are described in recent literature.[1,2] The tachometer described here is another approach toward the problem of constructing a tachometer with a small noise-to-signal ratio which has the required linear response. The operation of this tachometer is based upon the familiar current balance principle.

Description

The four principal elements of the tachometer are shown in Fig. 1. Rotation of the magnet mounted on the input shaft induces eddy currents in the disk, which in turn produce a torque on the disk proportional to the speed of rotation. This torque will tend to move the shaft holding the disk mirror, and coil. A movement of the mirror will deflect

---

Paper 53-292, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 16, 1953; made available for printing May 4, 1953.

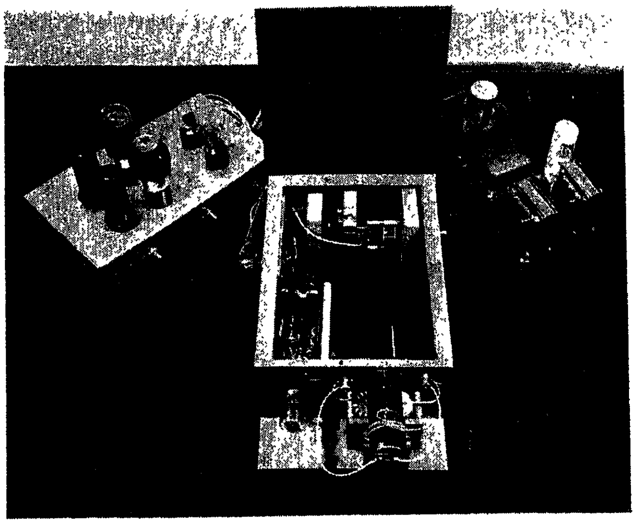

Fig. 3 (right). The completed commutatorless d-c tachometer

the beam of light and will cause one phototube to receive a larger proportion of the light. This will cause an unbalance between the currents of the phototubes, thereby producing a voltage signal which is then amplified. The output of the amplifier is impressed upon the coil of a D'Arsonval-type instrument and a series resistance. Thus the deflection of the mirror produces a current in the coil. This current will exert a restoring torque on the coil in such a direction as to oppose the original movement of the shaft, and of such magnitude as to balance the torque produced on the disk by the rotation of the magnet. Since the current in the coil also flows through the resistance, the voltage drop across this resistance will be proportional to the speed of the input shaft.

The magnet and disk assembly is identical to one employed in a commercial indicator tachometer.[3] This element has the important function of exerting a torque on the disk shaft which is a linear function of the input angular speed.[4]

A beam of light and phototube system is employed for the shaft position detector. The maximum signal occurs for a 1-degree deflection of the mirror. Other standard types of position detectors could have been employed.

The direct-coupled amplifier, including the two phototubes, is shown schematically in Fig. 2. Differential amplifier stages are employed throughout in order to minimize drift and to reduce the effect of variations in the power supply voltage. The output stage consists of four *6L6*'s paralleled two by two, and gives a source impedance of about 650 ohms, with a current capacity of ±60 milliamperes. Each stage of voltage amplification has a balance arrangement, and the gain control is the variable resistor shunting the grids of the second *6SL7*.

The D'Arsonval movement is from a 30-milliampere meter, the coil frame of which was altered to eliminate the damping effect of the frame. The torque of this coil is a linear function of the coil current. The maximum current produces a signal of ±1.2 volts across the resistance in series with the coil.

The completed tachometer shown in Fig. 3 consists of three separate units. The first contains the d-c power supply and two separate a-c heater supplies. The second unit contains the input shaft, the disk, coil, and mirror assembly, the beam of light, and phototube system, and the first stage of voltage amplification. The third unit contains the amplifier with the exception of the first amplification stage.

Fundamental Concepts

The tachometer will now be analyzed to determine the way in which its accuracy and frequency response depend on the constants of the closed loop system. For convenience of analysis the elements shown in the pictorial diagram of Fig. 1 are represented by the block diagram of Fig. 4. In this diagram Q_{in} represents the torque exerted on the disk by the rotation of the input shaft, while Q_c represents the electrical torque produced by the current flowing in the coil. Q_e is the net torque exerted on the moving system consisting of the disk, mirror, and coil. Thus

$$Q_e = Q_{in} - Q_c \qquad (1)$$

However, Q_c will be related to Q_e by some frequency dependent function which is called the loop gain and is denoted as $K_1G_1(jw)$, or

$$Q_c(jw) = [K_1G_1(jw)]Q_e(jw) \qquad (2)$$

By eliminating Q_e from equations 1 and 2, it can be shown that

$$\frac{Q_c(jw)}{Q_{in}(jw)} = \frac{K_1G_1(jw)}{1+K_1G_1(jw)} \qquad (3)$$

In reference 4 it is shown that

$$Q_{in} = K_2N_{in} \qquad (4)$$

and the characteristics of a D'Arsonval instrument movement and Ohm's law require that

$$Q_c = K_3E_R \qquad (5)$$

where E_R is the voltage across the resistor

Table I. Noise-to-Signal Ratio of the Commutatorless Tachometer and of a Standard D-C Generator Tachometer

Speed, Rpm	Noise to Signal Ratio	
	Standard Tachometer	Commutatorless Tachometer
120	0.4	0.046
240	0.5	0.029
450	0.46	0.020
650	0.36	0.020
800	0.167	0.021
1,000	0.04	0.017
1,100	0.03	0.013

in series with the coil. Substitution of equations 4 and 5 in equation 3 yields

$$\frac{E_R}{N_{in}}=\frac{K_2}{K_3}\left[\frac{K_1G_1(jw)}{1+K_1G_1(jw)}\right] \tag{6}$$

Inspection of equation 6 shows that for signals having frequency components such that

$$K_1G_1(jw)\gg 1 \tag{7}$$

the tachometer will yield an output voltage signal which is proportional to the angular speed of the input shaft. An analytical expression for $K_1G_1(jw)$ may be obtained from the differential equations of the components.[5] It is important to realize, however, that the nature of $K_1G_1(jw)$ is such that special precautions must be taken in order that the system will be stable when $K_1G_1(jw)$ is increased to a suitable level. The problem of obtaining a stable system can be solved by the application of techniques developed for automatic control systems.[6] These techniques include careful design of the mechanical system to minimize the principal time lags and the introduction of compensating networks.

Test Results and Conclusions

The tests carried out on the tachometer included measurements to allow the determinations of $K_1G_1(jw)$ as a function of frequency and three performance tests on the tachometer.

Amplitude and phase loci of $K_1G_1(jw)$ obtained from the test data are shown in Fig. 5. The curves shown with solid lines represent the completed system which includes the resistance-capacitance compensating network in the voltage amplifier. For suitable operation it is necessary to limit the phase of $K_1G_1(jw)$ to approximately 150 degrees at the frequency for which the amplitude $K_1G_1(jw)$ is zero decibels. A comparison of the solid and dashed curves will show that the inclusion of the compensating network made it possible to increase K_1 by 60 decibels and still meet the criterion mentioned previously for suitable operation.

The results of the first performance test, shown in Fig. 6, indicate that the output signal is a linear function of the input angular velcoity. So long as the condition stated in equation 7 is met, the calibration of the instrument is dependent only upon K_2 and K_3. As defined in equation 4, K_2 is the constant of the magnet and disk assembly. The particular unit used was designed to be accurate within 10 rpm up to a speed of 3,000 rpm.[3] As defined in equation 5, K_3 is the constant of the D'Arsonval instrument and the output resistor. These components can be designed for very high accuracy.

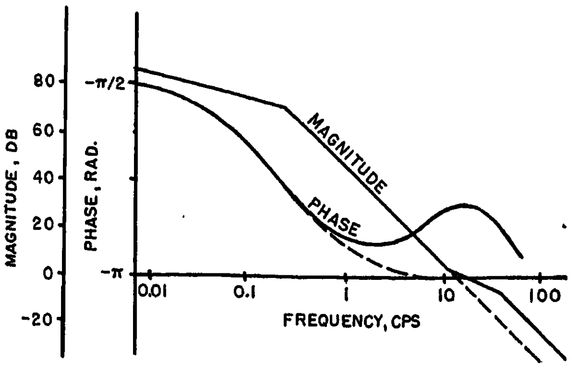
The second performance test determined the output voltage per revolutions per minute as a function of frequency. The input function of angular velocity was obtained by the oscillations of a weight clamped to the input shaft which was acted on by the torsional resilience of a long, slender wire. The frequency could be varied by clamping the wire at various lengths in a stationary vise. Thus the input assumes the form of a sinusoid with easily determined constants. The output signal was recorded by a type *BL202* Brush Development Company magnetic recorder. The calculated values of the maximum output signal voltage divided by the maximum input revolutions per minute as a function of frequency are plotted in Fig. 7. The low-frequency portion of the curve is asymptotic to 0.885 millivolt per rpm. This value is obtained from Fig. 6. Although no data were obtained for signal frequencies in excess of 15 cycles per second, the curve in this region can be expected to approach K_2/K_3 times the solid curve in Fig. 5. This is true since above 15 cycles per second $K_1G_1(jw)$ is less than 1, and equation 6 reduces to

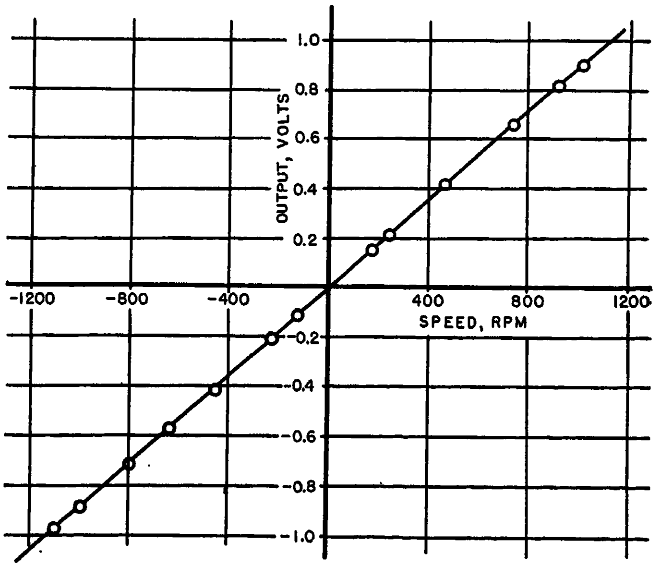
$$\frac{E_R}{N_{in}}\approx\frac{K_2}{K_3}K_1G_1(jw) \tag{8}$$

The final test determined the noise-to-

Fig. 5 (below). Magnitude and phase of $K_1G_1(jw)$ as a function of frequency. Dashed lines indicated uncompensated system

Fig. 6 (right). Output voltage as a function of input angular velocity





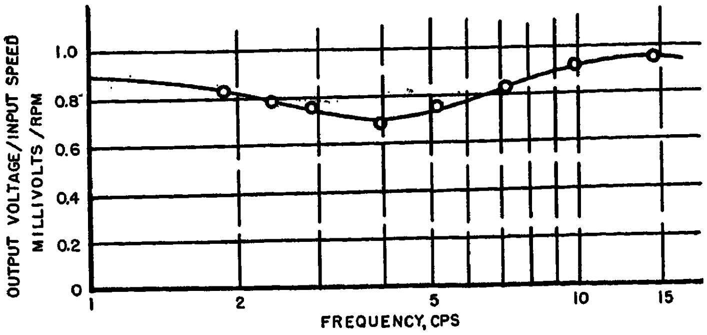


Fig. 7 (above). Ratio of output voltage to input speed as a function of frequency

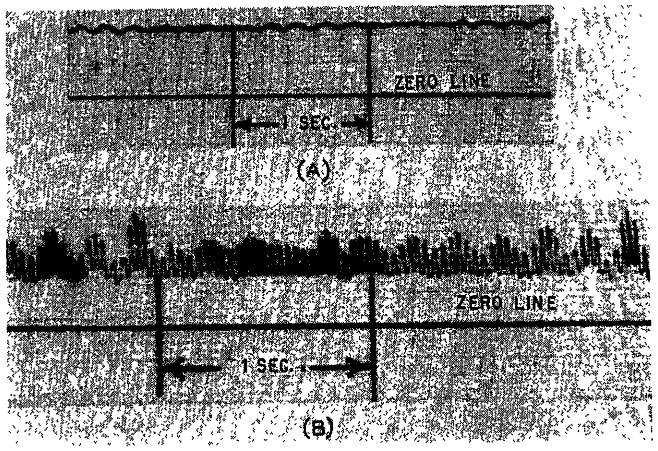

Fig. 8 (right). The output voltage of the commutatorless d-c tachometer and of a normal d-c generator for the same input speed

signal ratio of the commutatorless tachometer and of a normal d-c generator tachometer. Fig. 8 shows sample oscillograms of the output voltages for the commutatorless tachometer and a d-c generator tachometer with the same angular speed input. It should be noted that the low-frequency component of voltage is common to both oscillograms and is unquestionably caused by a variation in the shaft speed. The noise-to-signal ratio for various shaft speeds of both tachometers is tabulated in Table I.

From these tests it can be concluded that the basic principle of operation of this type of tachometer is sound. There would need to be some definite improvements in the mechanical construction of the disk, position detector, and coil assembly to allow a further increase in the frequency response, as the shape of $K_1G_1(jw)$ is primarily determined by this assembly.[5] The ability of the tachometer to respond to significant high-frequency components of speed with reasonable amplifier power is also determined by the D'Arsonval movement. With a D'Arsonval movement having characteristics matching those of the pen motor described in reference 5, a tachometer could be designed which would respond to frequency components of speed ranging from direct current to a frequency of 200 cycles per second.

Discussion

Perry A. Borden (The Bristol Company, Waterbury, Conn.): In outlining the development of a null-type magnetic-drag tachometer, the authors have made no reference to one problem which is always present in devices of this class. I refer to the effect of temperature changes on the resistivity of the disk or cup which forms the rotor. I recall certain experiments in which I participated some years ago in an attempt to produce a precision servo-actuated null-balance watt-hour meter. The principle will be understood from Fig. 9. Power was measured by a Kelvin watt balance, whose moving element carried a magnet or group of magnets in whose field rotated an armature in the form of a nonmagnetic metal disk driven by a variable-speed motor mechanism. The speed of the driving mechanism was regulated by the torque developed on the moving element of the wattmeter, with a resultant continual tendency for the rate of rotation of the disk to be proportional to the measured power.

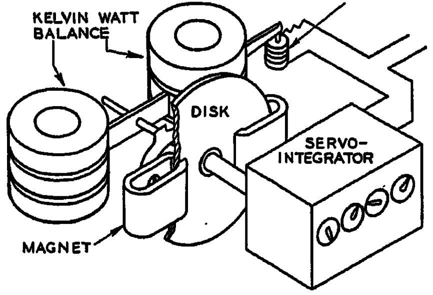

Fig. 9. Servo-actuated watt-hour meter

By virtue of the driving force and the retarding influence both being exerted on a common conducting member, the conventional watt-hour meter is to some extent self-compensating for temperature effects on the rotor; but the experimental instrument lacked this advantage, and changes in the resistivity of the rotor material with temperature directly affected its accuracy. These experiments, it may be said, were carried out in the summer of 1914, and were prematurely terminated by the outbreak of World War I. The lack of today's sensitive servo systems necessitated a maximum reaction between the rotor and the magnet. The disks were formed of aluminum, and while copper might have made more control influence available, both these metals have high variations of resistivity with temperature changes. The high resistance of any alloy then known as having a negligible temperature coefficient would have reduced the effective torque to a prohibitively small value. In view of these obstacles, it may be that the termination of the experiment was no more premature than was the experiment itself. It would be of interest to learn how the authors of the present paper have met and overcome this important source of error.

A. R. Eckels and W. P. Peck: The authors wish to express their appreciation for Mr. Borden's comments and for the very interesting description of an early example of the family of devices based upon the current balance principle.

Construction details of the magnet and disk assembly were omitted from this paper, as they are fully described in references 3 and 4 of the paper. The two principal means employed to reduce the sensitivity to temperature changes are to make the disk of an aluminum-manganese alloy which has a low temperature coefficient, and to use temperature-sensitive magnetic shunts in the magnet assembly. The output resistor must in this case possess a low temperature coefficient.

However, unlike the watt-hour meter described in the discussion, the tachometer can be made inherently self-compensating. Referring to the paper, equations 4 and 5 can be written

$$Q_{in} = K_2'B_2\gamma_2N_{im} \tag{4A}$$

$$Q_c = K_3'B_3\gamma_3E_R \tag{5A}$$

The additional symbols are

B_2 = disk-magnet field strength
B_3 = D'Arsonval movement-magnet field strength
γ_2 = disk conductivity

γ_3 = output-resistor conductivity

Thus, if the magnetic and conducting elements of each assembly employ similar materials in corresponding parts, equation 6 will become

$$\frac{E_R}{N_{in}}=\frac{K_2'}{K_3'}\left[\frac{K_1G_1(jw)}{1+K_1G_1(jw)}\right]$$

Thus the temperature-sensitive components do not affect the results. This assumes the same ambient temperatures and thermal transient properties for corresponding parts and neglects very small effects such as expansion and contraction.

It should also be noted that where speed variations are being measured, slow changes of calibration are relatively unimportant.

Theory of Magnetic Amplifiers with Square-Loop Core Materials

H. F. STORM
MEMBER AIEE

Synopsis: The purpose of this paper is to explain the operation of magnetic amplifiers and to express power out, power gain, and time constant of the amplifier in terms of core and rectifier properties. The magnetic amplifiers under discussion are of the so-called low-control circuit-impedance type.[1] To reduce the complexity of the analysis, many simplifying assumptions are made. While these assumptions introduce inaccuracies in the equations, the latter still serve effectively in establishing first-order relations among the variables. A large part of the analysis is applicable to core materials whose dynamic hysteresis (B-H) loop is not strictly rectangular, such as grain-oriented silicon steel.

THE FOLLOWING analysis applies to magnetic-amplifier circuits of the center-tap, bridge type, or a-c variety. Such circuits are called amplistats,[2] Magamps,[3] transductors,[4] self-saturated magnetic amplifiers,[5] etc. Fig. 1 shows the circuit diagram of the center-tap amplistat.

Circuit

The secondary *TS* of the supply transformer energizes the gate windings (between *X*1, *X*2) of two transformerlike structures *A* and *B*. From there the gate currents flow through rectifiers $REC_{1,2}$ to the load resistance, and return to the neutral *N* of transformer *TS*. The secondaries between *Y*1, *Y*2 of transformers *A* and *B* form the control circuit and hence are called control windings. In most practical applications, a single control winding is used which embraces both legs of units *A* and *B*. In this case, units *A* and *B* are called a saturable reactor. With the assumptions to be listed, the function of the amplistat is the same for two separate, or one common, control winding.

Nomenclature

A_{Fe} = area of active core cross section, centimeters^2
AT = magnetomotive force (mmf), ampere-turns, instantaneous
AT_c = mmf for zero flux on symmetrical dynamic hysteresis loop, ampere-turns, instantaneous
B = flux density, gausses, instantaneous
B_s = saturation flux density, gausses, instantaneous
$B_{s,1}$ = saturation flux density for reactor, being load-matched and operating at maximum permissible temperature, gausses, instantaneous
D_P = dynamic power gain, seconds^{-1}
E = line-to-neutral voltage of supply transformer secondary, volts, average
E_C = control voltage, volts
$e_{G,A}$, $e_{G,B}$ = gate voltage on saturable reactor *A* or *B* respectively, volts, instantaneous
e_O = (nominal) output voltage, volts, instantaneous
E_O = (nominal) output voltage, volts, average
e_r = rectifier reverse voltage, volts, instantaneous
f = supply frequency, cycles per second
H = component of magnetic intensity produced by winding, oersteds, instantaneous
$H_c = H$ for zero flux on symmetrical, dynamic hysteresis loop, oersteds, instantaneous
i_C = control current, amperes, instantaneous
I_C = control current, amperes, average
$\mathfrak{i}_C$ = per-unit control current
$i_{C,r}$ = control current required by rectifier reverse current, amperes, instantaneous
$I_{C,r}$ = control current required by rectifier reverse current, amperes, average
I_E = exciting current, amperes, average
$\mathfrak{i}_E$ = per-unit exciting current
$i_{G,A}$, $i_{G,B}$ = gate current in saturable reactor *A* or *B*, respectively, amperes, instantaneous
$i_{G,r}$ = gate current caused by rectifier reverse current, amperes, instantaneous
$i_{G,s}$ = saturation component of gate current, amperes, instantaneous
$i_{G,x}$ = exciting component of gate current, amperes, instantaneous
i_L = load current, amperes, instantaneous
$i_{L,s}$ = saturation component of i_L
$i_{L,x}$ = exciting component of i_L
I_L = load current, amperes, average
$I_{L,s}$ = saturation component of I_L
$I_{L,r}$ = exciting component of I_L
$I_{L,m}$ = maximum load current, amperes, average
i_r = rectifier reverse current, amperes, instantaneous
$I_{r,m}$ = maximum rectifier reverse current, amperes, averaged over 1/2 cycle
$\mathfrak{i}_r$ = per-unit rectifier reverse current
k_f = form factor of load current
K_{AT} = ampere-turn gain
$K_{AT,s}$ = saturation component of K_{AT}
$K_{AT,s,o} = K_{AT,s}$ with zero rectifier reverse current
$K_{AT,s,r} = K_{AT,s}$ with rectifier reverse current present
$K_{AT,x}$ = exciting component of K_{AT}
K_E = voltage gain
K_I = current gain
K_P = power gain
l_{Fe} = length of mean path of magnetic circuit, centimeters
N_C = number of turns of one control winding
N_G = number of turns of one gate winding
P_L = useful power in R_L, watts
R_C = control circuit resistance, ohms
$R_{G,A}$, $R_{G,B}$ = gate resistance in saturable reactor *A* or *B*, respectively, ohms
R_L = load resistance, ohms
R_O = nominal output resistance, ohms
R_r = simulated rectifier reverse resistance, ohms
t = time, seconds
T = time constant, seconds
α = starting angle of saturation, radians
κ = see equation 47
μ_{sq} = square-loop permeability, gausses per oersted
ϕ_A, ϕ_B = core flux in saturable reactor *A* or *B* respectively, maxwells, instantaneous
Φ_1 = starting flux, maxwells, instantaneous
Φ_s = saturation flux, maxwells, instantaneous
ω = angular frequency, seconds^{-1}

Assumptions

The control-circuit resistance R_C is assumed small enough to prevent appreciable interference with the a-c components of the control current; the net voltage in the control circuit is so small that the resultant core-flux changes can be neglected.

Paper 53-284, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 16, 1953; made available for printing April 29, 1953.

H. F. Storm is with the General Electric Company, Schenectady, N. Y.

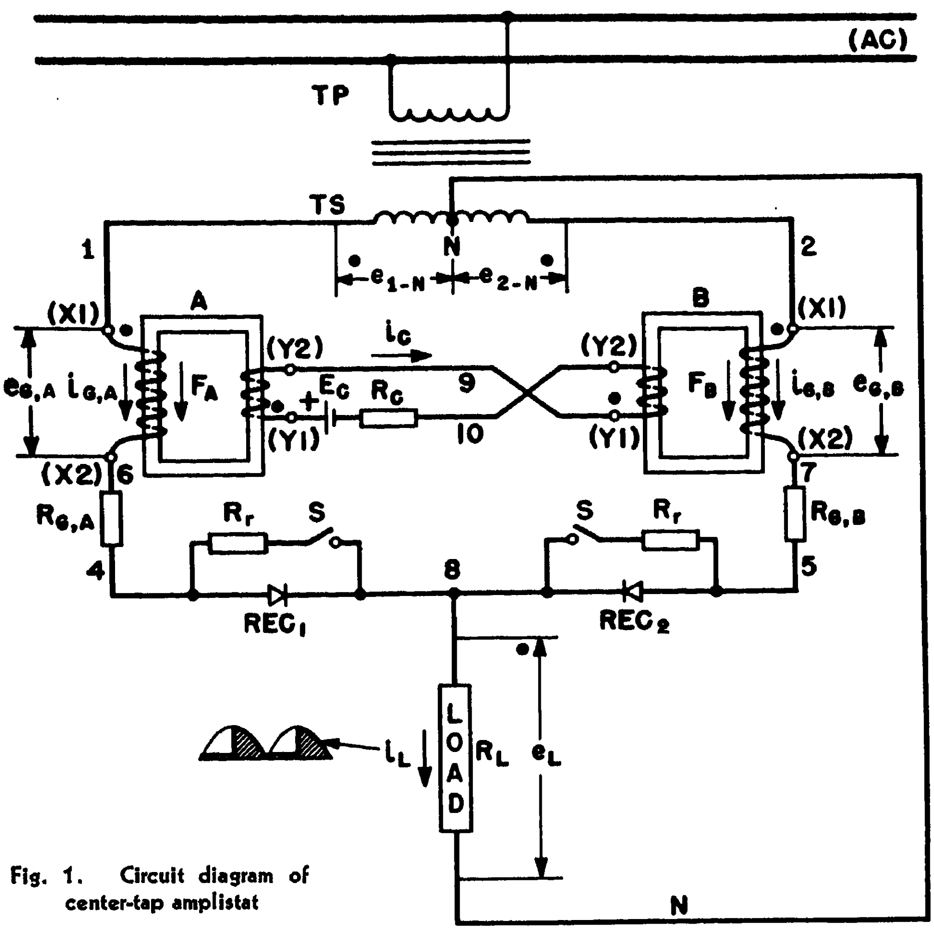

Fig. 1. Circuit diagram of center-tap amplistat

During the exciting interval $0<\omega t<\alpha$ the resistances encountered by the load current are neglected; during the saturation interval ($\alpha<\omega t<\pi$), the reactances encountered by the load current are neglected. The rectifiers have constant forward resistance, and the reverse resistance is considered infinite for the time being.

When referring to the B-H loop, the dynamic loop is always meant, relating flux densities B to exciting ampere-turns iN. This loop is obtained[6-8] by the energization of core A or B with a sinusoidal voltage e_{1-N}

$$e_{1-N}=\frac{\pi}{2}E\sin\omega t \qquad (1)$$

and frequency f

$$\omega=2\pi f \qquad (2)$$

at which the operation of the amplistat is to be investigated. Assuming a theoretical rectangular B-H loop, as shown in Fig. 2, the magnitude of the applied a-c voltage is just sufficient to cause a sinusoidal flux swing equal to the saturation flux Φ_s

$$E=4f\Phi_sN_G10^{-8} \qquad (3)$$

where

$$\Phi_s=B_sA_{Fe} \qquad (3A)$$

When dealing with a real B-H loop, B_s and Φ_s are replaced by the actual amplitudes of flux density and flux.

The exciting ampere-turns iN are usually expressed in the form

$$H=0.4\pi iN/l_{Fe} \qquad (4)$$

The actual magnetic intensity in the core is different from that expressed by equation 4 on account of eddy currents.[9] However, for purposes of circuit analysis, it is precisely the relation between flux and exciting ampere-turn which is of interest.

The ampere-turns indicated by the dynamic B-H loop for zero flux are called, for lack of a better term, coercive ampere-turns AT_c, and the magnetic intensity H_c produced by AT_c is called the coercive force

$$H_c=0.4\pi AT_c/l_{Fe} \qquad (5)$$

The symmetrical B-H loop is approximated by a rectangle, Fig. 2. The unsymmetrical hysteresis loops[10] are derived by preserving the top and the positions of the sides of the symmetrical B-H loop, and by varying the position of the horizontal bottom of the B-H loop.

Exciting Interval

It is assumed that at $\omega t=0$ the core flux $\phi_A=\Phi_1$ and the core flux $\phi_B=\Phi_s$, point 1, Figs. 2(A,2), 2(B,2). The line-to-neutral voltage e_{1-N} requires an increasing core flux ϕ_A in saturable reactor A

$$\Phi_A=\Phi_1+\int_0^{\omega t}e_{1-N}10^8N_G^{-1}d(\omega t) \qquad (6)$$

for $0\leqslant\omega t\leqslant\alpha$

and substituting from equations 1 and 3

$$\phi_A=\Phi_1+\Phi_s(1-\cos\omega t) \qquad (7)$$

for $0\leqslant\omega t\leqslant\alpha$

To make the rising flux ϕ_A possible, the operating point on the B-H loop of core A moves toward the right from 1 to 2, Fig. 2(A,2); this path, being horizontal, indicates that the gate winding A will not exhibit inductance. Since the circuit resistance is assumed to be zero during the exciting interval, the gate current $i_{G,A,x}$ increases abruptly, as illustrated in Fig. 2(A,4). During the same interval, the exciting gate current $i_{G,B,x}$ of saturable reactor B, Fig. 2(B,4) is zero because of the blocking action of rectifier REC_2, Fig. 1, and the absence of any induced voltage from saturable reactor A.

When the current $i_{G,A,x}$ has increased to such a value that its ampere-turns $i_{G,A,x}N_G$ equal the coercive ampere-turns AT_c, the vertical ascending part of the B-H loop, Fig. 2(A,2), is reached at point 2. The time is still $\omega t=0$. The flux ϕ_A becomes ready to increase along the vertical side 3–4 and saturable reactor A can function as a transformer. The gate voltage $e_{G,A}$ being now identical with the supply voltage e_{1-N} is transformed into the control circuit. As a result, control current i_C will flow, moving operating point 2, Fig. 2(B,2), on the B-H loop of saturable reactor B toward 3. Because 2–3 is horizontal, the inductance of the control winding of saturable reactor B is zero and the control ampere-turns i_CN_C increase abruptly until $i_CN_C=-AT_c$, Fig. 2(L,5), assuming negligible control-circuit resistance. To maintain in saturable reactor A net ampere-turns equal to AT_c, exciting gate ampere-turns $i_{G,A,x}N_G$ must increase to $2AT_c$, from point 2 to 3, Fig. 2(A,4).

At point 3 the vertical, descending branch of the B-H loop of core B is reached. Neglecting the voltage drop in the control circuit, gate voltage $e_{G,A}$, transformed into saturable reactor B, causes a core flux ϕ_B.

$$\phi_B=\Phi_s\cos\omega t \qquad (8)$$

for $0\leqslant\omega t\leqslant\alpha$

As a further result of this transformation, voltage $e_{G,B}$, Fig. 2(B,1), appears across the terminals of the gate winding of saturable reactor B. It will be seen from equations 7 and 8 that core flux ϕ_B

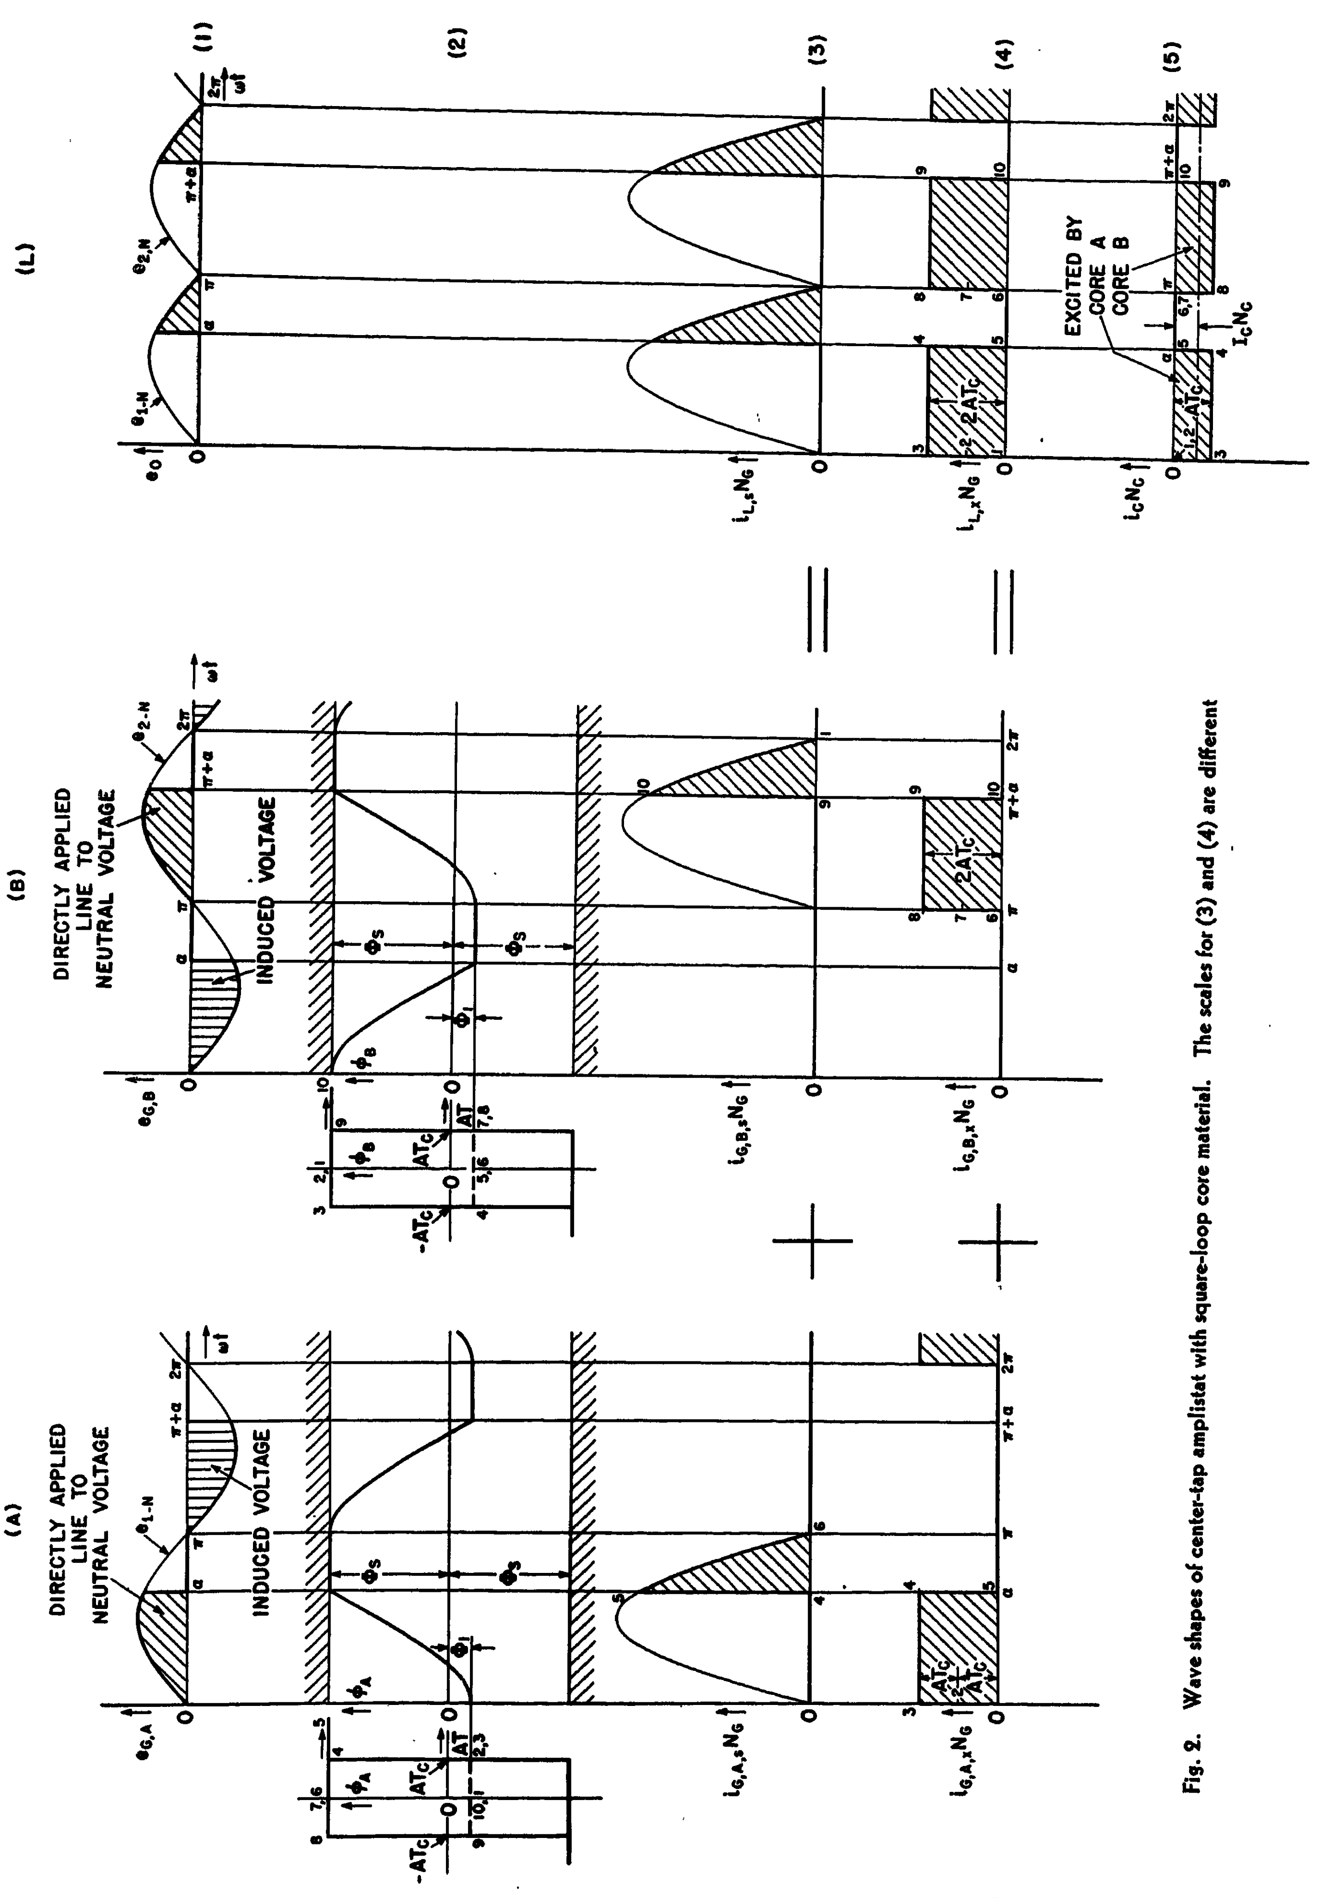

Fig. 2. Wave shapes of center-tap amplistat with square-loop core material. The scales for (3) and (4) are different

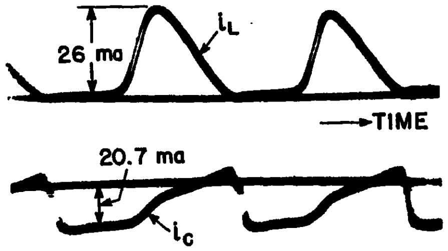

Fig. 3. Oscillogram of load current i_L and control current i_C

decreases toward 4, Fig. 2(B,2), at the same rate at which flux ϕ_A increases toward 4, Fig. 2(A,2).

Saturation Interval

At $\omega t=\alpha$, flux ϕ_A reaches saturation and the gate current, now designated by $i_{G,A,s}$ becomes limited by the nominal output resistance R_0 only, Fig. 2(A,3). The saturation component $i_{G,A,s}$ is usually several decades larger than the exciting component $i_{G,A,x}$ and therefore the saturation components $i_{G,A,s}$ and $i_{G,B,s}$ are shown Fig. 2(A,3) and 2(B,3), on different scales. For $\omega t>\alpha$ the gate ampere-turns of saturable reactor A swing way into the saturation branch 5, Fig. 2(A,2), of the B-H loop and return as the line voltage decreases. At $\omega t=\pi$, the gate ampere-turns $i_{G,A,s}N_G$ are again zero, and point 6 is reached.

In practice, the front of the gate current is not vertical, and the rising gate current produces by mutual induction a negative voltage in the control circuit. Then with the gate current declining, a positive voltage is induced in the control circuit. It is obvious that the rigorous tracking of the flux and control current may become quite complicated. For reasons of simplicity, it will be assumed that during the saturation interval the flux in the unsaturated core remains constant and the average value of the control current is zero. This condition is borne out by the oscillogram in Fig. 3; for different saturation angles, different core materials, and different core constructions, the agreement may not be as close. A further simplification is introduced by assuming the instantaneous values of the control current as zero during the saturation interval, Fig. 2(L,5).

At $\omega t=\pi$ the cores have traded their positions on the B-H loop with respect to $\omega t=0$; during the following half cycle, $\pi<\omega t<2\pi$, the events are analogous to those of the previous half cycle. The total gate ampere-turns are obtained by adding sections (A,3) to (B,3) and (A,4) to (B,4) in Fig. 2 after applying the proper scale factors. The total load current is obtained by adding all gate currents, Figs. 2(L,3), 2(L,4).

An oscillogram of load current i_L and control current i_C is shown in Fig. 3; the applied control voltage E_C is pure d-c. The test specimen consists of two spiral cores, having an outside diameter of $1^{25}/_{32}$ inches, and an inside diameter of $1^{15}/_{32}$ inches, a width of 1/2 inch, $e_{Fe}=$ 12.96 centimeters (cm), $A_{Fe}=0.457$ cm^2, a thickness of nickel alloy laminations of 0.002 inch, B-H loop at 60 cycles per second, according to Fig. 4; $N_G=1{,}000$ turns, $N_C=50$ turns; to eliminate reverse current, a tube rectifier *6AL5* is used. The excursion of the control current i_C is 20.7 milliamperes (ma) according to the oscillogram shown in Fig. 3, which value checks closely with equation 5. It will be noticed that the actual control current does not show as abrupt changes as the theory, Fig. 2(L,5), indicates, the mutual inductance between gate and control windings during the saturation interval; the mutual inductance is largely caused by the finite slope of the B-H loop in the saturation region.

Nominal Output Voltage E₀

The nominal output voltage e_0 is defined as the active voltage during the saturation interval

$$e_0=e_{1-N} \qquad e_0=e_{2-N} \tag{9}$$

$$\text{for } \alpha\leqslant\omega t\leqslant\pi \qquad \text{for } \alpha+\pi\leqslant\omega t\leqslant 2\pi$$

then the average nominal output voltage E_0 becomes, as shown in equations 9 and 1

$$E_0=\frac{1}{\pi}\int_\alpha^\pi \frac{\pi}{2}E\sin\omega t d(\omega t)=\frac{1+\cos\alpha}{2}E \tag{10}$$

where α is the angle at which saturation starts.

Load Current I_L

The load i_L consists of two parts: the saturation load current $i_{L,s}$ and the exciting load current $i_{L,x}$ as shown in Figs. 2 (L,3 and 4)

$$i_L=i_{L,s}+i_{L,x} \tag{11}$$

The saturation load current $i_{L,s}$ is

$$i_{L,s}=e_0/R_0 \tag{12}$$

where R_0 is called the nominal output resistance. The average value $I_{L,s}$ follows from equation 10

$$I_{L,s}=\frac{E}{R_0}\frac{1+\cos\alpha}{2} \tag{13}$$

The exciting load ampere-turns $I_{L,x}N_G$ are, as shown in Fig. 2(A,4), 2(B,4), and 2(L,4)

$$I_{L,x}N_G=2AT_c\frac{\alpha}{\pi} \tag{14}$$

From equations 11, 13, and 14 one finally obtains the average value of the load current I_L

$$I_L=I_{L,s}+I_{L,x}=\frac{E}{R_0}\frac{1+\cos\alpha}{2}+2AT_c\frac{\alpha}{\pi}\frac{1}{N_G} \tag{15}$$

Control Current

From Figs. 2(L,4 and 5), and equation 14, control ampere-turns I_CN_C are

$$I_CN_C=-\frac{1}{2}I_{L,x}N_G=-AT_c\frac{\alpha}{\pi} \tag{16}$$

hence

$$\alpha=-\frac{I_CN_C}{AT_c}\pi \tag{17}$$

Control Characteristic

By substituting equation 5 in 17, and equation 17 in 15, the load current as function of the control ampere-turns is obtained

$$\boxed{\begin{gathered} I_L=\underbrace{\frac{E}{R}\frac{1+\cos\dfrac{0.4I_CN_C}{H_cl_{Fe}}\pi}{2}}_{I_{L,s}}\underbrace{-2\frac{I_CN_C}{N_G}}_{I_{L,x}} \\ \text{for } -\frac{H_cl_{Fe}}{0.4\pi N_C}\leqslant I_C\leqslant 0 \end{gathered}} \tag{18}$$

It can be recognized that the load current consists of a cosine function $I_{L,s}$ and a linear function $I_{L,x}$ of the control ampere-turns.

Except in the vicinity of $\alpha=\pi$, the predominant component is $I_{L,s}$. One concludes that the control characteristic will look very much like a cosine function and that the slope of the control characteristic is inversely proportional to coercive force H_c of the dynamic B-H loop.

Exciting Current and Lower End of Control Characteristic

For $\alpha=\pi$, $I_{L,s}=0$; the load current equals $I_{L,x}$ which, for $\alpha=\pi$, is called exciting current I_E, equations 18, 16, and 5

$$I_{L,x}=I_E=\frac{2AT_c}{N_G}=\frac{2H_cl_{Fe}}{0.4\pi N_G} \tag{19}$$

for $\alpha=\pi$

This is the same exciting current as is obtained when the reactor is connected as an ordinary, parallel-connected, saturable reactor.

When connected as amplistat, the con-

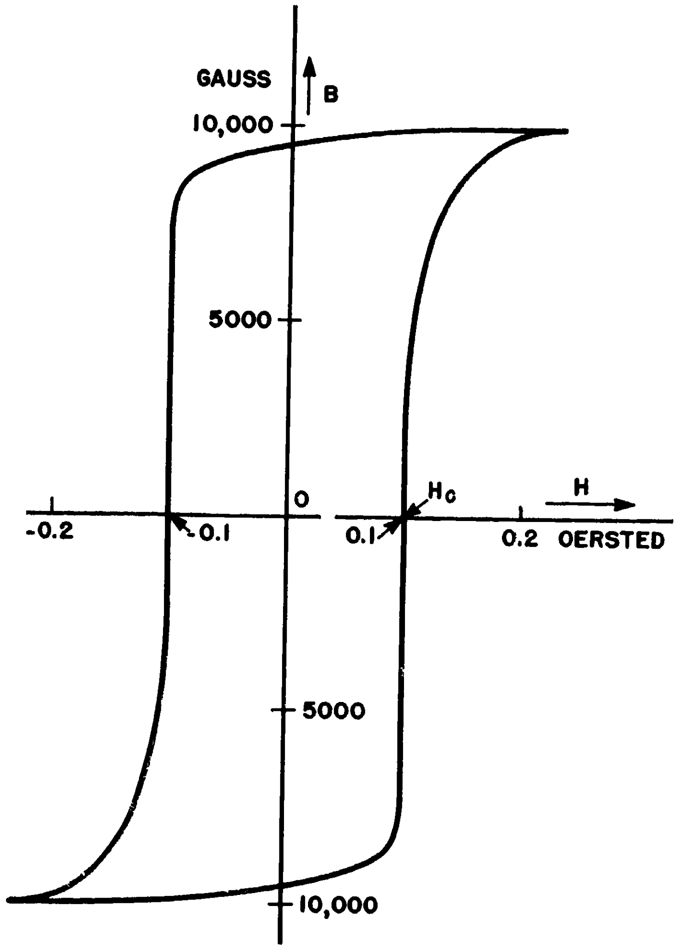

Fig. 4. Dynamic hysteresis loop, taken with sinusoidal voltage at 60 cycles per second

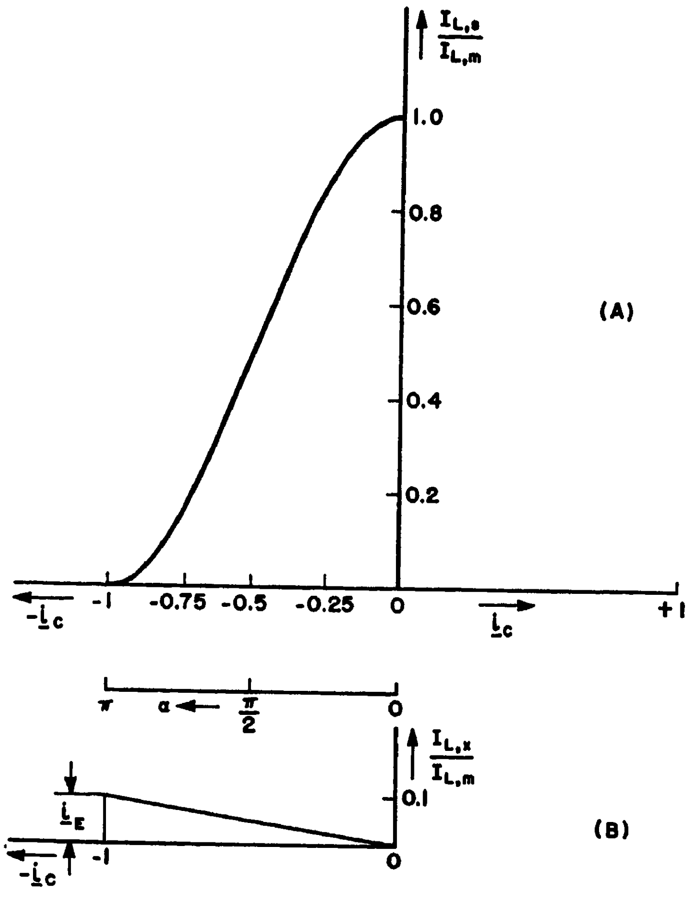

Fig. 5. Synthesis of control characteristic. (A) Per-unit saturation component of load current. (B) Per-unit exciting component of load current versus per unit control current

trol ampere-turns, which are necessary for the lower end of the control characteristic $\alpha=\pi$, $I_L=I_E$, point M in Fig. 5, follow from equations 16 and 5

$$\boxed{I_C N_C = -\frac{H_c l_{Fe}}{0.4\pi} \quad \text{for } \alpha=\pi} \tag{20}$$

These control ampere-turns can also be expressed by the exciting current, equation 16, $I_{L,x}=I_E$

$$\boxed{I_C N_C = -\frac{1}{2} I_E N_G \quad \text{for } \alpha=\pi} \tag{21}$$

Depending on whether H_c or I_E has been determined by direct measurement, equation 20 or 21 respectively is preferable.

Nondimensional (Normalized) Control Characteristic

When expressed in nondimensional form, the control characteristic of any amplistat with square-loop core material can be expressed, as far as the saturation component is concerned, by the same curve (cosine function). The only variation may occur because of the (linear) exciting component, the latter being usually very small.

Let us denote the per-unit control current of an amplistat by $\mathfrak{i}_C$ and define

$$\mathfrak{i}_C = \frac{I_C N_C}{H_c l_{Fe}/0.4\pi} \tag{22}$$

Further, let the per unit basis for the load and exciting currents be the load current $I_{L,m}$ obtained from equation 15 by letting $\alpha=0$

$$I_{L,m} = E/R_0 \tag{23}$$

then the control characteristic of the per unit saturation component $I_{L,s}/I_{L,m}$ becomes for any amplistat, Fig. 5(A)

$$\frac{I_{L,s}}{I_{L,m}} = \frac{1+\cos \mathfrak{i}_C \pi}{2} \tag{24}$$

The control characteristic of the per unit exciting component $I_{L,x}$ is obtained by substituting equation 19 in 15; and equations 16, 22, and 5

$$\mathfrak{i}_C = -\frac{\alpha}{\pi} \tag{25}$$

$$\frac{I_{L,x}}{I_{L,m}} = -\frac{I_E}{I_{L,m}} \mathfrak{i}_C \tag{26}$$

Finally, denoting by $\mathfrak{i}_E$, the per-unit exciting current

$$\mathfrak{i}_E = \frac{I_E}{I_{L,m}} \tag{27}$$

one obtains for the per-unit exciting component $I_{L,x}/I_{L,m}$

$$\boxed{\frac{I_{L,x}}{I_{L,m}} = -\mathfrak{i}_E \mathfrak{i}_C} \tag{28}$$

as illustrated in Fig. 5(B). The total control characteristic is obtained by adding $I_{L,x}/I_{L,m}$ to $I_{L,s}/I_{L,m}$ as in Fig. 6.

With increasing size of the saturable reactor, the per-unit exciting current $\mathfrak{i}_E$ declines. Amplistats of 100 watts output, 60 cycles per second, may be expected to have an $\mathfrak{i}_E$ within 0.01 to 0.03.

Validity Check

To obtain a check for exciting current I_E, the previously mentioned reactor is connected as an ordinary, parallel-connected, saturable reactor. The applied voltage follows from equations 3 and 3(A) $E=4\times60\times0.457\times10{,}000\times1{,}000\times10^{-8}=10.9$ volts at 60 cycles per second. The exciting current is measured $I_E=2.2$ milliamperes. Calculating the exciting current from equation 19 results in $2\times0.1\times12.96/(0.4\pi\times1{,}000)=2.04$ ma. Connecting the saturable reactor into the circuit of Fig. 1, and fully saturating the reactors, one obtains by measurement $I_{L,m}=22$ milliamperes, hence $R_0=10.9/.022$ amperes$=495$ ohms, equation 23. The per unit exciting current $\mathbf{i}_E=2.2$ ma/22 ma$=0.1$ as shown in Fig. 5(B). Adding the two components results in the characteristic drawn in full line in Fig. 6; actually measured points are shown by circles in the same illustration.

In many practical cases, the agreement between theoretical and practical characteristics may not be as good as shown in Fig. 6, because some of the assumptions leading to this theory are not sufficiently fulfilled in practice. On the other hand, it can be shown that if the B-H loop is not a rectangle, but a parallelogram with sloping sides and horizontal top and bottom, the slope of the control characteristic at $I_{L,s}/I_{L,m}=0.5$ (midcharacteristic) is still the same as for the case with rectangular B-H loop; the aforementioned statement is restricted to slopes of the B-H loop larger than the square-loop permeability μ_{sq}, equation 52.

Negative Region

The control characteristic in the negative region is approximated without further proof by

$$I_L=\frac{1}{2}I_E-I_CN_C/N_G \tag{29}$$

$$\text{for}\quad\left(-I_{L,m}+\frac{H_cl_{Fe}}{0.4\pi N_G}\right)\frac{N_G}{N_C}\leqslant I_C\leqslant-\frac{H_cl_{Fe}}{0.4\pi N_C}$$

The normalized characteristic is the extension of the straight line, S (1,0) to M $(-1, \mathbf{i}_E)$, as illustrated in Fig. 6.

Ampere-Turn Gain

By definition, the ampere-turn gain $K_{AT}=$

$$K_{AT}=\frac{dI_L}{dI_C}\frac{N_G}{N_C} \tag{30}$$

As in equation 15, K_{AT} can be split into saturation component $K_{AT,s}$ and exciting component $K_{AT,x}$

$$K_{AT,s}=\frac{dI_{L,s}}{dI_C}\frac{N_G}{N_C} \tag{31}$$

$$K_{AT,x}=\frac{dI_{L,x}}{dI_C}\frac{N_G}{N_C} \tag{32}$$

$$K_{AT}=K_{AT,s}+K_{AT,x} \tag{33}$$

By differentiating equation 15 and substituting from equations 23, 27, and 19, one obtains for the positive region of the control characteristic

$$K_{AT,s}=\frac{1}{\mathbf{i}_E}\pi\sin\alpha \tag{34}$$

$$K_{AT,x}=-2 \tag{35}$$

$$\boxed{K_{AT}=\frac{1}{\mathbf{i}_E}\pi\sin\alpha-2} \tag{36}$$

In the negative region, equation 29

$$K_{AT}=-1 \tag{37}$$

With the ampere-turn established, the current gain $K_I=dI_L/dI_C$ can be easily calculated for any given turns ratio.

It is interesting to note that the ampere-turn gain is an index to the effectiveness of the amplistat circuit over the ordinary, parallel-connected saturable-reactor circuit. The latter has a constant ampere-turn gain[11] of 2. The ratio $K_{AT,s}/2$ therefore indicates the factor by which the amplistat circuit increased the ampere-turn gain of the ordinary saturable-reactor circuit, neglecting the exciting currents. If one averages $K_{AT,s}$ over the entire control range, equation 34, this average $K_{AT,savg}$ equals $2/\mathbf{i}_E$. On this basis, the amplistat increased the ampere-turn gain of the saturable reactor by the factor $1/\mathbf{i}_E$. This leads to the conclusion that the effectivness of the amplistat circuit is controlled by $1/\mathbf{i}_E$, and from this point of view a low per unit exciting current $\mathbf{i}_E$ is most desirable.

Power Gain

The power gain K_P is defined by

$$K_P=\left(\frac{dI_L}{dI_C}\right)^2\frac{R_L}{R_C}k_f^2 \tag{38}$$

Substituting from equation 30, the power gain can be expressed by the ampere-turn gain

$$K_P=K_{AT}^2\frac{R_L}{R_C}\left(\frac{N_C}{N_G}\right)^2k_f^2 \tag{39}$$

Substituting from equation 36 into 39, one obtains for the power gain

$$\boxed{K_P=\left(\frac{1}{\mathbf{i}_E}\pi\sin\alpha-2\right)^2\frac{R_L}{R_C}\left(\frac{N_C}{N_G}\right)^2k_f^2} \tag{40}$$

One concludes that a small per-unit exciting current $\mathbf{i}_E$ is conducive to a high power gain. In the linear region (vicinity of $\alpha=\pi/2$), the power gain is approximately inversely proportional to the square of the per-unit exciting current $\mathbf{i}_E$.

Time Constant

With no circuits, including eddy currents, coupled to the control windings, time constant T in the positive region is[12]

$$T=\frac{1}{2f}K_E\frac{N_C}{N_G} \tag{41}$$

where $K_E=$the nominal voltage gain

$$K_E=\frac{dE_O}{dE_C} \tag{42}$$

and

$$E_C=I_CR_C \tag{43}$$

From equations 10, 16, 19, 41, 42, and 43 one obtains the time constant

$$\boxed{T=\frac{1}{2f}\frac{1}{I_E}\frac{E}{R_C}\left(\frac{N_C}{N_G}\right)^2\pi\sin\alpha} \tag{44}$$

The time constant varies with the angle α, being a maximum in the linear part $\alpha=\pi/2$ of the control characteristic. The time constant can be calculated from the exciting current I_E, which is, as previously mentioned, easily obtainable from measurement.

If a control characteristic is available, the time constant can be obtained from the ampere-turn gain.[13] First, the voltage gain and the saturation ampere-turn gain can be related by equations 10, 13, 31, 42, and 43

$$K_E=K_{AT,s}\frac{N_C}{N_G}\frac{R_O}{R_C} \tag{45}$$

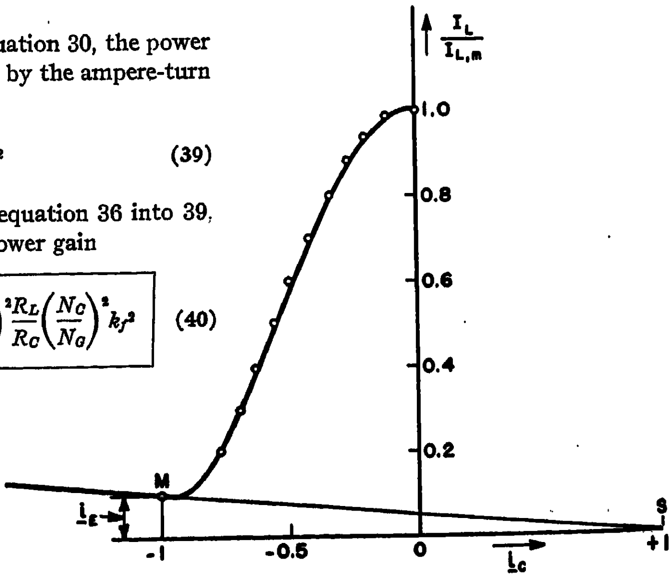

Fig. 6. Control characteristic for amplistat ($\mathbf{i}_E=0.1$). Solid curve from theory, Fig. 5; dots indicate measured points

Table I. Effect of Saturation Flux Density Bs, Coercive Force Hc, and Square-Loop Permeability μ_{sq} on Performance of Magnetic Amplifier

Operation of Magnetic Amplifier with	Power Output P_L	Power Gain K_P	Time Constant T	Dynamic Power Gain D_P
	are Proportional to			
Maximum power transfer	B_s^2	$\left(\frac{B_s}{H_c}\right)^2=\mu_{sq}^2.$	$\frac{B_s}{H_c}=\mu_{sq}$	$\frac{B_s}{H_c}=\mu_{sq}$
Maximum winding temperature	$(2B_s-B_{s,1})B_s.$	$\frac{(2B_s-B_{s,1})B_s.}{H_c^2}$	$\frac{B_s}{H_c}=\mu_{sq}$	$\frac{\left(2-\frac{B_{s,1}}{B_s}\right)B_{s,1}}{H_c}$

With equations 30, 31, 32, and 41 one obtains

$$\boxed{T=\frac{1}{2f}K_{AT}\frac{R_O}{R_C}\left(\frac{N_C}{N_G}\right)^2(1+\kappa)} \qquad (46)$$

where

$$\kappa=\frac{-K_{AT,x}}{K_{AT}}=\frac{\mathfrak{i}_E}{\frac{\pi}{2}\sin\alpha-\mathfrak{i}_E} \qquad (47)$$

Equations 44 and 46 are not recommended for the lower portion of the control characteristic. There, the actual performance of the amplistat becomes a mixture of the performance in the positive and the exciting region (vicinity of $\alpha=\pi$). Since the transient response in the exciting region may vary over a wide range, depending on the per unit excitation and the magnitude of the control voltage, the time constant of the magnetic amplifier cannot be dependably described by the method given when approaching or operating in the exciting region.

Dynamic Power Gain

The dynamic power gain D_P is defined by[14]

$$D_P=K_P/T \qquad (48)$$

From equations 39 and 46 is obtained

$$\boxed{D_P=2fK_{AT}\frac{R_L}{R_O}\frac{1}{1+\kappa}k_f^2} \qquad (49)$$

The ratio R_L/R_O is subject only to minor variations, namely, from 0.5 for small reactors to 0.8 to 0.9 for large reactors. The term $1+\kappa$ usually is near unity in the linear region. Hence, the only dominating terms are frequency f and ampere-turn gain K_{AT}.

At a given frequency, the ampere-turn gain is a basic parameter indicating the dynamic power gain.

Substituting into equation 49 from 36, and 47

$$\boxed{D_P=2f\frac{1}{\mathfrak{i}_E}\frac{R_L}{R_O}\frac{1}{(1+\kappa)^2}\pi\sin\alpha k_f^2} \qquad (50)$$

One recognizes again the key position of per unit exciting current $\mathfrak{i}_E$. The smaller $\mathfrak{i}_E$ of the saturable reactor, the higher is the dynamic power gain of the amplistat circuit.

In view of the importance of per unit exciting current $\mathfrak{i}_E$, it is expressed in terms of core parameters. Utilizing equations 27, 23, 3, 3(A), and 19

$$\boxed{\mathfrak{i}_E=R_O\left(2f0.4\pi\frac{B_s}{H_c}\frac{A_{Fe}}{l_{Fe}}N_G^2 10^{-8}\right)^{-1}} \qquad (51)$$

The ratio B_s/H_c is called the square-loop permeability μ_{sq}

$$\mu_{sq}=B_s/H_c \qquad (52)$$

When determining μ_{sq} from a real B-H loop, the term B_s in equation 52 is replaced by the amplitude of the actual flux density.

The square-loop permeability is an abstract quantity; it shall not be construed that the performance of a square-loop core material can be approximated by a single-valued, straight B-H line with the slope of μ_{sq}. The practical significance of μ_{sq} can be observed from Table I.

Evaluation of Core Properties

The most important properties of magnetic amplifiers usually are: power output P_L, power gain K_P and time constant T, the latter two quantities being expressed by the dynamic power gain D_P. To evaluate the effect of core material, the procedure will be to replace one core material in the saturable reactor by another core material without causing any change in the core configuration. The core materials will be described by the saturation flux density B_s and the coercive force H_c of the dynamic hysteresis loop. The following evaluation is based on the assumptions outlined at the beginning of the paper. It is recognized that for accurate design calculations more information regarding core and core materials is necessary; however, for an analysis of first-order effects, B_s and H_c will be considered sufficient.

Power Output P_L

To obtain maximum power transfer, the load must be matched to the gate winding of the saturable reactor and the rectifier. With matched, that is, constant load resistance, and a core material of higher saturation flux density B_s, the line voltage E can be increased in proportion, equations 3 and 3(A); the power output will increase by E^2 and B_s^2 respectively. As the result of increased load current, the winding temperature will increase and for a certain voltage, called E_1, corresponding to $B_{s,1}$, the maximum permissible temperature of the winding will be reached. If one wishes to replace the core material by another one such that $B_s>B_{s,1}$, the line voltage can again be increased; however, not to ex-

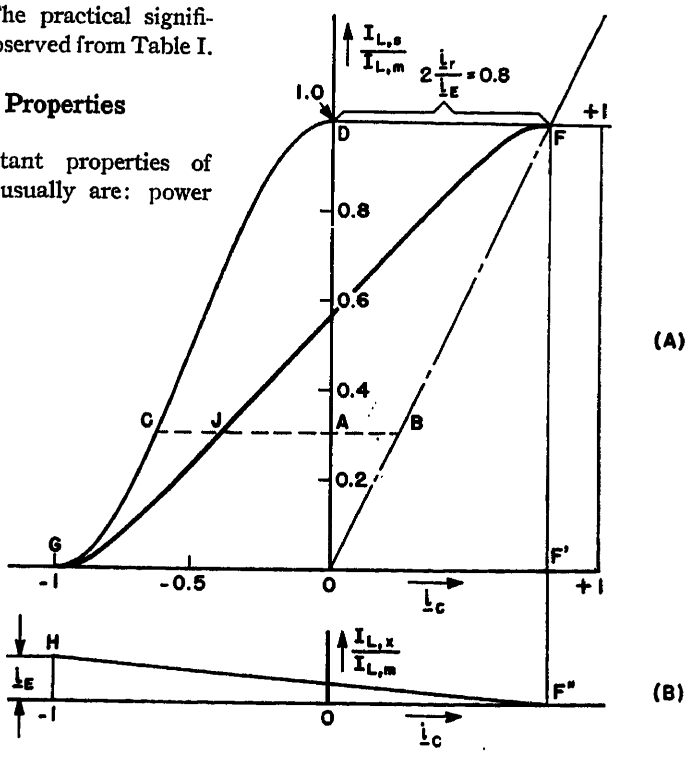

Fig. 7. Synthesis of the control characteristic in the presence of rectifier reverse current

ceed the maximum winding temperatures, the load current must be kept constant. This means that the load resistance R_L must be increased. It can be shown that the load resistance must increase according to $R_L/R_0=1-(1/2)E_1/E$. Then, the power output increases by $(2E-E_1)E_1$, and the corresponding flux density relations are shown in Table I.

Power Gain K_P

From equation 38 it is deduced that K_P is proportional to P_L and inversely proportional to I_C^2, and hence inversely proportional to H_c^2, equations 16 and 5.

Time Constant T

The time constant can be written in the following form, equations 44, 3, 3(A), and 19

$$T=0.4\pi\mu_{sq}\frac{A_{Fe}}{l_{Fe}}N_C^2 10^{-8}\frac{1}{R_C}\pi\sin\alpha \tag{53}$$

The time constant is proportional to the square-loop permeability μ_{sq}.

Dynamic Power Gain D_P

Dynamic power gain follows from equation 48; see Table I.

One of the conclusions is that a small coercive force H_c of the dynamic loop is always desirable, and that a high saturation flux density B_s is desirable in most cases.

An extension of this theory to the B-H loop with sloping sides but horizontal top and bottom indicates that a finite slope has no effect on the maximum power output, nor has a finite slope any effect on gain and time constant in the linear part (vicinity of $\alpha=\pi/2$) of the characteristic, provided the slope is not less than the square-loop permeability μ_{sq}.

Effects of Rectifier Reverse Current

Up to this point it has been assumed that the rectifiers did not pass any reverse current. To simulate effects of rectifier reverse current, the switches S in Fig. 1 are closed, thereby reducing the resistance of each reverse current path from infinity to R_r. The gate and rectifier forward resistance are lumped with the load resistance.

During the saturation interval, a reverse voltage appears across one of the rectifiers. For instance, during $\alpha<\omega t<\pi$, a voltage equal to $2e_0$ appears on REC_2 and the result is a reverse current $i_{G,r}$. Saturable reactor B is unsaturated and functions as a transformer, with the control circuit as the secondary

$$-i_{G,r}N_G=i_{C,r}N_C \tag{54}$$

Since the control-circuit resistance R_C is small, the voltage drop on R_C is small, and hence the rate of flux change $d\phi_B/dt$ is also small. As a result, the eddy currents will be comparatively small, and hence the B-H loop for the transformation of reverse current will, in general, be much narrower than shown in Fig. 4; for reasons of simplification, its width will be assumed zero for the transformation of reverse current.

As shown in the Appendix, the per unit control ampere-turns can be expressed by

$$\boxed{\mathfrak{i}_C=-\frac{1}{\pi}\operatorname{arc\,cos}\left(2\frac{I_{L,s}}{I_{L,m}}-1\right)+2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}\frac{I_{L,s}}{I_{L,m}}} \tag{65}$$

with $\mathfrak{i}_r$ being the per unit reverse current, equation 60. This equation permits the rapid construction of the control characteristic. The first addend of equation 65 (Fig. 7, *GCD*) is identical with the cosine function of Fig. 5(A); the second addend represents a straight line *OF* (Fig. 7), such that $DF=2\mathfrak{i}_r/\mathfrak{i}_E$. By adding the abcissas (by making $CJ=AB$), one obtains quickly the characteristic *GJF*, representing the saturation component of the load current in the presence of reverse current.

One recognizes that the reverse current causes a reduction of gain[15]; furthermore, reverse current makes the characteristic cross the ordinate axis. The higher the reverse current, the lower is the crossing point. If rectifiers are used whose reverse current varies with temperature and age, the control characteristic will vary accordingly.

If one wishes to add the exciting component $I_{L,x}/I_{L,m}$, the characteristic of Fig. 5(B) is stretched to cover the new base GF', Fig. 7

$$\boxed{\frac{I_{L,x}}{I_{L,m}}=\mathfrak{i}_E\left(2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}-\mathfrak{i}_C\right)\Big/\left(2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}+1\right)} \tag{66}$$

The total characteristic (not shown in Fig. 7) is obtained by adding the ordinates

$$\frac{I_L}{I_{L,m}}=\frac{I_{L,s}}{I_{L,m}}+\frac{I_{L,x}}{I_{L,m}} \tag{67}$$

One of the most important effects of rectifier reverse current is a reduction of gain. Let us call the saturation ampere-turn gain with rectifier reverse current $K_{AT,s,r}$ and without reverse current $K_{AT,s,o}$, then one obtains from the geometry of Fig. 7, equation 34, and for the linear region, $\alpha=\pi/2$

$$\boxed{\frac{K_{AT,s,r}}{K_{AT,s,o}}=\frac{1}{1+\pi\dfrac{\mathfrak{i}_r}{\mathfrak{i}_E}}} \tag{68}$$

It is important to recognize that the gain reduction is caused by the ratio $\mathfrak{i}_r/\mathfrak{i}_E$. When cores of higher performance (smaller $\mathfrak{i}_E$) are used, rectifiers of lower reverse current (smaller $\mathfrak{i}_r$) must be applied if one does not wish a disproportionate gain reduction. Furthermore, since rectifier reverse current is usually proportional to the area of the rectifier, the application of a rectifier which is rated for a current in excess of the actual current produces more reduction of gain.

The reduction ratio of equation 68 applies as a good approximation not only to the ampere-turn gain, but also to the time constant, equation 44, $\alpha=\pi/2$, and the dynamic power gain, equation 50, $\alpha=\pi/2$. To obtain the power gain, equation 40, the square of the reduction ratio is applied. When determining power gain and dynamic gain from equations 39 and 49, the reduction ratio does not enter these equations.

The ampere-turn gain $K_{AT,s,r}$ in the presence of reverse current can be calculated for the linear part of the characteristic from equations 68 and 34

$$\boxed{K_{AT,s,r}=\frac{1}{\dfrac{\mathfrak{i}_E}{\pi}+\mathfrak{i}_r}} \tag{69}$$

It is recognized that core and rectifier quality jointly determine the performance of the amplistat. There is little to be gained by using a high-performance core (small $\mathfrak{i}_E$) together with low-quality rectifiers (large $\mathfrak{i}_r$). To realize the full advantage of high-performance cores, such cores must be matched to rectifiers of correspondingly small reverse current.

Appendix

The reverse gate current $i_{G,r}$ can be approximated by the reverse voltage e_r

$$i_{G,r}=e_r/R_r \tag{55}$$

The reverse voltage =

$$e_r=-2e_0 \tag{56}$$

and the average reverse gate current

$$I_{G,r}=\frac{1}{\pi}\int^{\pi}i_{G,r}d(\omega t)=\frac{1}{\pi}\frac{1}{R_r}\times\int_{\alpha}^{\pi}e_r d(\omega t)=-2\frac{E_0}{R_r} \tag{57}$$

From equations 54 and 57

$$2\frac{E_0}{R_r}N_G=I_{C,r}N_C \tag{58}$$

The maximum, average reverse current $I_{r,m}=$

$$I_{r,m}=-2E/R_r \tag{59}$$

Let us denote by $\mathfrak{i}_r$ the per-unit reverse current

$$\frac{|I_{r.m}|}{I_{L,m}}=\mathfrak{i} \tag{60}$$

From equations 23 and 59*

$$R_0/R_r=\frac{1}{2}\mathfrak{i}_r \tag{61}$$

Substituting into equation 58 for $E_O=I_{L,s}R_O$, equation 12, and from equation 61, one obtains the control ampere turns caused by reverse current

$$I_{C,r}N_C=\mathfrak{i}_r I_{L,s}N_G \tag{62}$$

The control ampere-turns in the absence of reverse current are (equations 13, 23, 17, 16, and 19)

$$I_CN_C=\frac{H_cl_{Fe}}{0.4\pi}\left[-\frac{1}{\pi}\text{arc cos}\left(2\frac{I_{L,s}}{I_{Lm}}-1\right)\right] \tag{63}$$

In the presence of reverse current, the total control ampere-turns are obtained as the sum of the control ampere-turns, equations 62 and 63. In view of equations 19 and 27 one obtains for the total control ampere-turns

$$I_CN_C=\frac{H_cl_{Fe}}{0.4\pi}\left[-\frac{1}{\pi}\text{arc cos}\left(2\frac{I_{L,s}}{I_{L,m}}-1\right)+2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}\frac{I_{L,s}}{I_{L,m}}\right] \tag{64}$$

By substituting equation 22 into 64 one obtains

$$\mathfrak{i}_C=-\frac{1}{\pi}\text{arc cos}\left(2\frac{I_{L,s}}{I_{L,m}}-1\right)+2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}\frac{I_{L,s}}{I_{L,m}} \tag{65}$$

The per-unit exciting component is obtained by spreading the straight-line characteristic of Fig. 5(B) below the new characteristic $-1\leqslant\mathfrak{i}_C\leqslant 2\mathfrak{i}_r/\mathfrak{i}_E$

$$\frac{I_{L,x}}{I_{L,m}}=\mathfrak{i}_E\left(2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}-\mathfrak{i}_C\right)\Big/\left(2\frac{\mathfrak{i}_r}{\mathfrak{i}_E}+1\right) \tag{66}$$

The total per-unit load current becomes the sum of $I_{L,s}/I_{L,m}$ and $I_{L,x}/I_{L,m}$, equation 11. In the last derivation it has been tacitly assumed that the reverse current is so small with respect to the load current that its subtractive effect on the latter is negligible.

Discussion

Harold W. Lord (General Electric Research Laboratory, Schenectady, N. Y.): The analysis of the magnetic amplifier which Dr. Storm has presented is certainly a step forward in this field. The proof of its value lies in the very close agreement he shows in Fig. 6 between theory and measurement. I understand that Dr. Storm has obtained similar results for cores of several other materials.

I would like to show that this analysis has some limitations which, incidentally, Dr. Storm freely admits in his paper. It assumes the control current to be zero during the conduction period. A very rectangular hysteresis loop material which nearly conforms to this assumption is 65 Permalloy. A pair of 0.005-inch-thick strip-wound core specimens of such a material were used for checking the validity of Dr. Storm's analysis. They had static loop coercive forces of approximately 0.02 oersted, and 60-cycle dynamic loop coercive forces of approximately 0.17 oersted. In Fig. 8 the circles indicate experimentally determined test points. Curve *A* was calculated using equation 18. Curve *B* was calculated using a modification of his analysis, which is equivalent to shearing the top of the control characteristic curve to the left to an extent corresponding to the static coercive force, and using the difference between the dynamic and static coercive forces as the value for H_c in equation 18. Note that this minor modification improves the accuracy of the results for this type of material.

The use of this modification for materials having very rectangular static hysteresis loops of the order of 50 per cent of the dynamic loop widths were not so successful. Fig. 9 shows the results for 0.002-inch-thick strip-wound Deltamax cores having static coercive forces of approximately 0.09 oersted and 60-cycle dynamic coercive forces of approximately 0.17 oersted. The nomenclature is similar to that for Fig. 8.

The measured control curve for this material falls between the two calculated curves *A* and *B*. After observing this, a second modification of equation 18 was tried, which empirically gives a better fit for the very rectangular hysteresis loop materials. For this calculation, equation 18 was modified in a manner which is equivalent to shearing the top of the control characteristic curve to the left to an extent corresponding to one-half the static coercive force. The difference between the dynamic and one-half the static coercive forces was used as the value for H_c in equation 18. Curve *C* of Fig. 9 was calculated in this manner. This modification provided good checks with experimental curves for the several other very rectangular loop core materials tested.

This empirical approach was adopted after studying the manner in which the wave form of the current in the control circuit varied throughout the control range. Fig. 10 shows composite oscillograms of such current wave forms for the cores of 65 Permalloy and Deltamax referred to.

This demonstrates that an analysis which would account for the indicated changes in the wave form of the control current probably would be very complex and would involve, in addition to the static and dynamic hysteresis loops, such parameters as saturation-region permeabilities, initial permeabilities, and load currents. It is probable that one of the latter parameters, namely, saturation-region permeability, had sufficient magnitudes in the materials Dr. Storm used for validity checks to compensate in large measure for the effects of the static loop widths, thereby providing good checks of an analysis which neglects the effects of both of them.

D. G. Scorgie (Naval Research Laboratory, Washington, D. C.): This paper is on a very timely subject. In several recent papers[1–3] magnetic circuits with unique properties have been developed. In each case the unique circuit properties depend upon the square-loop characteristic or, more particularly, upon a high remanent flux in the magnetic cores. High permeability conserves input power but is not essential to proper circuit operation. Quite the contrary, for, with cores characterized by high permeability and low remanent flux, the circuits do not operate at all. As the title of Dr. Storm's paper indicates, he recognizes the disparity which exists, and the resulting need for developing a special theory of magnetic amplifiers where cores with high remanent flux are used.

Our remarks are concerned with additions

to, rather than changes in, the substance of what Dr. Storm has already said. The heart of his analysis lies in the two sections which discuss the exciting interval and the saturation interval. The control circuit resistance and control voltage were assumed negligible and the analysis showed that each half cycle the cores trade their positions on the B-H loop, thus describing a steady-state condition. It should be pointed out that under the basic assumptions the steady-state output current depends only upon the initial condition of saturation of the two cores. That is to say, if points 1 and 2, Fig. 2 (A, 2), were chosen at a different arbitrary flux level, the analysis would have shown a correspondingly different steady-state output current. As shown in Fig. 2, the average control current is determined by the point at which the saturation of core *B* occurs, hence is also determined by the initial conditions of core saturation. The relationship between output and control current given by equation 18 is valid for the assumed conditions. An interesting result is found when to the conditions assumed by Dr. Storm one adds current flow in a separate d-c bias winding. Instead of simply shifting the control characteristic bodily to the right, the bias current increases its slope. The magnitudes of both the exciting component and the saturation component, Fig. 5, are decreased at the lower end of the characteristic, leaving the upper end unaffected.

If $E_c=0$ and a small control circuit resistance R_c is introduced, control current flow through R_c causes a voltage drop in such a direction as to drive the amplifier to full saturation output. A negative E_c must be added to shut the amplifier off. Yet an analysis which takes into account E_c and

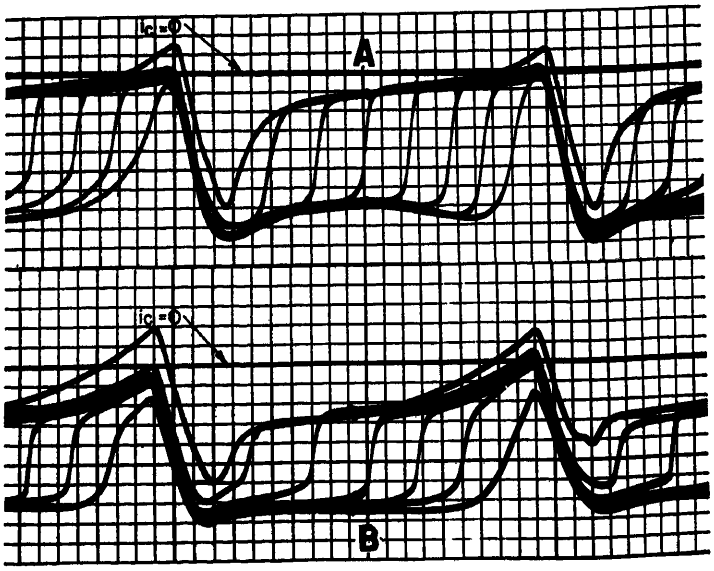

Fig. 10. Composite oscillograms of control circuit current

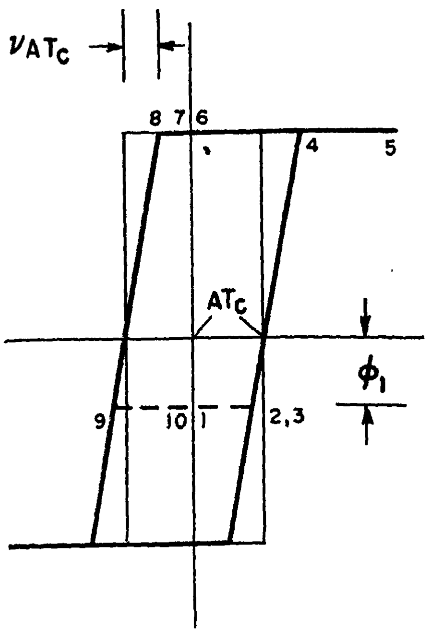

Fig. 11. Parallelogrammatic B-H loop

R_c as small but finite quantities reveals some strange behaviour for amplifiers with ideal rectifiers and perfectly square-loop cores. In fact one is forced to conclude that these idealized amplifiers have unstable regions in their voltage transfer characteristics. The substantiating argument is too lengthy to be given here but is included in a paper which has been submitted to the AIEE for publication in the *Transactions*. When one assumes a small fixed control resistance R_c and dries to derive a transfer characteristic between output and control voltages, the assumption of square-loop cores and perfect rectifiers leads to stability difficulty. This is not the triggering effect commonly observed in the lower portion of the transfer characteristic, but rather is a theoretically infinite voltage gain calculated over the entire range of outputs.

In practice there are other effects, mentioned by Storm in his section on rectifier leakage, which would prevent this infinite voltage gain even with square-loop cores, namely rectifier leakage and the narrowing of the B-H loop as the rate of change of flux decreases. When E_c is changed so as to increase the amplifier output, the B-H loops become slightly narrower and more back voltage is applied to the rectifier in series with the resetting core. The resulting change in the I_cR_c voltage drop is an effective negative voltage feedback which tends to reduce the voltage gain and prevent this type of instability.

In setting up the physical assumptions, E_c and R_c were assumed equal to zero while the current equations were derived. Later the derived control current was multiplied by R_c to determine E_c. This line of reasoning overlooks effects which can become important, especially in very high gain amplifiers. A more careful consideration of E_c and R_c would form a valuable addition to the literature.

R. A. Phillips (General Electric Company, Schenectady, N. Y.): With his clear-cut analytical approach, the author should dispel many false notions which have appeared in the literature in the past about the influence of the dynamic loop upon the control characteristic of a magnetic amplifier.

Dr. Storm mentions that, if the B-H loop is not a rectangle but a parallelogram with sloping sides and horizontal top and bottom, the slope of the saturation component of the control characteristic at $I_{L,s}/I_{L,m}=0.5$ (mid-characteristic) is the same as for the case with rectangular B-H loop. I feel that a short proof would be of help to others in the field. The complete control characteristic is also developed.

In the interest of brevity, I will use the author's equations directly where applicable. Actually it is necessary to write but three new equations and draw a B-H loop, shown in Fig. 11, where a new constant ν is defined. The exciting components of the load current in cores A and B are

$$i_{L,xA}=\frac{AT_C}{NG}\left[1+\frac{\phi_A}{\phi_s}\right]0\leqq\omega t\leqq\alpha \tag{70}$$

$$i_{L,xB}=\frac{AT_C}{N_G}\left[1-\frac{\phi_B}{\phi_s}\right]0\leqq\omega t\leqq\alpha \tag{71}$$

$$i_{L,x}=i_{L,xA}+i_{L,xB} \tag{72}$$

Substituting equations 70, 71, 7, and 8 into 72

$$i_{L,x}=\frac{AT_C}{N_G}\left[2+\left(\frac{\phi_1}{\phi_s}+1-2\cos\omega t\right)\right] \tag{73}$$

The average exciting component of load current is

$$I_{L,x}=\frac{1}{\pi}\int_0^\alpha i_{L,x}d(\omega t) \tag{74}$$

Substituting equation 73 into 74 and integrating

$$I_{L,x}=\frac{AT_C}{N_G}\left\{\left[(2+\nu)+\frac{\phi_1}{\phi_s}\right]\alpha-2\nu\sin\alpha\right\} \tag{75}$$

The quantity ϕ_1/ϕ_s may be determined by evaluating equation 8 at $\omega t=\alpha$. From this

$$\frac{\phi_1}{\phi_s}=\cos\alpha \tag{76}$$

Substituting equation 76 into 77

$$I_{L,x}=\frac{AT_C}{\pi N_G}(2+\nu)\alpha+\nu\alpha\cos\alpha-2\nu\sin\alpha \tag{77}$$

The saturation component is identical to equation 13

$$I_{L,s}=\frac{E}{2R_0}(1+\cos\alpha) \tag{78}$$

The control current which is flowing during the portion of the cycle for $0\leqq\omega t\leqq\alpha$ is

$$i_CN_C=-N_Gi_{L,xB} \tag{79}$$

Substituting equations 71 and 8 into 78

$$i_C=-\frac{AT_C}{N_C}1-\nu\cos\omega t \tag{80}$$

The average control current may be determined from an equation similar to 68

$$I_C=-\frac{AT_C}{\pi N_C}[\alpha-\sin\alpha] \tag{81}$$

Going now to per-unit quantities used by the author

$$\frac{I_{L,x}}{I_{L,m}}=\frac{\bar{i}_E}{2\pi}[(2+\nu)\alpha+\nu\alpha\cos\alpha-2\nu\sin\alpha] \tag{82}$$

$$\frac{I_{L,s}}{I_{L,m}}=\frac{1+\cos\alpha}{2} \tag{83}$$

$$\bar{i}_C=-\frac{1}{\pi}[\alpha-\nu\sin\alpha] \tag{84}$$

Equations 82, 83, and 84 readily reduce to those shown in the paper for $\nu=0$. Fig. 12 shows the results for $\nu=0.5$ as well for a comparison.

Ampere-turn gain may be readily determined by differentiating equations 77, 78, and 81 and substituting them into equations 31 and 32.

$$K_{AT,s}=\frac{1}{\bar{i}_E}\pi\left[\frac{\sin\alpha}{1-\nu\cos\alpha}\right] \tag{85}$$

$$K_{AT,x}=-\left[\frac{(2-\nu)-\nu\cos\alpha-\alpha\nu\sin\alpha}{1-\nu\cos\alpha}\right] \tag{86}$$

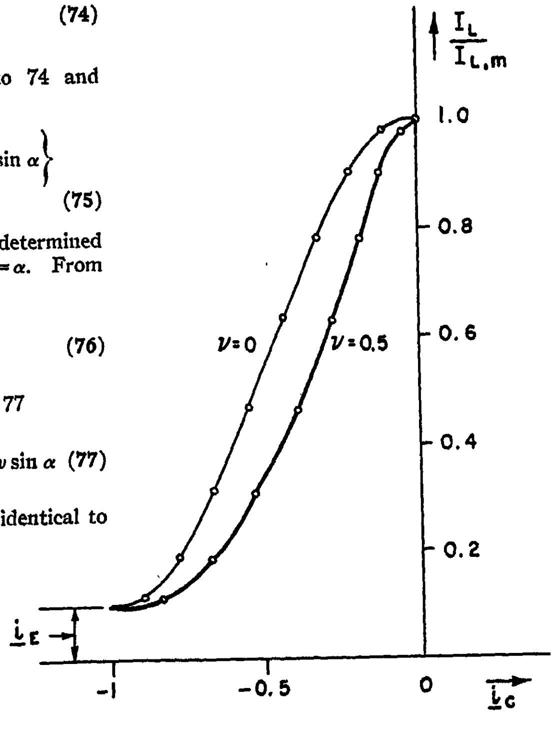

Fig. 12. Control characteristic for amplistat for $\nu=0$, 0.5

Table II

v	$K_{AT'S}$	$K_{AT'X}$
0	$\frac{\pi}{\mathfrak{i}_E}$	−2
0.5	$\frac{\pi}{\mathfrak{i}_E}$	−1.72
1.0	$\frac{\pi}{\mathfrak{i}_E}$	−1.43

At mid-characteristic ($\alpha=\pi/2$), equations 85 and 86 reduce to

$$K_{AT,s}\Big|_{\alpha=\frac{\pi}{2}}=\frac{\pi}{\mathfrak{i}_E} \qquad (87)$$

$$K_{AT,x}\Big|_{\alpha=\frac{\pi}{2}}=-(2-v)+\frac{\pi}{2} \qquad (88)$$

A tabular evaluation of equations 87 and 88 is shown in Table II. In a practical case $\mathfrak{i}_E$ lies between 0.01 and 0.1.

Several conclusions may now be drawn. Table II gives numerical values for the saturation component and the exciting component of ampere-turn gain. Since in the practical case exciting current is small, the contribution of $K_{AT,x}$ (the exciting component) to the total ampere-turn gain is decidedly a second-order effect. One may then say that the saturation component of the ampere-turn gain of a magnetic amplifier is not affected and the total ampere-turn gain is affected hardly at all by the deviation from the vertical of the steep sides of the B-H loop as long as the differential permeability of the steep sides of the B-H loop exceeds the square loop permeability, $\mu_{sq}(B_s/H_c)$. In a feedback control system the important thing about the shape of the control characteristic of a component magnetic amplifier is its slope over its operating region and not its position. Fig. 11 shows that the slope over the operating region (mid-characteristic) is changed very little by the sloping sides of the B-H loop.

In some magnetic materials the steep sides of the dynamic B-H loop actually have a negative slope. This analysis applies equally well for this case. The quantity takes on a negative value.

(The discusser is indebted to the students of the Electrical C Class of the General Electric Company's Advanced Engineering Program who first extended the analysis in the manner shown here as a homework assignment.)

H. F. Storm: I wish to thank R. A. Phillips for his thorough proof demonstrating that the saturation component of the gain of a magnetic amplifier at mid-characteristic is invariant with respect to the slope of the dynamic B-H loop, provided the slope is larger than the square loop permeability.

I wish to express gratitude to H. W. Lord for his efforts to make validity checks of the theory, and to find empirical correction factors for the theory. I believe that the concluding remark of Mr. Lord's discussion would have been more revealing by stating that the theory is based on the case where the opposing effects of static loop and mutual inductance are cancelling each other, as will become clearer from the following:

Let us assume zero gate reactance during the saturation interval. The cores will operate during this interval on a B-H loop which is much narrower than the dynamic B-H loop, and which, as Mr. Lord suggests, is the static B-H loop. If one denotes the ratio of widths between static and dynamic B-H loops by $\mathfrak{p}$, equation 18 becomes

$$I_L=\frac{E}{R_0}\,\frac{1}{2}\left(1+\cos\frac{\dfrac{0.4\pi I_C N_C}{H_c l_{Fe}}+\mathfrak{p}}{1-\mathfrak{p}}\right)-I_E\,\frac{\dfrac{0.4\pi I_c N_c}{H_c l_{Fe}}=\mathfrak{p}}{1-\mathfrak{p}} \qquad (89)$$

Equation 89 describes a cosine function of shorter period, but having a common end point and $\mathfrak{p}_C=-1$; see Fig. 5(A). One concludes that the introduction of the static B-H loop shifts the control characteristic to the left.

In the presence of mutual inductance during the saturation interval, voltages are induced from the gate winding into the control winding. The interesting part of these voltages is the positive one. It will be seen from Fig. 3 and Fig. 9(A) and (B) that this voltage counteracts the effect of the static loop by driving the control current in a positive direction, thereby reducing the deviations of the theoretical control characteristic (equation 18) from the measured values. In many cases, full compensation between these two opposing effects takes place, as assumed in the paper, and the average value of the control current during the saturation interval can be assumed zero. When not fully compensated, the measured control characteristic is to the left or right of the control characteristic of equation 18.

Mr. Lord made an interesting point by stating that the actually measured control characteristic may be obtained for practical purposes from the theoretical characteristic by a shearing operation. It will be observed from the paper and Fig. 7 that the effect of rectifier reverse current is also obtained by a shearing operation. More specifically, the distance DF in Fig. 7 is a nondimensional quantity and has the significance of a (negative) feedback factor. It follows that the deviations of the measured characteristic from the theoretical one (with zero rectifier reverse current) can be expressed by a positive or negative shearing factor. One concludes that the control characteristic of a magnetic amplifier can be closely described by the dynamic B-H loop and a shearing factor. If rectifier reverse current is present, the total control characteristic is obtained by the method set forth in the paper and shown in Fig. 7, and by using a distance DF comprising both the rectifier reverse current factor and the shearing factor.

The author does not care to take issue with the various statements made by Mr. Scorgie, except his concluding paragraph. As pointed out in the synopsis of the paper, it applies to the so-called low-control circuit-impedance type. This type is characterized by a control circuit resistance which is small by comparison with the unsaturated control winding reactance. A typical value of the ratio of control circuit resistance to control winding reactance is in the vicinity of 0.01. During the exciting interval, one core is excited by the other. Since the control circuit resistance is only approximately 0.01 of the exciting reactance of the control winding, the control circuit resistance has only a minor effect on the excitation of the second core. Once the excitation has been thus determined, the control voltage E_C and the control circuit resistance R_C can be related, as shown by equation 43.

Without giving any substantiation, Mr. Scorgie claims that "This line of reasoning overlooks effects which can become important, especially in high gain amplifiers." If this is so, the author can only regret that Mr. Scorgie did not substantiate this claim.

Propagation Mechanism of Impulse Corona and Breakdown in Oil

T. W. LIAO
MEMBER AIEE

J. G. ANDERSON
ASSOCIATE MEMBER AIEE

Synopsis: The breakdown mechanism of oil dielectric has not been fully understood. Information on impulse corona and breakdown are particularly meager. Breakdown theories postulated in the past are, in general, based on voltage measurements and are mostly restricted to uniform field conditions and slow-varying voltages. In the nonuniform field, previous results[1] obtained with a point-to-plane configuration indicated a difference in streamer formation between the positive and negative polarities. The study, then, was based on corona-current measurements, and the formation mechanism was not completely clear. To study this further, data were obtained simultaneously with high-speed camera, still camera, and photocell, as well as current measuring devices, thus giving a correlated and clear picture of the breakdown process of oil.

OIL HAS BEEN extensively used in electric apparatus as insulation for many years. During this time, a number of investigators[2-6] have postulated the breakdown mechanism of oil and the factors that affect its strength. However, those investigations were generally restricted to uniform field conditions and slow-varying voltages. Since impulse acceptance tests are becoming increasingly important in the electrical industry, and since the complex insulating structure in apparatus always contains some nonuniform field regions, an investigation of the impulse breakdown mechanism in a diverged field is therefore of practical interest. Komelkov[7] has used a point-to-plane arrangement to study the mechanism of impulse breakdown of liquids, including oil, and has obtained very interesting results. However, in his investigation a large value of resistance (of the order of 10^5 to 10^6 ohms) was placed in series with the test gap. The objection to such a technique is that it might seriously distort the mechanism being studied. These studies were made by the authors without insertion of resistances between the test gap and the output of the impulse circuit, which is a 1,100-micromicrofarad capacitor.

A point-to-plane test gap was chosen for several reasons. It permitted larger gap spacings without using excessively high voltages and was simple and needed little attention. Also, since nonuniform field regions are frequently found in electrical apparatus, a point-to-plane gap would more nearly duplicate these fields than uniform-field electrodes. In addition, even in some cases of quasiuniform-field regions in oil, the first breakdown streamer starting across the gap would distort the field of the gap, giving it nonuniform characteristics.

Definition of Terms

Since there has been a lack of accepted definitions for some of the terms that are used to describe certain phenomena discussed in this paper, an attempt is made to define such terminologies in the following, to facilitate a consistent usage.

CORONA is an intense ionization which modifies the dielectric characteristics of the oil or other insulation and causes light emission.

GLOW is a type of corona which in appearance is a visual glow of indefinite shape.

STREAMER OR CORONA-STREAMER is a type of corona having a distinct path of relatively long length.

INITIATING STREAMER is the first streamer in the oil, from which the subsequent formation of the corona mechanism begins.

STEP OR STEPPED STREAMERS denotes one or more streamers which follow after the initiating streamer in a manner of successive discrete steps.

GAP-BRIDGING STREAMER is a streamer which spans completely from one electrode to another electrode or to a barrier which arrests the further progress of the streamer in the oil gap.

RESTRIKE is any gap-bridging streamer which occurs after the first gap-bridging streamer.

DISCHARGE is a general term describing any of these phenomena.

Instrumentation

A sketch of the basic equipment used in these studies is shown on Fig. 1. A copper point was suspended 3 inches above a copper ground plane in good quality *10-C* oil, in a clear Lucite tank. A 3/8-inch insulating barrier was placed on the ground plane to limit the final breakdown current and light emitted, thereby permitting studies of the propagation of relatively faint corona streamers in oil by means of high-speed photography.

The impulse wave used in all these experiments was a 1.5x40-microsecond wave, because it is the standard wave for impulse testing. The crest voltages for the positive and negative polarities were 190 kv and 240 kv respectively. These voltages were just slightly higher than the critical breakdown voltage for a 3-inch gap in the oil used.

Three still cameras were arranged around and above the tank to obtain right angle views of each discharge. One of these still cameras was generally replaced by a high-speed *f2.3*-Boys camera,[8] which was used to obtain a continuous time sequence of the propagation of each discharge. This camera had a film velocity of about 1.6 mils per microsecond, allowing resolution of events about 1 microsecond apart in time when the film negatives were viewed in a microscope. The widths and light intensities of the discharge channels could then be determined with a microdensitometer. No shutter was used since the discharge itself supplied the necessary light. Since the film was moving at 1.6 mils per microsecond, the width of the discharge would appear on the film 1.6 mils wider than its actual width, if the discharge sustained for a microsecond of time; 3.2 mils wider for two microseconds, and so on. Therefore, the channel width or diameter reported here would be the apparent value, which is somewhat larger than the actual value.

As a supplemental method of studying the light emitted by the discharges, two photocells were placed at right angles around the Lucite tank and their outputs were connected through suitable amplifiers to a cathode-ray oscillograph. These photocells were heavily shielded against external radiation, and their viewing windows were screened by slit arrangements so that the upper photocell was

sensitive only to light emitted near the point electrode, and the lower one only to light emitted at the insulating barrier or ground electrode surface. In this manner it was possible to record light pulses either near the point, or at the barrier, or both simultaneously, with two amplifiers and two oscillographs. In some cases, in order to save one amplifier and an oscillograph for measuring streamer currents, composite-light oscillograms were obtained by connecting the upper photocell to the first stage of a 3-stage amplifier and the lower photocell to the second stage of the same amplifier. Thus a streamer near the point would cause a deflection in one direction on the screen, and that near the barrier would result in a deflection of the reverse direction. However, the reverse deflections were many times smaller because they were only amplified by the two stages of the amplifier, unless the light intensity was very much stronger at the barrier.

In the electric circuit, current pulses were produced by the discharges in the oil. These current pulses were passed through a noninductive shunt, and the resulting voltages produced were amplified by a pulse amplifier and displayed on another cathode-ray oscillograph. The current pulses recorded by this method could then be compared with the light pulses picked up by the photocells to obtain a correlation between the current produced by a discharge and the light emitted from that discharge.

Streamer Propagation and Breakdown Mechanism

A set of typical photographs of the streamer propagation and oscillograms of the current and light pulses measured are presented in Figs. 2(A) and (B) for positive and negative polarities, respectively. Due to the loss of definition in the printing process, the high speed Boys photographs have been touched up slightly to show the fine details appearing on the negatives. The streamer propagation and breakdown mechanism to be described in the following are based on these results, and can be divided into four steps for each polarity.

Positive Point-to-Plane Gap, Fig. 2(A)

1. *Initiating Streamer:*

The breakdown starts at the point in the form of a glow, which lasts for a few microseconds. During this time, intense ionization occurs along a channel, developing into an initiating streamer.

2. *Successive Streamer Sropagation:*

The initiating streamer is followed by a series of stepped streamers with several microsecond time intervals between streamers, and with a channel diameter of approximately 10 mils. Each streamer is distinct from the preceding streamer, but all follow the same channel which progresses toward the ground plane. When the streamer branches into two parts, no appreciable change of its channel diameter or light intensity is observed. The streamers may further branch as they propagate toward the plane.

3. *Gap Bridged:*

The streamers eventually reach to and are arrested by the barrier on the ground plane, and the oil gap is then totally bridged by the streamers. If the barrier is removed, a breakdown will result.

4. *Restrikes:*

Successive streamers, each following the same path, may occur when the ground plane is covered by an insulating barrier, until the applied voltage drops to approximately half-crest value.

Negative Point-to-Plane Gap, Fig. 2(B)

1. *Initiating Streamer:*

The breakdown starts at the point in the form of a streamer with a channel diameter of approximately 35 mils and may span as much as half the gap within a microsecond of time.

2. *Successive Streamer Propagation:*

The initiating streamer is followed by a series of stepped streamers, with 1 to 5 microsecond time intervals and of much smaller channel diameter and light intensity. Unlike the positive stepped streamers, the tips of the negative stepped streamers appear to blend into a glow which progresses toward the ground plane. The number of the negative stepped streamers is, in general, two or three times that of the positive ones. There is no large branching like the positive streamer unless the initiating streamer has branches.

3. *Gap Bridged:*

When the glow reaches or approaches very close to the barrier on the ground plane, the gap-bridging streamer travels from the barrier back to the point electrode. The diameter of the streamer channel decreases toward the point, being approximately 50 mils near the barrier and about 25 mils at the point. The light intensity along the channel varied similarly. When a different material is used for the barrier, the light intensity and channel diameter of the gap-bridging streamer are also changed. It is shown in Fig. 3 that the gap bridging streamer with the glass barrier has a smaller channel. This dependence on the barrier material has not been found for the positive polarity. It is interesting to note that the transparency of the glass barrier has permitted so much light to be received by the lower photocell that the light pulse for the gap bridging streamer is actually reversed. If the barrier is removed, a breakdown will naturally result.

4. *Restrikes:*

When the ground plane is covered with an insulating barrier, one or more restrikes may occur with 10 to 15 microseconds interval between them, while the applied voltage drops to less than half-crest value. The light intensity is lower than that of the gap-bridging streamer but is much more uniform; the channel diameter was about 20 mils. The reversal of light pulses on the light oscillograms seems to indicate that there are ionizations on the barrier prior to and after the restrike, and in some cases, even prior to the gap-bridging streamer. The much stronger light intensity of the negative-polarity gap-bridging streamer near the barrier is also an indication of ionization on the barrier which provides a source of charges to flow in the channel of the gap-bridging streamer. No reversal of light pulses is found for the positive polarity, and as can be seen from Fig. 2(A), the light intensity along the channel of the positive gap-bridging streamer is much more uniform.

Comparison of Mechanisms of Lightning and Impulse Corona or Breakdown

Fig. 4 shows the remarkable similarity that exists between the mechanisms of natural lightning to open terrain, and the impulse critical breakdown of a negative point-to-plane gap in *10-C* oil, although the latter is on a much smaller scale.

Both phenomena appear to start with an electron avalanche rushing toward the ground plane from the negatively charged cloud or point. In the case of lightning, this avalanche may reach a distance of 150 feet and is known as a step leader.[9-11] For oil, the avalanche may reach a distance of 1 inch or so for a 3-inch gap having a crest voltage of 240 kv, and has been labeled an initiating streamer. This initial avalanche for both air and oil is then followed by a series of successive streamers which follow down the same channel, each streamer being longer than the previous one, until the ground plane is reached. The lightning streamers, or steps of the stepped-leader process, have

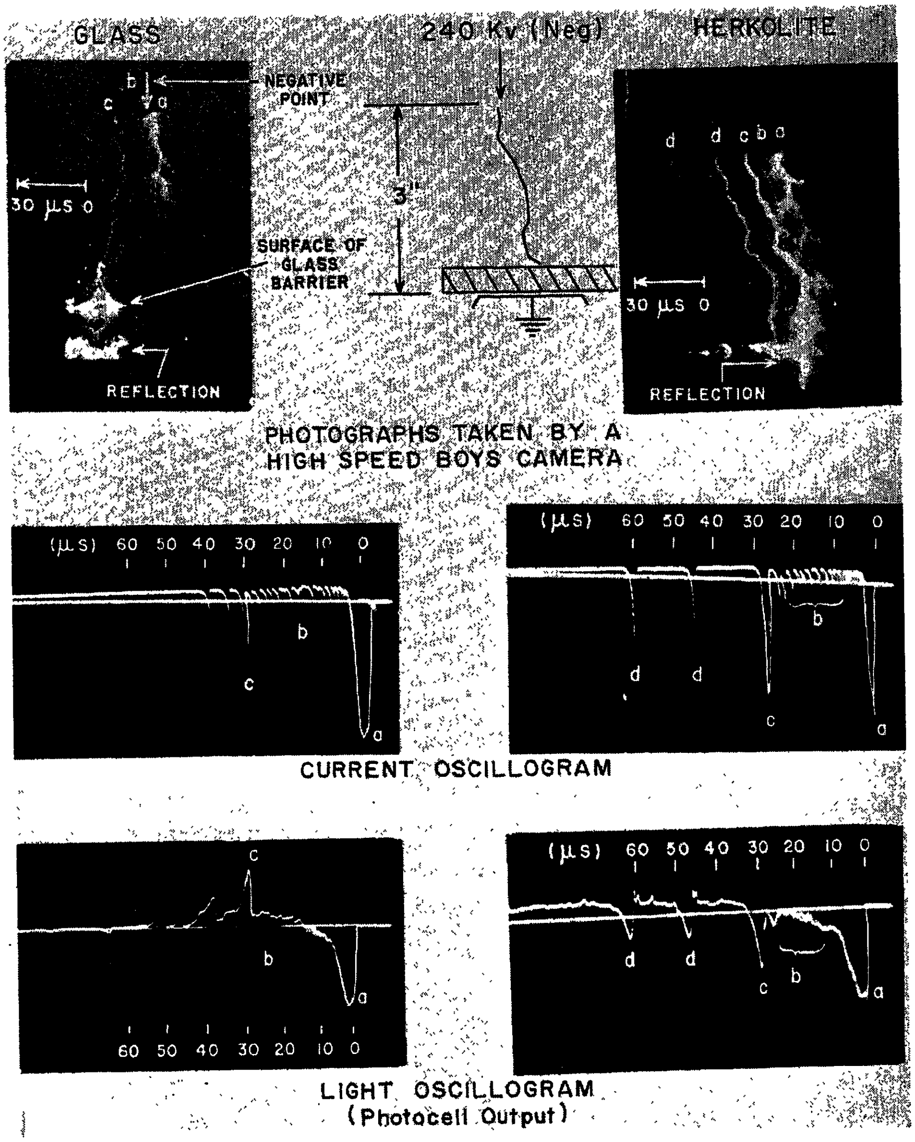

Fig. 3. Photographs and oscillograms comparing negative-polarity oil corona streamers striking glass and Herkolite

an apparent velocity of about 150 feet per microsecond, but since the interval between steps may be 50 microseconds, the over-all propagation velocity of the stroke is much slower. The order of magnitude reported[9] is about 5 inches per microsecond. In oil, the velocity of the individual stepped streamers is unmeasurable with the equipment used, but should be over 4 inches per microsecond. The over-all velocity of propagation toward the ground plane, caused by delay of 1 to 5 microseconds between streamers, is of the order of 0.1 inch per microsecond. Thus, the breakdown process may take 30 microseconds to cross a 3-inch gap in oil.

It has been theorized[9–11] that the stepped leaders in lightning strokes are produced as an aftermath of the gradual progression to earth of a faint pilot streamer having a velocity equal to the over-all propagation velocity.

In Fig. 4 this pilot streamer is sketched in dashed lines. The high-speed photographs of breakdown in oil actually show an equivalent pilot streamer, progressing downward from the tip of the initiating streamer to the ground plane, in a manner very similar to that postulated for lightning. This equivalent pilot streamer has a velocity which is the same as the over-all propagation velocity of the breakdown, and appears as a faint hazy glow with occasional small branching.

As a stepped streamer for oil or a step leader for air reaches the ground plane, a heavy return stroke (or gap-bridging streamer) rushes upward from the ground plane to the cloud or point electrode as shown in Fig. 4. In the case of oil, when the ground plane is covered by insulation

on its surface, the lower portion of the returning gap-bridging streamer is much more intense than the upper portion. This fact has occasionally been observed in lightning strokes to open terrain.[11] At intervals of 2 to 20 microseconds after the gap-bridging streamer occurs in oil, from the insulated ground plane, restrikes (subsequent gap-bridging streamers) are noted very similar to the multiple strokes occurring in lightning, except that their intervals are measured in microseconds, instead of tenths of seconds common to lightning observations.

However, if the ground plane in the point-to-plane oil gap is not protected by insulation, the gap will break down immediately when a stepped streamer reaches the ground plane, and no subsequent restrikes are possible.

Further Evaluation of Results

Relation between Corona Current and Light Emission

It has been found experimentally[12] that the light emitted from the channels of lightning strokes is, in general, proportional to the current in the stroke channel, but that the light has longer duration. Therefore, it is interesting to see whether this relation between light and current also holds for corona streamers in oil. The light pulses were recorded with a photocell and the current pulses were measured as described in "Instrumentation." About 30 current and light pulses were measured for each polarity of corona discharge, and their crest magnitudes were plotted in Figs. 5 and 6, with light as the ordinate and current as the abscissa, in arbitrary units. The points were somewhat scattered, but a straight-line relation appeared feasible when the data were analyzed statistically.[14] Such an analysis also gives confidence limits within which 95 per cent of all future points within this range can be expected to fall. Note, however, that the most probable curve in Fig. 6 does not pass near zero light intensity at zero current. This is due to the difference of the offset of the current and light oscillograms with respect of their zero lines. The oscillograms in Figs. 2(A) and (B) show that the time duration of the light from the streamers is considerably longer than the corresponding duration of current pulses, as is similarly found in gaseous discharges.

The variations of light intensity along the streamer channels were also determined. This was done by measuring the image density on the photographic negative with a microdensitometer[12] and computing the intensities from known density-intensity relationships. A large difference was found between the positive and negative polarities. Fig. 7 shows the fluctuation of the light density along the positive-streamer channel. However, the light intensities of the branching streamers and of the main streamer are about the same. But for the negative polarity, the difference of the light intensities between the initiating and the gap-bridging streamers is far more pronounced. The light intensity of the initiating streamer decreases gradually as the streamer leaves the point, whereas, for the gap-bridging streamers the intensities increased greatly near the barrier. The relative intensity and its rate of change is different for different barrier materials, see Fig. 8. The variation of the light intensity along the streamer channels for both polarities can also be seen from Figs. 2(A) and (B).

Lichtenberg Figures

A number of Lichtenberg figures for both positive and negative polarities were obtained by laying a sheet of Kodak 5 by 7-inch Super-X photographic film on the barrier, where it was struck by corona streamers. The purpose was to determine how far the streamers splashed along the surface of a barrier when it was struck by them.[15,16] The emulsion side of the film was placed in contact with the

barrier, and photographs were taken simultaneously with a camera located directly above the barrier. A set of prints for each polarity is shown in Fig. 9. These prints further show the difference between the positive and negative streamers, when they strike a barrier. For positive polarity, there is a bright and faint type of branching on the Lichtenberg figure. The bright patterns correspond to the splash of the gap-bridging streamers which actually dig into the film and cause permanent damage to the film. These patterns are also found on the picture taken by the camera. However, the faint patterns do not show on the picture, and they are probably caused by discharges between the barrier and the film. Nevertheless, the Lichtenberg figure gives a fairly good record of the area covered by the splash of the positive streamer. For the negative polarity, however, the Lichtenberg figure is caused only by the discharges between the barrier and the film and there appears to have been very little splash on the back of the film to expose the emulsion side. Only a very faint pattern was recorded by the camera and the film used for the Lichtenburg figure was not damaged by the negative discharge. The general treelike patterns are somewhat similar to those obtained in air,[17,18] especially for the positive polarity. For the negative polarity, the patterns produced by oil discharges are less diffused. This is probably due to smaller lateral diffusion of ions in each discharge channel; consequently the pattern is more distinct. It is expected that these figures can be used to measure approximately the barrier voltage, by comparing them with those produced with a point directly on the film, in oil, on top of the barrier.

Conclusions

1. The impulse breakdown of oil in the nonuniform field is a streamer mechanism.
2. A remarkable similarity to the stepped leader of natural lightning strokes exists for the negative streamer at the critical breakdown voltage.
3. The overall velocity of propagation of the streamer tip in oil is about 1/50 that of the stepped lightning leader.
4. Channel diameters in the oil gap ranged between 10 and 50 mils.
5. The maximum intensity of light emitted from a corona streamer channel is approximately proportional to the current in the electric circuit produced by the streamer.

◆

Discussion

G. M. L. Sommerman (Battelle Memorial Institute, Columbus, Ohio): The results obtained on the breakdown mechanism in oil are highly original and mark an important step forward in our understanding of the fundamental processes involved. This achievement has been possible because the authors have brought to bear simultaneously a number of recently developed measuring techniques on a basic arrangement of dielectrics and electrodes.

The writer, together with E. L. C. Larson and C. J. Bute (see refs. 15 and 16 of the paper), has measured streamer propagation velocities in liquids by the use of Lichtenberg figures obtained with impulse waves chopped at various time intervals. The propagation velocities were found to be much greater for positive streamers in chlorinated liquids than for either positive or negative streamers in hydrocarbon oils. This suggests that if the authors of the paper should try a chlorinated liquid in their setup and with their techniques, they would obtain results which differ in important respects from those reported for the hydrocarbon oil. Such results would give further information on the breakdown mechanism as it is related to the chemical structure of the medium.

Although, as the authors show, there is considerable similarity between their results with oil and the results of field investigations on natural lightning, the underlying mechanisms need not be similar in some cases. For example, in the case of restrikes, those observed in lightning may be caused by subsequent release of charge from portions of the cloud that are distant from that which released the initial charge. The restrikes found by the authors in oil must arise from a different cause. The following hypothesis is suggested: 1. After the initial discharge from a negative point, electrons are sprayed over the upper surface of the insulating barrier, thereby raising the potential of this surface to a high negative value. 2. The potential of the negative point continues to decrease because a $1^1/_2$x40 wave is applied to it. 3. After a lapse of several microseconds, the potential of the upper barrier surface is sufficiently more negative than that of the point that a reverse breakdown can occur along the original path where ions in the original discharge have not recombined completely. This hypothesis could be checked by repeating the experiment with a much longer wave, say $1^1/_2$x500, and observing if the restrikes in oil are eliminated or occur after much longer time intervals. Also, if the authors succeed in measuring the potential of the upper surface of the barrier from Lichtenberg-figure analyses, as suggested in the last paragraph of the paper, this might give information which would support the hypothesis.

B. F. J. Schonland (Bernard Price Institute for Geophysical Research, University of the Witwatersrand, Johannesburg, S. Africa): The authors are to be congratulated on a valuable piece of work. Although the pilot-streamer has been recorded as a preliminary to long-spark breakdown by Allibone[1] and by Hagenguth and Anderson (ref. 13 of the paper), it has never before been photographed either in lightning or the long spark as a streamer which creates the conditions for the establishment of a series of steps.

It is to be hoped that the work can be extended to breakdown in other liquid dielectrics, and perhaps in solids as well. This would afford most valuable information about the nature of the pilot process. In the writer's opinion, this process builds up a streamer mainly by photoionization in front of its advancing tip and not by collisional ionization. If this view is correct, further study in different media would add a great deal of knowledge to the general subject of impulsive breakdown.

Before seeing this paper, the writer had sent forward for publication a discussion of the pilot and step processes in lightning and the long spark, in the course of which a new explanation of the step process was put forward. Since it may be of value in estimating the possibilities of other media for step-breakdown studies, the main equation derived from this theory is quoted here

$$r/l + r^2/l^2 = 2X_2/X_1$$

where

r = the radius of the streamer (pilot or leader)

l = the length of a step

X_1 = the steady-field breakdown strength of the medium

X_2 = the average value of the field-strength required for long-spark breakdown over the whole gap.

For air $X_1/X_2 = 5$ hence $l/r = 6$, a value which agrees fairly well with observations on lightning and the long spark. In 10-*C* oil breakdown the quantity X_1, the writer is informed, is 500 kv per centimeter and X_2, from the authors' data, is 31.5 kv per centimeter. Hence l/r should be about 8. For negative streamers in oil $l = 0.25$ inch and $r = 0.025$ inch; hence $l/r = 10$, in reasonable agreement with the theory.

This theory of the step process requires that though the luminosity may vary abruptly, the flow of current should be fairly constant throughout the whole process, the pilot streamer carrying steadily forward the same charge per unit length as the good conducting channel behind it. The transient pulsations recorded on the authors' current oscillograms should thus be superimposed on a continuous background of current which flows in the intervals between pulsations, and which is of such magnitude that the quantity transported in the intervals between pulsations considerably exceeds that transported during the pulsation or step periods. The writer understands that the circuit arrangements used did not permit of measurement of this interstep current, but he would appreciate the authors' comments on this question and would ask whether in future work it will be possible to measure both the pulsating and the continuous components of the current. Such measurements would be of considerable interest but, as they will have to be made on the high-voltage side of the circuit, they may be difficult to achieve.

References

1. Development of the Spark Discharge, T. E. Allibone. *Nature*, London, England, vol. 161, 1948, pp. 970–71.

T. W. Liao and J. G. Anderson: We agree with Dr. Sommerman's hypothesis for the mechanism of restrikes in oil. Recent test results of the measurement of barrier potentials produced by impulse discharges indicate that potentials of the same order of magnitude as the applied wave are produced on the barrier surface. These potentials decay at a very slow rate over a period of many seconds. Hence, the point potential does decay at a much faster rate than the barrier potential, causing large reverse voltages to be produced across the gap. These reverse voltages may cause the restrike discharges to occur along the original preionized path.

The authors are pleased to learn that a reasonable agreement is obtained for the streamer propagation process in oil with Dr. Schonland's theory on the propagation processes in lightning and long sparks in air. At present no data are available on the interstep current. Measurements of such currents not only might provide a check of his theory applied to the oil medium but might also give some information on the mobility of ions in oil.

It is apparent from the written discussions and from some oral discussions with other investigators that a study of the streamer propagation processes in liquids is of general interest. The authors feel that this could be a very fruitful field of investigation for many workers, and hope that this paper may stimulate greater interest in the subject.

Pulse Response Characteristics of Rectangular-Hysteresis-Loop Ferromagnetic Materials

JOSEPH WYLEN
ASSOCIATE MEMBER AIEE

MAGNETIC CORES made with rectangular-hysteresis-loop ferromagnetic materials have recently gained prominence as binary elements in digital data-processing machines. The ability of the core to store binary information reliably and without power dissipation, and the ease with which the information can be read out or changed in a few microseconds make the core a useful and versatile component. Wherever they are applicable, magnetic-core circuits offer advantages over vacuum-tube circuits; the cores are rugged, have indefinite life, and require little power. Cores made with rectangular-hysteresis-loop ferromagnetic materials are being used in shift resisters,[1] in memory systems,[2,3] and in logical and control circuits.[4-6]

Because of the nonlinear nature of ferromagnetic materials the data on core characteristics that are needed for magnetic-circuit design must be obtained empirically. This paper defines some of the important properties of core materials and describes one method for measuring the quantities that are of interest in pulse applications. The test technique is described, and the results of tests made with several different core types are presented.

Definitions of Terms

Fig. 1 shows an idealized d-c hysteresis loop for a ferromagnetic material. The quantities that are of particular interest for this discussion are $\mathbf{B}_r$, the residual magnetization; $\mathbf{B}_m$, the maximum or tip magnetization; and $\mathbf{H}_c$, the coercivity or coercive force. Binary information can be stored in a core as the sense of the residual magnetization; $+\mathbf{B}_r$ is usually designated as binary "1"; $-\mathbf{B}_r$, binary "0."

Each system that employs magnetic cores depends on some unique set of characteristics, and hence places different specifications on the ferromagnetic material. Two properties of magnetic cores that are of general interest and importance are the squareness ratio and the switching time. The squareness ratio is the ratio of the residual magnetization $\mathbf{B}_r$ to the maximum magnetization $\mathbf{B}_m$. The switching time is here defined as the time required for the magnetization state to change from $-\mathbf{B}_r$ to $+\mathbf{B}_m$ when an unloaded core is subjected to a step of magnetizing force of amplitude $\mathbf{H}_m$. Other definitions of switching time, possibly more useful for circuit design, will not be treated here. Once a core has been switched from $-\mathbf{B}_r$ to $+\mathbf{B}_m$ its state has effectively been changed; the core will assume the $+\mathbf{B}_r$ state when the magnetizing force is removed.

Squareness Ratio

The importance of the squareness ratio $\mathbf{B}_r/\mathbf{B}_m$ is evident when one considers the effect of pulsing a core with a positive step of magnetizing force. Assume that a core having a cross-sectional area A and a hysteresis loop like that shown in Fig. 1 is initially in the $-\mathbf{B}_r$ state; when magnetizing force $\mathbf{H}_m$ is applied, the resulting change in flux will be $A(\Delta\mathbf{B}_s)$. If, however, the core had initially been in the $+\mathbf{B}_r$ state, the change will be $A(\Delta\mathbf{B}_n)$. Since the average voltage induced in a winding on the core is proportional to the total change in flux, the ratio $\Delta\mathbf{B}_s/\Delta\mathbf{B}_n$ is a measure of the signal-to-no-signal ratio that can be realized when the core is used in an information processing circuit. The relation between $\Delta\mathbf{B}_s/\Delta\mathbf{B}_n$ and the squareness ratio is stated in equation 1

$$\frac{\Delta\mathbf{B}_s}{\Delta\mathbf{B}_n}=\frac{1+\mathbf{B}_r/\mathbf{B}_m}{1-\mathbf{B}_r/\mathbf{B}_m} \qquad (1)$$

The commercially available ferromagnetic materials that are of particular interest for use in digital computer circuits have maximum squareness ratios ranging from 0.90 to 0.96. In the saturation regions the slope of the hysteresis loop is nonzero, and the value of $\mathbf{B}_r/\mathbf{B}_m$ decreases, as the amplitude of the applied magnetizing force is increased. However, for the very rectangular loop materials, and for the values of $\mathbf{H}_m$ that are used, the change in squareness ratio is usually unimportant.

Switching Time

The cores that lend themselves for use in digital machines can readily be switched when unloaded, in times ranging from less than 1 microsecond to 10 or 20 microseconds. The switching time for a given material is a function of $\mathbf{H}_m$. For values of $\mathbf{H}_m$ much greater than $\mathbf{H}_c$ the switching time is approximately proportional to the quantity $1/(\mathbf{H}_m-\mathbf{H}_c)$. In applications where fast switching for small applied field is desired, a material having a small coercivity is needed.

The switching time of a metallic ferromagnetic core, fabricated from lamina-

JOSEPH WYLEN is with the Burroughs Corporation, Philadelphia, Pa.

The author wishes to acknowledge the assistance of his associates in the magnetic development sections of the Burroughs Research Laboratory, and in particular C. F. Devenny for his help and Isaac L. Auerbach for his interest and encouragement. The author is also indebted to the various manufacturers who supplied some of the magnetic cores and data that were used.

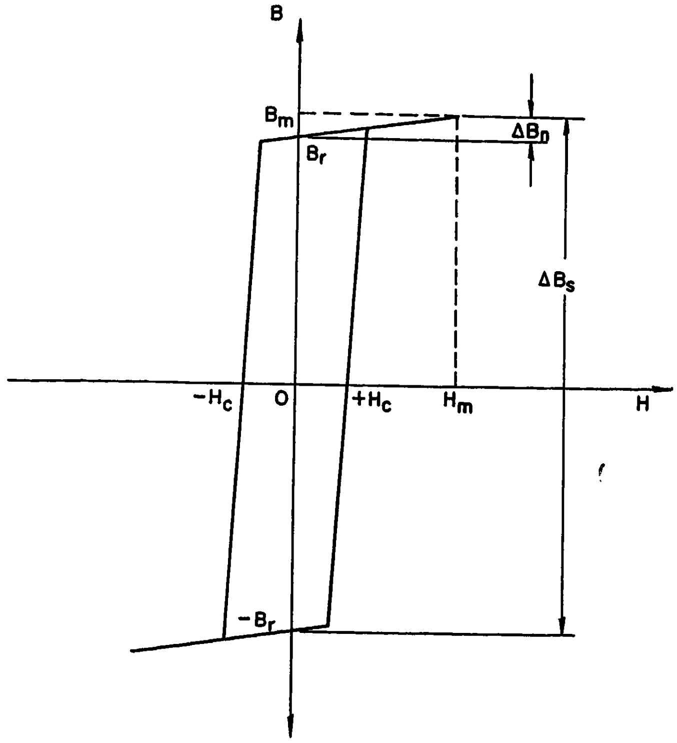

Fig. 1. Idealized d-c hysteresis loop

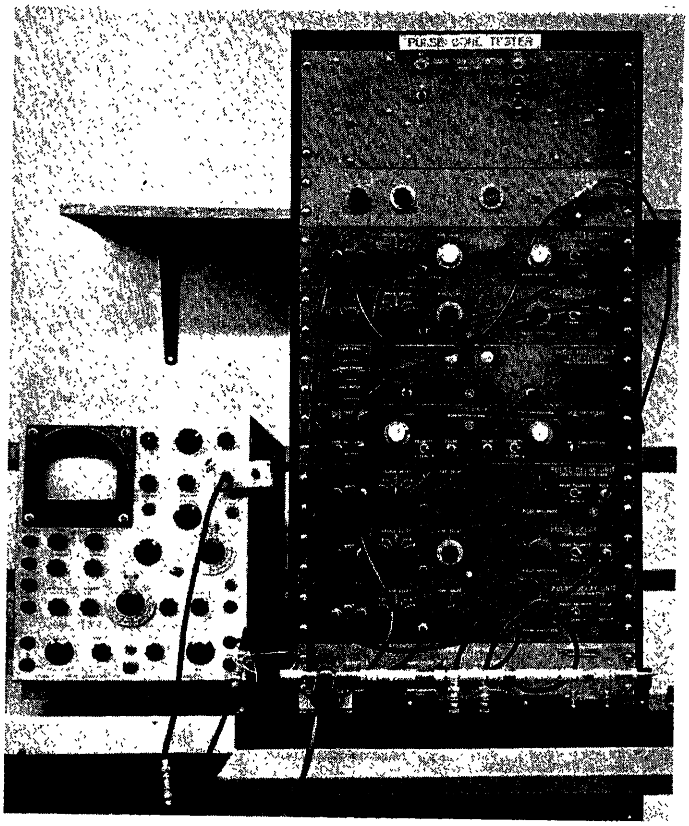

Fig. 3. Setup for toroidal core test. The equipment on the rack is used to generate the desired pulse pattern. The current drivers are not shown

tions thicker than 1/2 mil, is limited primarily by the eddy currents that flow within the core material during the flux change. The magnitude of the eddy currents is a function of the lamination thickness, the conductivity of the metal, and the magnitude of $\Delta\mathbf{B}_s$, see Fig. 1; eddy-current effects are minimized when all three of these factors are minimized. Hence, for a given value of $\mathbf{H}_m$, the fastest switching times are obtained with cores fabricated with ultrathin materials having small $\mathbf{H}_c$, small $\Delta\mathbf{B}_s$, and large resistivity. It is interesting to observe that although hysteresis loss in computer cores is negligible, fastest switching can be realized with the materials that have the smallest hysteresis loop.

The switching time of a core that is fabricated from laminations thinner than 1/2 mil cannot be predicted when only the eddy current effects are considered. Extensive investigation is being conducted to determine the factors that limit the switching speed of the very thin metallic tapes.

Ferromagnetic resonance and domain-wall relaxation and resonance, all of which contribute to core loss at high frequencies,[7] are possibly the phenomena that limit the switching times of the ferromagnetic ferrites. The eddy currents are not a significant factor; they are negligibly small because of the large resistivities of the ferrites. The coercivities of the commercially available rectangular-loop ferrites are more than ten times those of the useful metals; however, this fact alone is not sufficient to explain the delay in switching.

Materials

Recently developed ferromagnetic materials than can be switched rapidly and that have squareness ratios greater than 0.90 are of two types: grain-oriented ultrathin alloys, and ferrites. The two most important alloys, both available in strip as thin as 1/8 mil(0.000125 inch), are 48-per-cent nickel-iron and *4-79* Permalloy, a molybdenum-nickel-iron alloy. The processing, fabrication, and d-c hysteresis-loop characteristics of these two alloys have been fully described in a recent paper.[8] It will serve to mention that the alloys are cold reduced to the desired gauges with large percentage reductions at each step, slit into ribbon, usually 1/8-inch wide, coated with an insulating material, and wrapped onto ceramic toroidal bobbins. The free end of the outer wrap is tacked, either with a light spot weld or by other means. The assembly is annealed in a dry hydrogen atmosphere to maximize the squareness ratio of the magnetic material. The annealing process is critical, and must be carefully controlled if optimum results are to be achieved.

The coercivity of both of the rectangular loop alloys mentioned above increases as the gauge is made thinner, at least down to 1/8-mil gauge. This fact limits to some extent the advantages that can be realized by using thinner materials, as is illustrated in the experimental results presented below for 1/4-mil and 1/8-mil *4-79* Permalloy.

The maximum squareness ratio that can be obtained with a given alloy seems

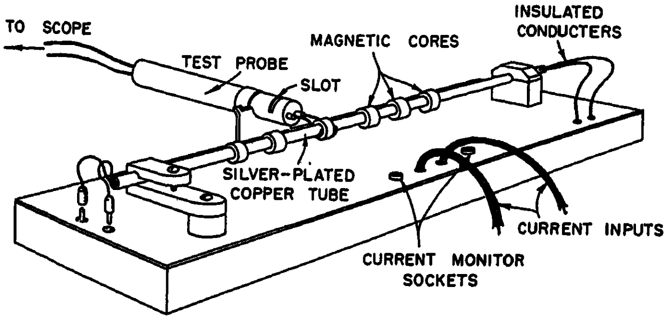

Fig. 2. Test equipment for toroidal magnetic cores

B. Typical core output voltage. The switching voltage is e_s; the nonswitching voltage is e_n
C. Magnetic flux or flux density

to be a function of the thickness to which it is rolled. In the case of the 48-per-cent nickel-iron, the squareness ratio decreases as the gauge is made thinner, while for the *4-79* Permalloy, the largest squareness ratio is achieved with the thinnest gauge.

The manufacturing processes and typical properties of the ferrites are described in the literature.[9,10] Finely powdered mixtures containing magnetite, various bivalent metals, and an organic binder are pressed into the desired shape and fired at high temperatures. The resulting compounds are ferromagnetic. The ferrite *MF 1118*, recently made available, has an exceptionally rectangular hysteresis loop, and is available in toroids having outside diameters as small as 0.06 inch.

Test Equipment

To facilitate the testing of large numbers of toroidal cores without recourse to winding each and every core, special test equipment was constructed. Because of its simplicity, the equipment is also useful for tests on single cores. Fig. 2 is a sketch showing the type of test jig that is used. The silver-plated copper tube serves both to support the cores, and as part of the single-turn output winding. Each of the insulated conductors that are threaded through the tube serves as a common single-turn input winding for all of the cores. One wire is used for applying positive magnetizing forces, the other, negative magnetizing forces. Because of the large permeability of the test cores, it is not necessary in practice to center the conductors within the tube.

The single-turn input windings are each connected as the plate load of their respective current drivers. The output stages of the two current drivers that were used to obtain all of the data presented below consist of eight *6CD6* beam-power tetrodes connected in parallel. Each driver can deliver current pulses that are continuously variable in amplitude from 0 to 7 amperes, and have a fixed rise time, without overshoot, of 0.4 microsecond. For purposes of safety, the cathodes of the output tubes are at a negative potential and the output circuits are nominally at ground level. The current pulses are observed by monitoring across precision 1-ohm resistors that are in series with the input windings.

The test probe consists of a two-tined fork, as shown in Fig. 2. Each tine makes electrical contact with the silvered tube on one side of the test core, and the tube surface and the two tines constitute a single-turn output loop. This loop encloses an area that is much greater than the cross-sectional area of the test core, and hence has induced in it by the air-coupled flux a relatively large voltage. The effect of this undesirable voltage is eliminated by including within the probe several turns that are oriented in such a way that the voltage induced in them exactly cancels the undesirable voltage. Since these reversed turns do not enclose the test core, they have no effect on the observed core output voltage. The reversed turns are inside the test probe, just behind the tines. An opening in the probe, see Fig. 2, permits adjustment of the size and orientation of the reversed windings; the self-positioning feature of

Table I. Description of Test Cores

the tines eliminates the necessity of frequent adjustments.

The laboratory setup used for core testing is shown in Fig. 3. The two large current drivers, normally at the bottom of the rack, are not shown. The pulse-control equipment above the test-jig shelf is used to generate the pulse train that triggers the drivers. The test probe is connected to the vertical input terminal of an oscilloscope either directly or, as noted in the following, through an integrating network.

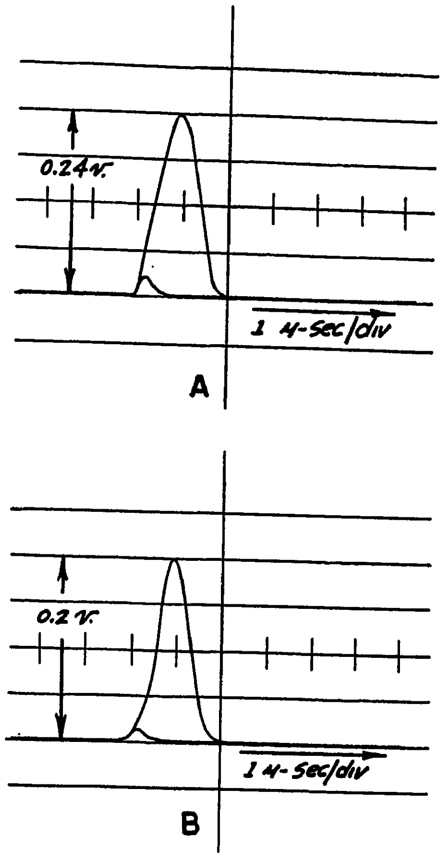

Fig. 6. Switching and nonswitching voltages for 4–79 Permalloy, $H_m=0.5$ oersted

A. Test core no. 4, 1/4 mil, $B_r/B_m=0.90$
B. Test core no. 5, 1/8 mil, $B_r/B_m=0.92$

Test Method

The pattern of applied magnetizing force that it used in the basic core test is shown in Fig. 4(A). If the test core is initially in the $-\mathbf{B}_r$ state, see Fig. 1, pulse P_1 will switch the core to the $+\mathbf{B}_m$ state. During the change, the switching voltage e_s, shown in Fig. 4(B), will be generated in the single-turn output winding. The duration of the switching voltage, t_s in Fig. 4(B), is the switching time of the core.

At the end of pulse P_1, the applied magnetizing force returns to zero and the core moves to the $+\mathbf{B}_r$ state. The decrease in flux density is small if the core has a rectangular hysteresis loop, and a small negative voltage is induced in the output winding, as shown in Fig. 4(B), at time t_1.

A second positive pulse P_2 is applied to the core at time t_2, and the core is changed from the $+\mathbf{B}_r$ state to the $+\mathbf{B}_m$ state. The voltage e_n that is induced in the output winding by this change is the nonswitching voltage; it is always smaller in amplitude and shorter in duration than the switching, or signal, voltage. If the area under the e_s curve is designated S, and the area under the e_n curve is designated N, the area ratio is related to the squareness ratio of the core by equation 2

$$\frac{S}{N}=\frac{1+\mathbf{B}_r/\mathbf{B}_m}{1-\mathbf{B}_r/\mathbf{B}_m} \qquad (2)$$

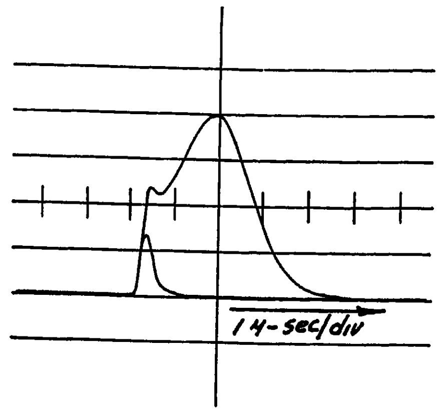

Fig. 7. Switching and nonswitching voltages of 1/4-mil 4–79 Permalloy core, test core no. 4, $H_m=0.2$ oersted. (Note the prominent double peak in the switching voltage)

Note that since the electromotive force induced in a single-turn winding is given by the rate of change of flux in the core, the area under a voltage curve is equal to the total change of flux that induced it. Hence, equations 1 and 2 are equivalent.

For test purposes, the oscilloscope sweep is triggered just before pulses P_1 and P_2 are applied, and the voltages e_s and e_n are observed superimposed on the oscilloscope screen. The switching time t_s can be measured directly if the sweep speed is properly calibrated. And since equation 3 can be obtained from equation 2 by slight manipulation

$$\frac{\mathbf{B}_r}{\mathbf{B}_m}=\frac{S-N}{S+N} \qquad (3)$$

the superimposed voltage pattern offers a means for measuring the squareness

ratio—a planimeter can be used to measure both (S−N) and (S+N) directly from a copy of the oscilloscope pattern.

The planimeter method for obtaining the squareness ratio is too slow and tedious to be generally useful. However, the superimposed voltage pattern is adaptable for use in the acceptance testing of large numbers of cores. Specifications can be set on the amplitude, duration, or waveshape of both the signal and no-signal voltages, and the limits marked directly on the oscilloscope screen. The test on each core can be completed in a few seconds.

At time t_3, Fig. 4, the applied magnetizing force becomes zero again and the core returns to the $+\mathbf{B}_r$ state. Pulse P_3 causes the core to be reset to the $-\mathbf{B}_r$ state, after which the cycle is repeated. The voltages generated by these last events are unimportant, and, though shown in Fig. 4(B), are not usually monitored during the test.

Fig. 4(C) shows the flux, or flux density, variations of the test core as a function of time. By placing a resistance-capacitance integrating circuit across an output winding on the core, and examining the output of the integrating circuit, such a pattern can be observed on an oscilloscope screen.

Because the core switching voltage is generally on the order of a few millivolts per output turn, and because the passive integrating circuit introduces a large attenuation, a multiturn output winding is usually used to drive the integrator when this technique is employed. A suitable amplifier might be used either before or after the integrator if the flux pattern is needed and winding is inconvenient.

The flux pattern offers a simple and direct method for measuring the squareness ratio $\mathbf{B}_r/\mathbf{B}_m$ to an accuracy that is adequate for most applications. One needs merely measure the levels of the $\mathbf{B}_r$ and $\mathbf{B}_m$ plateaus, as shown in Fig. 4(C), and take their ratio.

Pulse Response Characteristics

Listed in Table I are the descriptions of the magnetic cores that were used for obtaining the test data presented in this section. The metallic cores were fabricated on ceramic bobbins in the manner previously described. All of the cores were selected from commercial lots as typical samples, but are not intended to represent any mathematically defined average.

The oscillograms in Figs. 5 through 18 are tracings of photographs.

SWITCHING AND NONSWITCHING VOLTAGES

Fig. 5(A), shows, superimposed, the switching and nonswitching voltages for test core no. 1. Fig. 5(B) shows the same two voltages for test core no. 2. Both cores were taken from the same lot; the dissimilarity in the switching voltage waveforms is typical of the variations that occur. Variations in switching time can most likely be attributed to nonuniform ribbon thickness, to differences in coercivity, or to poor insulation between wraps. The variations in waveform might be caused by differences in the fabrication, such as unlike tensions during wrapping or nonuniform insulation thickness between wraps. The squareness ratio of core no. 1 is about 0.91; that of core no. 2, about 0.93.

The curvature of the switching voltage in the region of negative slope in both Figs. 5(A) and 5(B) is typical of the wave form usually obtained for materials of 1 mil or thicker gauge when they are switched with magnetizing forces that are much greater than their coercivity. This wave form has been predicted by Dr. Athanasios Papoulis in a mathematical analysis done for the Burroughs Corporation. In addition to explaining the switching voltage wave form, Dr. Papoulis' analysis predicts the time and voltage level at which the inflection point will occur. See Figs. 5(A) and 5(B).

Fig. 5(C) shows the switching and nonswitching voltages for test core no. 3. This core has a squareness ratio of about 0.90.

Figs. 6(A) and 6(B) show the switching and nonswitching voltages for test cores nos. 4 and 5, respectively, with $\mathbf{H}_m = 0.5$ oersted in each case. The 1/4-mil *4-79* Permalloy core has a squareness ratio of about 0.90; the 1/8-mil core, about 0.92.

Fig. 7 shows the switching and nonswitching voltages for test core no. 4 when $\mathbf{H}_m = 0.20$ oersted, a magnetizing force only about twice the coercivity of the core material. The double peak that is so prominent in Fig. 7 also occurs in many other switching-voltage wave forms and has been the subject of much discussion. The double peak has been observed by the author in metallic cores when $\mathbf{H}_m$ was not much greater than $\mathbf{H}_c$, and in the ferrite *MF-1118* when the positive and negative magnetizing forces were not equal, so that a nonsymmetrical **B-H** loop was traversed. Three possible

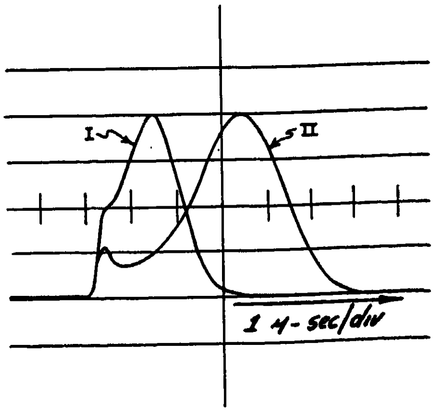

Fig. 11. The switching voltages of 1/4- and 1/8-mil 4–79 Permalloy compared for $H_m = 0.25$ oersted

- I. Test core no. 4
- II. Test core no. 5

causes for the double peak are:

1. Nucleation of the domains;
2. The sudden change in slope from the flat to the rising portion of the B-H loop;
3. Magnetostrictive effects.

Another possible reason could be a difference in coercivity between the regions near the surface of the core and the regions within the core, if the difference is large and if the surface coercivity is the greater of the two. Further study of the double-peak phenomenon, now being conducted at various laboratories, should lead to a satisfactory explanation.

Fig. 8 shows the switching and nonswitching voltages for the ferrite sample, test core no. 6. The pulse-measured squareness ratio of cores made of *MF-1118* is about 0.95 when the core is switched on the saturation hysteresis loop.

SWITCHING TIME VERSUS THICKNESS

Fig. 9 compares the switching times for test cores nos. 1, 3, and 4, all being switched by 1.0-oersted magnetizing pulses. The switching voltage for 1/4-mil *4-79* Permalloy is compared, in Fig. 9, with the two 48-per-cent nickel-iron samples to demonstrate that for a given value of applied field, fastest switching will be realized with a core that has the thinnest gauge, the lowest maximum flux density, and the smallest coercivity, see Table I.

The oscilloscope amplifier gain was adjusted to make the amplitudes of all three waveforms equal for the composite in Fig. 9 (as well as in the two composites which follow). This was done to give a better comparison of wave form and switching time. The amplitude of the switching voltage can be varied by changing the number of wraps of material on the bobbin or the number of turns of copper on the output winding, and is not dependent only on the properties of the material.

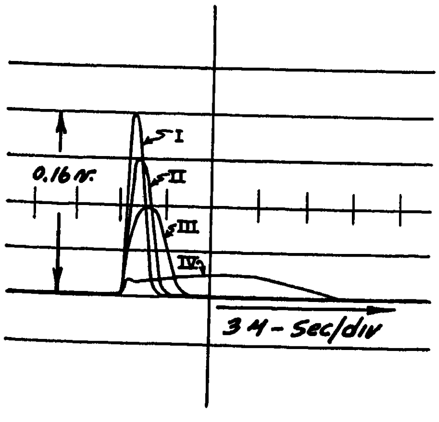

Fig. 12. The switching voltages of 1/2-mil 48-per-cent nickel-iron, test core no. 3, for four different values of applied magnetizing force

I. $H_m = 1.5$ oersteds
II. $H_m = 1.25$ oersteds
III. $H_m = 1.0$ oersted
IV. $H_m = 0.5$ oersted

Fig. 10 compares the switching voltages for 1/4-mil and 1/8-mil *4-79* Permalloy (test cores nos. 4 and 5) being switched by 0.5-oersted pulses. Both cores have the same switching time; it is only for values of $\mathbf{H}_m$ greater than 0.5 oersted that the 1/8-mil Permalloy switches more rapidly than the 1/4-mil Permalloy. Note that if eddy currents were the only factor that limited switching time, the 1/8-mil material would switch most rapidly.

Although the two wave forms pictured in Fig. 10 reach their peak values in the same time (about one microsecond), and decrease together, they have different curvatures on their leading edges. This may be dependent on the 0.4-microsecond rise time of the magnetizing pulse, although it is interesting to note that the switching voltages continue to increase for some time after the applied magnetizing fields reach peak value.

The rise time of the magnetizing force that is applied to a fast switching core does influence the pulse-response characteristics of the core. However, no data showing the effects of varying the rise time have been included in this paper.

Fig. 11 compares again the switching voltages for test cores nos. 4 and 5, this time for $\mathbf{H}_m = 0.25$ oersted. The 1/8-mil material, although of thinner gauge than the 1/4-mil material, switches much more slowly than the latter. In part, this is probably because of the larger coercivity of the 1/8-mil Permalloy, which results in a larger value for the quantity $1/(\mathbf{H}_m - \mathbf{H}_c)$. Since the double peak is very prominent in the switching voltage of the 1/8-mil sample, it is probable that a satisfactory theory concerning the double peak would explain further the slower switching of the thinner gauge material.

SWITCHING TIME VERSUS APPLIED MAGNETIZING FORCE

Fig. 12 is a composite that shows the four switching voltages that result for four different values of magnetizing force applied to test core no. 3. Wave form IV demonstrates that the double-peaked switching voltage is also obtained with the 48-per-cent nickel-iron cores when $\mathbf{H}_m$ is small. The areas under each of the four voltage wave forms are approximately equal, since each results from approximately the same total change of flux. Figs. 13 and 14, also composites, show the switching voltages of test cores nos. 4 and 6, respectively, each for three different values of $\mathbf{H}_m$.

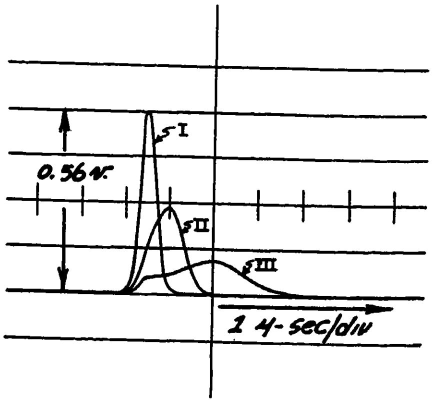

Fig. 13. The switching voltages of 1/4-mil 4-79 Permalloy, test core no. 4, for three different values of applied magnetizing force

I. $H_m = 1.0$ oersted
II. $H_m = 0.5$ oersted
III. $H_m = 0.25$ oersted

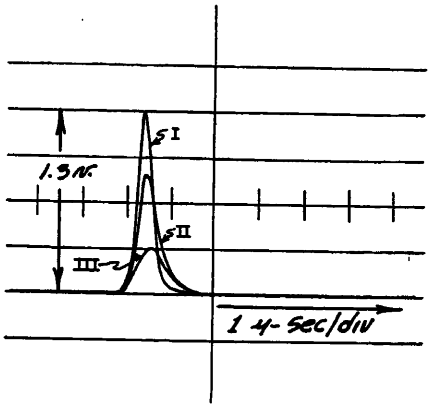

Fig. 14. The switching voltages of the ferrite MF-1118, test core no. 6, for three different values of applied magnetizing force. (The decreased area under wave form III indicates traversal of a minor loop)

I. $H_m = 4.0$ oersteds
II. $H_m = 3.0$ oersteds
III. $H_m = 2.0$ oersteds

The type of data shown in Figs. 12, 13, and 14 is necessary for the design of circuits that use the rectangular-hysteresis-loop ferromagnetic cores. Point-plotted curves of switching time t_s versus magnetizing force $\mathbf{H}_m$ are not generally useful, as is made evident by consideration of Fig. 14, the switching voltages for the ferrite sample. Though traversing the "saturation loop" of a material is spoken of loosely, none of the applied fields used in these tests, or in computer applications, is really sufficient to saturate the cores. Each different value of applied $\mathbf{H}_m$ causes the core to traverse a slightly different loop, and each loop has different

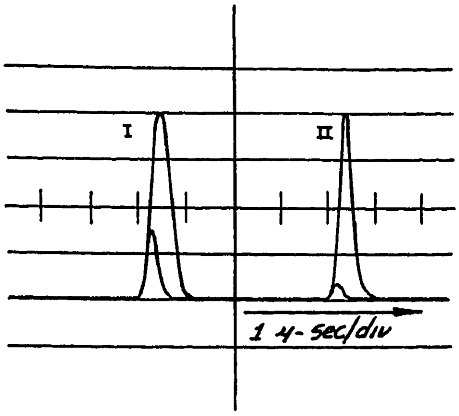

Fig. 15. The switching and nonswitching voltages of 1/2-mil and 1/4-mil 4-79 Permalloy for $H_m=2.0$ oersteds

I. Test core no. 7, $B_r/B_m=0.7$
II. Test core no. 8, $B_r/B_m=0.9$

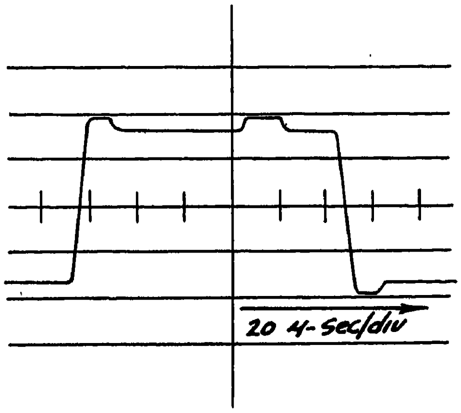

Fig. 16. Flux versus time pattern for 1-mil 48-per-cent nickel-iron, test core no. 1. The squareness ratio is about 0.91

values of H_c, B_r, and B_m. The switching times for $H_m=2.0$ oersteds and $H_m=3.0$ oersteds in Fig. 14 are equal, but it is obvious that the area under wave form III, representing the total change in flux for $H_m=2.0$ oersteds, is much less than the area under wave form II, which represents the total change in flux for $H_m=3.0$ oersteds. A curve of t_s versus H_m would indicate the same switching time for the two different values of H_m, but would not, of itself, indicate that two different hysteresis loops were involved. Hence, the importance of actual wave forms.

Squareness and Gauge

The composite in Fig. 15 is included to illustrate that the squareness ratio of 4-79 Permalloy increases as the gauge is decreased. The change in squareness ratio between 1/2-mil and 1/4-mil material is quite marked, and comparison of the switching and nonswitching voltages of the two samples makes it immediately apparent. The 1/2-mil sample has a squareness ratio of about 0.7; the 1/4-mil sample, about 0.90.

As stated earlier, the squareness ratio of 48-per-cent nickel-iron decreases as the gauge is decreased. Figs. 5(B) and 5(C) might be compared to illustrate this, although it is not obvious from simple inspection.

Flux Versus Time

Fig. 16 shows the flux versus time pattern for test core no. 1. Such a pattern depicts, within the limits of the accuracy of the integrating network, the total change in flux that has taken place within the core between any times t_a and t_b. However, it does not picture the manner in which the magnetic field actually penetrates the core. The flux pattern in Fig. 16 indicates that the core has a squareness ratio of about 0.91.

Effect of Load

Throughout this discussion, only unloaded cores have been treated; the single-turn output winding has negligible effect on the core characteristics. However, the operational characteristics of a core in a magnetic circuit are dependent largely on the load it must drive. In a typical application, the magnetic shift register,[1] the load consists of a similar core, several diodes, leakage inductance, and distributed capacity.

The treatment of the effects of various loads on core characteristics is beyond the scope of this paper. However, it is important to mention that the distributed capacity of a multiturn winding can have significant effect on the switching time, even when the winding is not connected to any external load. A 100-turn winding was placed on test core no. 1 in order to obtained the flux pattern shown in Fig. 16. Although it is not evident in the figure, a 20-per-cent increase in switching time resulted. A 300-turn distributed winding on a core like test core no. 4 can actually triple the observed switching time.

General

An interesting effect that can be observed with the ribbon-wrapped cores is illustrated in Fig. 17. Wave forms I are obtained when the single-turn output loop encloses the region diametrically opposite the spot-welded area of the ribbon; wave forms II are obtained when the output loop is directly about the spot-welded area. The difference in squareness ratio is immediately apparent. This effect is probably the result of flux leakage in the vicinity of the end of the ribbon, but an exact cause has not been assigned. Improved core operation can be realized in circuits where squareness ratio is important by placing the output winding in regions removed from the ribbon end.

Squareness ratios that approach unity are achieved in the alloys by subjecting the ferromagnetic materials to strain-relieving anneals in a dry hydrogen atmosphere at soak temperatures as high as 2,000 degrees Fahrenheit. Any event which will upset the results of the anneal will decrease the squareness ratio. Fig. 18 illustrates dramatically the effect of pressing a fingernail firmly on the metal of test core no. 1. Wave forms I are the "before"; wave forms II, the "after."

Fig. 18 is not intended to indicate that the metallic cores are too sensitive to be useful. The stress used to obtain these results was much greater than that which a core would receive in almost any realistic condition. The metal is normally protected by the ceramic bobbin,

		0.5	1.8 to 2.2	0.90
		0.25	3 to 4	
		0.2	4 to 6	
4–79 Permalloy	0.125	0.5	1.8 to 2.2	0.92
		0.25	5 to 6	
MF 1118		4.0	1.0 to 1.5	
		3.0	1.5 to 2.0	0.95
		2.0†	1.5 to 2.0	

* Changes in squareness ratio are negligible for the small changes in H_m that are considered.

† A minor hysteresis loop is traversed.

and proper packaging techniques can be used to provide whatever additional protection is required.

It should be mentioned that the phenomena illustrated in Figs. 17 and 18 are most prominent with cores that have only one or two wraps of metal, and that the use of five or more wraps on a bobbin serves to temper the effects of both rotation and externally applied stress.

Conclusions

Rectangular-hysteresis-loop ferromagnetic materials have already proved their value in shift registers and in magnetic memories. Research programs currently being conducted in several laboratories throughout the country give promise of still wider use of magnetic cores, both in data-processing machines and other types of applications.

The measurements problem is of basic importance to both the magnetic circuit designer and the core manufacturer. Present day circuit design is based largely on empirical data, and will continue to be so until adequate theoretical methods become available. It is the responsibility of the engineer to formulate core specifications that will permit the manufacturer to develop materials and processes that satisfy each new demand. Only an assemblage of meaningful reliable data will enable the designer to select and use magnetic cores wisely and the manufacturer to control his product. It has been the purpose of this paper to indicate the kind of data that is useful. The magnetic-core test equipment that has been described is equally adaptable for use as a laboratory instrument or as a semiautomatized production tester, and hence can serve both the designer and the manufacturer.

Typical pulse-response characteristics of some of the commercially available rectangular hysteresis loop materials have been presented and discussed. The significant data, which were presented in the form of oscillograms within the paper, are summarized in Table II.

A simple and direct technique for measuring the pulse response characteristics of magnetic cores has been described. The test method is an extension of work performed at the Burroughs Research Laboratory and reported in an earlier paper.[11] The switching time and squareness ratio were selected for presentation because of their fundamental significance. However, the same principle can be used for more specialized tests if the proper pattern of applied magnetizing force is selected. An important example is the test that is used to select cores for the coincident-current memory.[12]

Pulse testing might also be employed advantageously for cores that are intended for use in magnetic amplifiers; those skilled in the magnetic-amplifier art can perhaps attach new interpretations to the data and techniques that have been reported here.

Discussion

C. E. Ward (Armco Steel Corporation, Middletown, Ohio): Mr. Wylen's paper is an excellent and timely contribution to this relatively new field of magnetic investigations.

As a supplier of thin ferromagnetic tapes, my company is endeavoring to evaluate the effect of core dimensions on the magnetic properties of ultrathin materials as a means of arriving at true material properties. We have found that one of the major factors that must be taken into consideration is the degree of coupling that exists between the primary and secondary windings, with respect to leakage flux produced by the initial rapid change in exciting current.

The double peak in voltage that is referred to by Mr. Wylen as occurring at values of H_m slightly greater than the coercive force appears to be the result of the combined effect of air flux and iron flux. Normally, no initial voltage spike is observed for values of H_m considerably greater than H_c because the iron flux is changing rapidly and the voltage produced is large enough to mask the effect of air flux on the observed voltage pattern. However, when H_m is small the magnitude of the air flux voltage may appear to be quite large compared to the voltage produced by the iron flux. This is particularly true if the cross-sectional area of the iron is small relative to the area of the search coil and if the position of the windings are such that there is considerable leakage-flux coupling between the primary and secondary.

Our experiments have shown that the leakage field will be distorted by the presence of magnetic material. Therefore, it is possible that the compensation for air flux provided in the test probe of Mr. Wylen's equipment is correct with no sample in the field, and incorrect under actual test conditions.

The factors which influence the coupling between the primary and secondary winding with respect to leakage flux are 1. The placement of windings with respect to each other; 2. The ratio of cross-sectional area of iron to cross-sectional area of air encompassed by the search coil; 3. The dimension of the core bobbin.

Figs. 19(A) and (B) illustrate the type of voltage patterns produced by varying the coupling between primary and secondary windings from a maximum to a minimum for $H_m=0.5$ oersted. Figs. 20(A) and (B) were obtained under the same test conditions, except that $H_m=1$ oersted.

It is, of course, difficult to eliminate the effects of circuitry in magnetic measurements with pulse excitation. However, it is obvious that care must be exercised in both measuring techniques and commercial applications if the true characteristics of the core materials are to be utilized effectively.

It is expected that the results of our study of the effects of bobbin size, number of wraps of material, and placement of windings will be published in the near future.

B. Minimum coupling
$V=0.5$ volt per division
$T=5$ microseconds per division
$B_r/B_m=0.96$

The Permeability of Silicon-Iron at Very Low Flux Densities

EBERHARD BOTH
NONMEMBER AIEE

THE initial permeability of magnetic materials is a characteristic of great theoretical as well as practical importance. By definition, the initial permeability is equal to the ratio of the peak value of the flux density to the peak value of the exciting magnetizing field, when the latter approaches the value of zero. Due to the difficulties encountered in measuring the true initial permeability, the term is frequently applied in a rather loose manner to values which have been determined at peak flux density values of 5 gausses or more, or which have been obtained by extrapolating permeability-versus-field strength curves to the zero value of field strength.

This practice is apt to cause considerable confusion, when the characteristics of various materials are to be compared and evaluated for applications for which the permeability at extremely small field strength is of critical importance as, for instance, in transformers, chokes, and filters used in wire communication.

In this paper the term "initial permeability" is used for values which were determined at field strength of the order of 10 microoersteds corresponding to peak flux density values of the order of 5 to 20 milligausses.

In his classical study of the behavior of iron and steel under the operation of feeble magnetic forces, which was published in 1887, Lord Rayleigh found[1] that for very small fields the permeability-versus-field strength curve can be represented by the equation $\mu=\mu_i+\nu H$ and that the same constant which expresses the increase in permeability with increasing field strength appears as a factor in the equation for the hysteresis loss $W_h=\nu H^3/3\pi$ (ergs per centimeter per cycle).

The significance of this relationship, which is known as Rayleigh's law, for the characteristics required of magnetic materials operating in very small fields is obvious: Since hysteresis losses not only drain energy from the sometimes very feeble signal but also distort it by introducing harmonics, the ideal communication transformer material would have a ν value of zero, that is, its permeability would be absolutely constant over the operating field range and its hysteresis loss would be zero.

Due to the work of H. Jordan[2] and V. E. Legg[3] the hysteresis constant has been universally accepted as one of the quality criteria of magnetic powder cores used in Pupin coils, filters, and other components of long-distance telephone circuits.

In 1943, the German communication industry adopted a standard specification[4] in which a modification of the Rayleigh constant was used to determine the acceptability of nickel-iron and silicon-iron alloys for use in communication transformers.

The requirements for the permeability and the hysteresis loss constants as stipulated in the German specification are

Paper 53-259, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 3, 1953; made available for printing May 1, 1953.

EBERHARD BOTH is consultant with the Signal Corps Engineering Laboratories, Fort Monmouth, N. J.

The author acknowledges his indebtedness to his associates, R. J. Franklin, D. M. Grossman, M. C. Hankel and W. Schlosser, who prepared, treated, and tested the specimens, and who are to be credited with the intelligent analysis and resolution of many unexpected difficulties encountered in the course of this work.

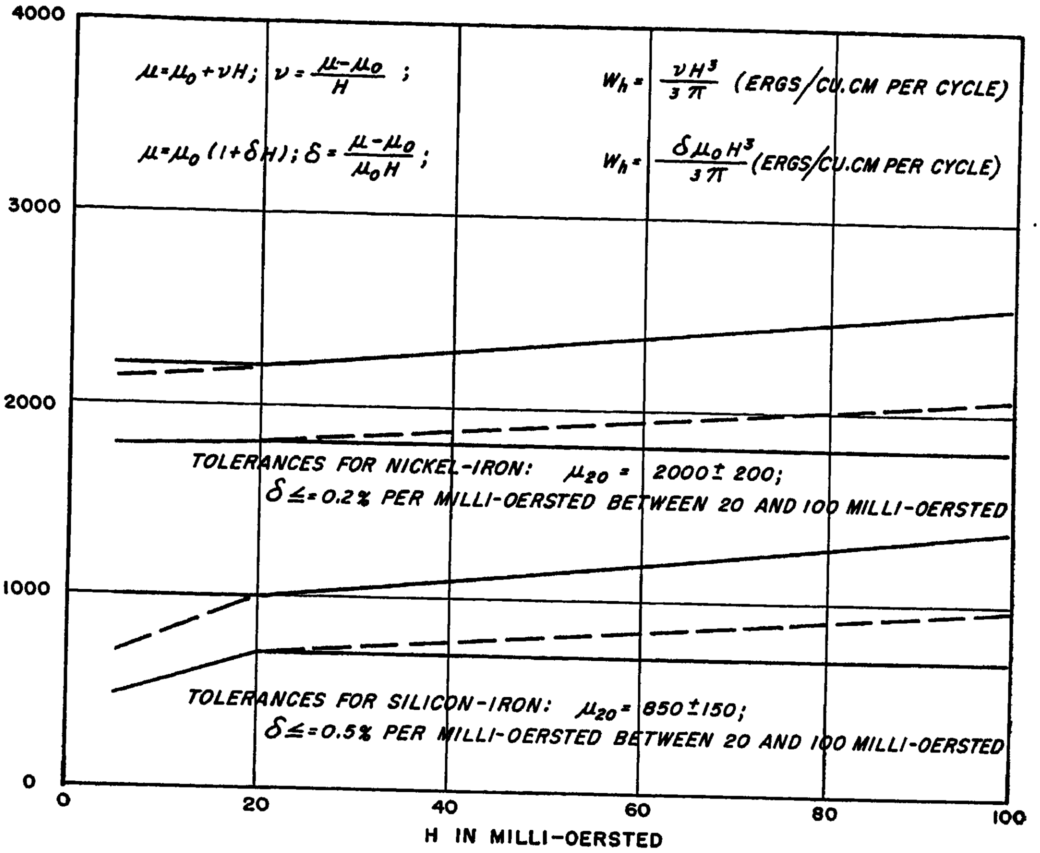

Fig. 1. Tolerances for permeability and hysteresis loss constants required for communication transformer materials according to the German Specification DIN E 41301

shown in Fig. 1. In the upper part of the figure, the Rayleigh equations for μ and W_h have been written in the original form using the constant ν, and in the modified form used in the specification, where the constant denoting the increase in permeability is called δ and is equal to ν/μ_0.

The two pairs of solid lines shown in the lower part of the figure represent the upper and lower permeability limits for nickel-iron alloys containing up to 40 per cent nickel and for silicon-iron alloys. For the former, the permeability tolerance at 20 millioersteds is 2000±200, for the latter 850±150; the maximum permissible δ-values are 0.2 and 0.5 per cent per millioersted respectively. For practical reasons the δ-values according to this specification are determined for the field strength range between 20 and 100 millioersteds.

It is beyond the scope of this paper to compare the performance characteristics of the nickel-iron materials commonly used in communication transformers in this country with their German counterparts, although it may be stated in passing that the adoption of the lower nickel contents prevalent in German materials would yield substantial savings in nickel without loss in performance characteristics.

For the problem at hand, however, a comparison of the representative silicon-iron grades presently available in this country with the German material Trafoperm *25N1* proves very informative. Such a comparison is made in Fig. 2, where data taken from current catalogues of the Armco Steel Corporation and the United States Steel Corporation have been plotted to the same scale as that used in Fig. 1.

It is at once apparent that in all the materials shown the change in permeability with field strength is many times higher than that exhibited by the Trafoperm *25N1* material. The δ-values calculated from these curves show a ratio of more than 100 to 1 between the topmost material TRAN-COR 3X-O and Trafoperm *25N1*, which means, of course, that under the assumption of equal perme-

900	1,330	1,600	2,320	0.75	0.56

ability the losses in a communication transformer containing the former material would be more than 100 times higher than those of one equipped with the latter material.

This statement will probably come as a shock to the manufacturers of grain-oriented steel, who are justly proud of the fact that their material has the lowest power losses of any of its kind produced anywhere. Paradoxically, however, this is the very reason for the fact that the losses at very low fields are particularly high, because achieving low power losses for operating flux densities of 10 or 15 kilogausses requires a narrow hysteresis loop, high maximum permeability, and consequently a steep rise of the permeability-versus-field strength curve from the initial permeability value to the maximum permeability. This in turn causes the Rayleigh constant to increase tremendously which, as was stated before, is equivalent to the rise in low field hysteresis losses.

Besides the undesirably high hysteresis constant, the regular silicon-iron grades do not even possess very attractive values of the initial permeability. Of course, this is true only if the term is used in its literal meaning rather than in the loose way so often encountered. At field strength values of several millioersteds, the permeability of some of the materials is impressively high, indeed, but one is reminded of the axiom: "The higher they climb, the lower they fall," when it comes to extrapolating the values to zero field strength.

It is noteworthy that in all the curves the rate at which the permeability drops for field strength values approaching zero is much greater than would be expected from an extrapolation of the almost linear portion of the curves at slightly higher fields. This behavior is characteristic of silicon-iron, and studies by J. L. Snoek,[5] F. Pawlek,[6] and others make it probable that the anomaly is due to very small impurities of carbon, nitrogen, oxygen, or possibly other elements contained in the metal.

In contrast to the materials just discussed, which might be classified as power transformer materials, the German Trafoperm *25N1* was exclusively developed for use in communication transformers. This development was undertaken by the author and his associates, most notably Dr. F. Assmus, at the Research Laboratory of the Vacuumschmelze in Hanau, Germany in 1941. It was prompted by the severe nickel shortage in Germany during World War II.

The notable features of the material, as shown in Fig. 2, are its relatively high initial permeability of about 830 in the curve shown (measured at 10 microoersteds) and the relatively small increase of the permeability, averaging 0.3 per cent per millioersted for the field range from 10 microoersteds to 100 millioersteds. On the other hand, the material is entirely unsuitable for use in power transformers, since it has a coercive force of 0.8 to 1 oersted and a maximum permeability of only about 6,000.

These characteristics are achieved by a process differing from the production of grain-oriented silicon-iron used in power transformers by a higher degree of cold reduction and a final anneal at a lower temperature.

In Table I the characteristics of the materials represented in Fig. 2 are summarized numerically.

The work reported here was done recently at the Signal Corps Engineering Laboratories. The material used in the study was obtained from the Allegheny Ludlum Steel Corporation in the form

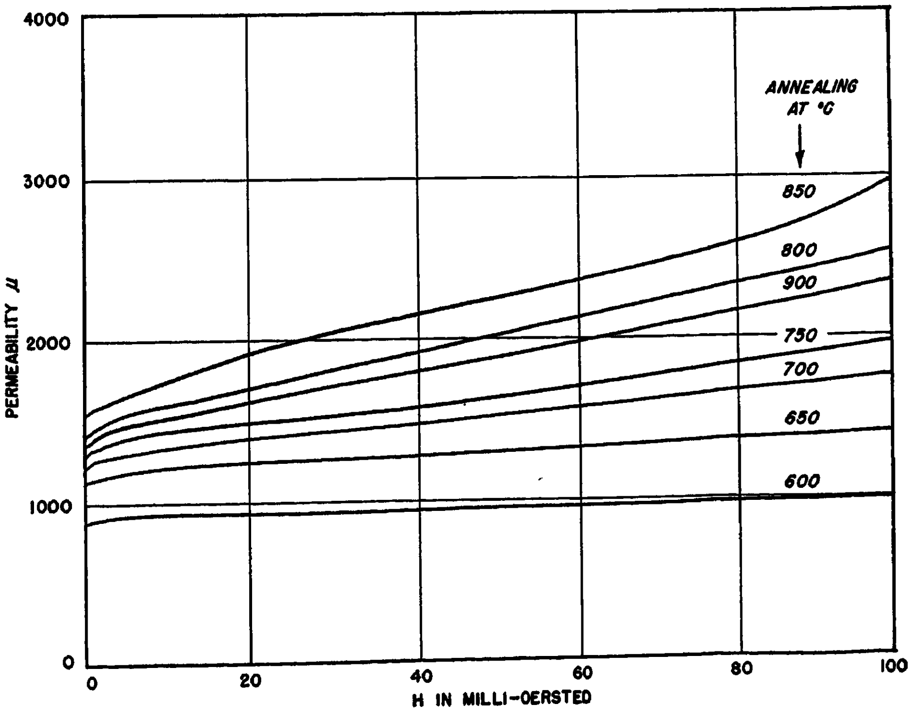

Fig. 3. Permeability of 3.25 per cent silicon-iron 2 mils thick after hydrogen anneals at various temperatures

of hard-rolled tape 0.5 inch wide and 5 mils, as well as 2 mils, in thickness. It had been produced from a fully annealed and oriented strip of 14 mils thickness, the normal power transformer material of the firm known as Silectron, by cold-rolling without intermediate anneal to the final thickness, thus resulting in a cold reduction of about 64 per cent for the 5-mil tape and of about 86 per cent for the 2-mil tape.

The material was coated with dry magnesium oxide powder for the purpose of insulating the adjacent layers of the tape and then wound to form toroidal cores with an inside diameter of about 1.5 inches and an outside diameter of about 2.0 inches. Individual series of cores were annealed in electrolytic hydrogen at peak temperatures ranging from 600 to 900 degrees centigrade in steps of 50 degrees centigrade. The annealing cycle consisted of a heating period of about 2 or 3 hours, a holding time of 2 hours, and subsequent furnace cooling. Upon removal from the furnace the cores were inserted into ring-shaped containers machined from resin-bonded paper to avoid mechanical stresses by the necessary handling and by the application of the test windings.

Table III. Permeability and δ-Values of 3.25 Per Cent Silicon-Iron 5 Mils Thick, Annealed at Various Temperatures

Annealing Temperature, Degrees Centigrade	Permeability at			$\delta_{0.01-100}$ Per Cent Per Millioersted	δ_{20-100} Per Cent Per Millioersted
	0.01	20 Millioersteds	100		
600	770	860	1,020	0.33	0.23
650	1,460	1,760	2,340	0.60	0.41
700	1,720	2,230	3,310	0.93	0.61
750	1,680	2,380	4,460	1.65	1.10
800	1,850	2,700	5,450	1.95	1.27
850	1,920	2,950	6,280	2.27	1.41
900	1,950	3,050	6,760	2.47	1.52

The cores were tested for their permeability by direct current as well as by alternating current. The d-c method was the standard Rowland ring method which, for this particular core size, the number of secondary turns applied, the prevailing magnitude of the permeability, and the sensitivity of the fluxmeter used, gave significant results down to a field strength of 5 or 10 millioersteds. The extension to lower field values required the use of a-c tests which were made at 0.1, 1.0, and 10 kc per second. In most cases a field value of 10 microoersteds was safely reached with 10 kc. This is particularly true for the 2-mil material, where significant readings could be taken in some cases close to, or even slightly below, 1 microoersted. For the 5-mil material the limiting frequency proved to be 1.0 kc per second for several of the cores annealed in the upper temperature range, probably due to inadequate insulation or relatively high permeability values. Even in the worst case, however, the readings taken at 50 microoersteds are considered reliable.

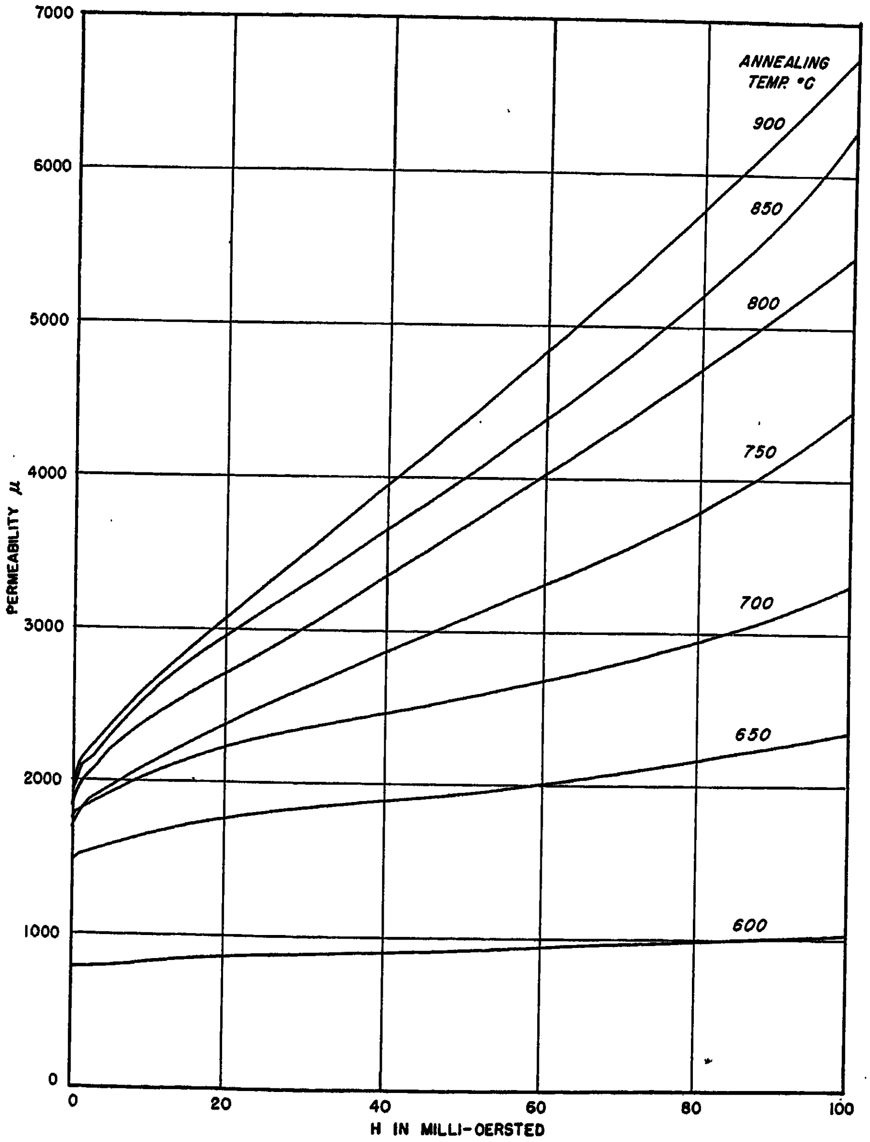

Fig. 4. Permeability of 3.25 per cent silicon-iron 5 mils thick after hydrogen anneals at various temperatures

The circuit for the a-c tests consisted of a Hewlett Packard oscillator model *650A* as the source, the test windings, and two Ballantine *VTVM*'s, one of which, model *310A*, was operated as a milliamperemeter for measuring the primary magnetizing current, while the other one, model 300, was used—sometimes in conjunction with an external preamplifier, model *220A*—to read the secondary voltage developed by the core. All instruments were carefully calibrated and the voltage and current wave shape was monitored for excessive distortion by means of an oscilloscope, but, as was to be expected at the very low flux densities, the wave shape remained as closely sinusoidal as could be judged by this check. It is estimated that the absolute accuracy of the results is well within 5 per cent of the true values, while the relative accuracy for repeated tests of one core is probably better than 2 per cent. It should be noted also that very close agreement between the a-c and d-c values was observed in all cases for the field range where both test methods overlapped.

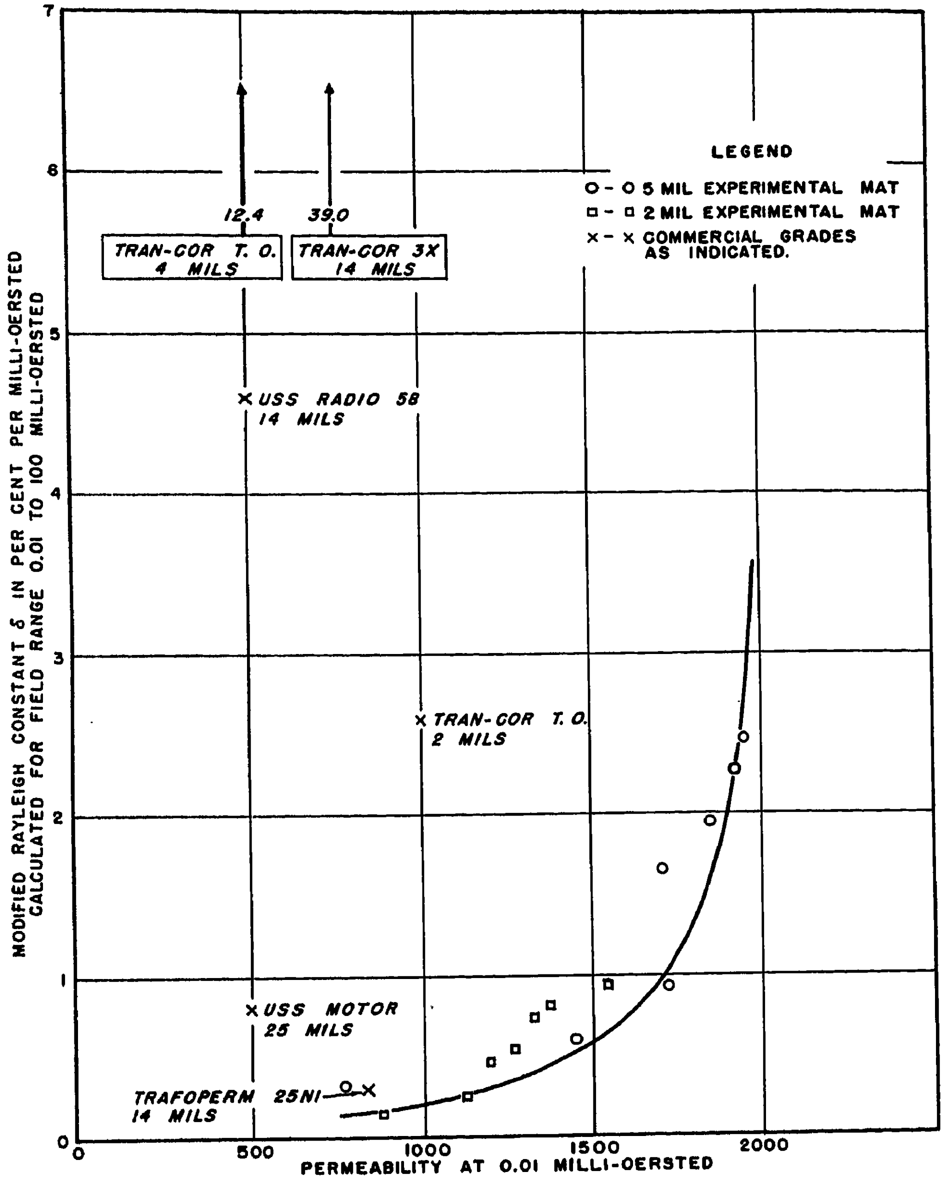

Fig. 5. Rayleigh constant versus initial permeability for various silicon-iron materials

Before the test, the cores were demagnetized by continuously reversing a direct current of slowly decreasing amplitude. This process was performed in two steps for which the number of primary turns was changed from 35 to 1, which allowed a very nearly continuous field reduction from a peak of 25 oersteds to below 10 microoersteds. This method of demagnetization proved to give much more consistent results than various a-c procedures which had been tried previously.

The results of the annealing experiments obtained with the 2-mil tape are plotted in Fig. 3, where the permeability-versus-field strength curves resulting from the seven different peak annealing temperatures are shown. Generally speaking, the initial permeability and the slope of the curves are seen to increase with increasing annealing temperature, with the exception of the 900-degree-centigrade anneal which yields a curve falling between those obtained from the 750- and 800-degree-centigrade anneals.

As mentioned previously, the initial permeability of all the 2-mil cores shown in Fig. 3 was tested at or below 10 microoersteds, corresponding to flux density values of 10 milligausses or less. All curves exhibit a certain permeability drop within the initial permeability range from about 3 millioersteds down to zero. The remarkable fact, however, is not that this drop exists, but that it is so much smaller than that exhibited by the regular grade materials shown in Fig. 2. The measured initial permeability at 10 microoersteds is in all cases less than 5 per cent below the values obtained by extrapolation of the nearly linear portion of the μ-versus-H curve. For the regular grades, accurate figures for this discrepancy cannot be determined, since information on the true initial permeability values is lacking, but it appears safe to say that it amounts to 50 per cent or possibly more in several cases.

The initial permeability values of the experimental cores range from 870 to 1,520 at 10 microoersteds. They may not appear to be spectacularly high, but it is believed that they are the highest ever reported for cores of 2-mil silicon-iron prepared from commercial material. They do not reach the values for nickel-iron alloys, but they approach them closely enough to warrant a study of their potential usefulness as a substitute material.

The variation of the permeability with field strength is much smaller than that of any of the regular materials. The δ-values calculated for the field range from 10 microoersteds to 100 millioersteds range from 0.138 per cent per millioersted for the material annealed at 600 degrees centigrade to 0.942 per cent per millioersted for that annealed at 850 degrees centigrade. This compares with δ-values based on conservatively estimated initial permeability values of the materials in Fig. 2 and Table I ranging from 0.8 to 30 per cent per millioersted. It is therefore evident that the experimental cores are by far superior to the regular silicon-iron materials with regard to permeability values as well as with regard to their hysteresis loss constants.

The numerical data for the characteristics of the cores represented in Fig. 2 are tabulated in Table II.

The results obtained with the 5-mil material are shown in Fig. 4, again for the seven annealing temperatures employed. Obviously, the initial permeability values here are much higher than those of the 2-mil material annealed at the same temperatures. They range from 1,460 to 1,950 with the exception of the core annealed at 600 degrees centigrade, which only reached a permeability of 770. The permeability drop in the initial range is present here, too, but as in the 2-mil material, the difference between measured initial permeability and extrapolation of the nearly linear portion of the curve is well below 5 per cent.

The permeability change with field strength is much greater than that observed in the 2-mil material with the δ-values ranging from 0.325 per cent per millioersted to 2.47 per cent per millioersted. It may be interesting to note, however, that the core annealed at 650 degrees centigrade, when evaluated in terms of the German standard specification, comes close to the permeability range of the nickel-iron class, having a permeability of 1,760 at 20 millioersteds, where a minimum of 1,800 is specified for nickel-iron, and that the δ-value for the field range from 20 to 100 millioersteds is well within the limit specified for the silicon-iron class, being 0.411 per cent per millioersted instead of 0.5 per cent per millioersted as specified.

It is possible that the poorer δ-values of the 5-mil material are at least partially due to the smaller amount of cold-reduction which this material has received, as was mentioned earlier.

Table III contains the summary of the numerical results of the cores represented in Fig. 4.

Fig. 5 represents an over-all review of the data discussed before. The δ-values of the regular grade silicon-iron as well as those of the experimental 2-mil and 5-mil material are plotted versus the initial permeability. It demonstrates once more that the regular grade materials possess extremely high hysteresis loss constants and poor initial permeability, while the experimental material is considerably better on both counts. From the tentative curve drawn to connect the optimum results of the experimental cores, it can be concluded that initial permeability values of 1,500 can be achieved, if the δ-value is limited to 0.5 per cent per millioersted as in the German specification, and it is hoped that further improvements are in the realm of possibility.

It should be noted that the results reported here are of a very sketchy nature. A systematic study of the problems involved is now in progress at the Allegheny Ludlum Steel Corporation under Signal Corps sponsorship. It is hoped that this will result in the commercial production of silicon-iron materials designed for use in communication transformers in this country, and it is expected that the amount of nickel-iron alloys presently used for this purpose can be substantially reduced.

Discussion

D. C. Dieterly (Armco Steel Corporation, Middletown, Ohio): Dr. Both is to be congratulated for this fine paper calling attention to the characteristics of his experimentally processed material at low field strengths. This type of development has received little attention in this country, partly because of the lack of a clear demand for the product, but primarily because there has been such a large unsatisfied demand for grain-oriented silicon-iron alloys processed for low losses and high permeability at high flux densities.

Because our regular commercial grades of grain-oriented silicon-iron alloys have been aimed primarily at high-density applications, our published data were obtained for the sort of operating conditions where most of the tonnage is used. Consequently, Dr. Both did not have either our best available data at very low inductions, nor was he aware of the large amount of data on experimental variations from our normal product. Therefore, we should like to comment on a few factors which may not be generally known or which are apt to cause some misleading conclusions.

Armco Steel Corporation has been a large-scale producer of grain-oriented silicon-iron alloys for 15 years; and for the last 10 years has been producing highly oriented material as thin as 0.001 inch. The performance characteristics of such materials, not only in the high-induction range but in the Rayleigh region as well, have received considerable study.

Our commercial grades of thin, grain-oriented silicon-iron alloy have long been produced by the same process as Dr. Both's experimental material except that the final annealing is normally chosen to produce material suitable for the usual high-induction applications. However, materials intended for special annealing treatments have been available when needed to meet special requirements, and when the demand warranted a new grade. These processes have been patented[1] and licensed for use by others.

Of the three grades of Armco materials listed in Table I, only 2-mil Armco TRAN-COR T-O has been given any processing especially calculated to give a lower Rayleigh constant than would normally result from the processing given for good high-induction properties. Permeability and hysteresis data on 2-mil Armco TRAN-COR T-O in the range from 1 millioersted upward have been published,[2] calling particular attention to initial permeability greater than 1,500 and very low hysteresis loss at low inductions.

A few of the factors involved in the low-induction testing of cores which can have considerable effect on values of so-called initial permeability obtained on materials at these low magnetizing forces deserve some mention here.

Our experience leads us to conclude that there is no unique value of true initial permeability that can be assigned to a given specimen of these materials. The apparent value of initial permeability varies with frequency by an amount significantly larger than test error. Drift of permeability with time after demagnetization, while not nearly so large in these materials as in some others, is still of significant magnitude in part of the test range. These factors make it risky to specify a value of permeability at extremely low field strengths unless the test procedure is also specified in such detail that comparisons can be made on the basis of values obtained by identical procedures.

Another factor of considerable importance in obtaining measurements of such minute exciting currents while using electronic instruments such as oscillators, vacuum-tube voltmeters and oscillographs, is the likelihood that minute leakage currents circulating back through the power supplies of these instruments to a common ground will affect the readings to an unknown degree. Such troubles can often go undetected unless they lead to obviously improbable results. In testing at the lowest levels of magnetizing force mentioned by Dr. Both, we find it necessary to employ a special coupling transformer between the oscillator and test specimen to insure an exceptional degree of isolation from such leakage currents. Then, too, the use of battery-operated vacuum-tube voltmeters, together with the judicious selection of a common grounding point between these electronic instruments, helps in getting sound data by minimizing chances of leakage and pickup. These factors, too, make it important that the effect of circuit connections, instrumentation, and procedures be investigated thoroughly and described in detail.

In Table I Dr. Both lists a value of 1,000 for the estimated permeability of 2-mil Armco TRAN-COR T-O at 0.01 millioersted based on extrapolations of our catalogue data which were obtained by a-c bridge tests on a demagnetized specimen after 10 hours' drift. Our extrapolation from the a-c test data (taken down to 3 millioersteds) gives a value of 1,670 for the permeability of this specimen at 0.01 millioersted, when measured immediately upon demagnetization. Extrapolation of d-c tests made on the same specimen down to slightly less than 1 millioersted gives a value of 1,930 for the permeability at 0.01 millioersted. These test values correspond to a permeability gradient of 1.1 per cent per millioersted for the 0.01-to-100 millioersted range by a-c tests, and only 0.80 per cent per millioersted by d-c tests. If we use the 1.1 value of gradient and an initial permeability value of 1,670 as being most comparable to Dr. Both's procedure, the correct location for the point representing 2-mil Armco TRAN-COR T-O in Fig. 5 paper is much more nearly in line with his experimental material of equal initial permeability level than his estimate of 2.6 for gradient and 1,000 for the initial permeability.

Although we feel that the 2-mil material comes closest to being a practical means of meeting the requirements for these specialized applications, our regular 1-mil Armco TRAN-COR T-O has superior constancy of permeability in the Rayleigh region. D-c test data on this grade give a permeability of 1,380 at 0.01 millioersteds by extrapolation from d-c tests as low as 1 millioersted, and a slope of 0.51 per cent per millioersted in the 0.01-to-100-millioersted range. This grade has the smallest Rayleigh constant of any of our regular materials.

Regardless of what test method we might choose in which to place greatest reliance at very low field strengths, we believe Dr. Both's use of what we call the a-c crest-current method of permeability measurement is quite acceptable for comparing cores of the same dimensions, the same basic material, and similar windings, to note the trend of differences. It is a method that rates the performance of cores in proper relationship to the factors generally considered to be of paramount importance in some communications components. However, we do feel that the use of slope criteria based on a test point at 10 microersteds puts too much emphasis on a point that can easily be of dubious accuracy. At such field strengths we observe many anomalies in the characteristics of material of this type which affect the test results to a marked degree, but are not too well understood. It is our feeling that a much more dependable and reproducible value for Dr. Both's slope criteria is obtainable over a range of perhaps 0.20 to 20 millioersteds, or perhaps even 1.0 to 20 millioersteds. Even though these tests may not seem to be made at sufficiently low field strengths, there is no reason to suspect that, when the slope is sufficiently low in the range of 1 to 20 millioersteds, it will not be proportionally low in the range 0.01 to 1.0 millioersted. We feel, too, that the extension of slope criteria up as high as 100 millioersteds may be unduly severe, unless the requirements of the application clearly indicate operation at such relatively high fields.

The foregoing discussion should not be construed as implying that we disagree with Dr. Both's experimental test results or with his procedures. On the contrary, we find that his data agree very well with our own on such experimental materials. We are heartily in accord with his suggestion that silicon-iron alloys, processed in the manner he describes, be considered for communications components where it is indicated that a relatively constant level of permeability over a wide range of low field strengths is more important than a high average level of permeability over that range. His presentation of the experimental data on these thin silicon-iron alloys is a valuable contribution to the literature. It is hoped that it will result in concrete efforts to determine how cores of these materials compare with other materials both from performance and cost standpoints.

This discussion is undertaken primarily to explain the ideas and position of one producer of such alloys, so that it would not be construed from the dearth of published information that commercial producers of magnetic materials in this country have not given consideration to, and investigated the properties of, materials for these specialized types of applications. Workers in the industrial field are seldom able to report any appreciable amount of the extensive experimental work which is undertaken in connection with the development of commercial magnetic materials. It is fortunate that careful, experienced workers like Dr. Both can perform a service of this kind, and see to it that the possibilities in some of these seemingly marginal applications are not overlooked.

1. PROCESS FOR DEVELOPING HIGH MAGNETIC PERMEABILITY AND LOW CORE LOSS IN VERY THIN SILICON STEEL, M. F. Littmann United States Patent No. *2,473,150*, June 14, 1947.

2. THIN-GAUGE IRON-SILICON ALLOYS FOR HIGH-FREQUENCY APPLICATIONS, D. C. Dieterly. *Electrical Engineering*, vol. 68, April 1949, pp. 335–36.

V. E. Legg (Bell Telephone Laboratories, Murray Hill, N. J.): Dr. Both is to be congratulated for the encouragement he has given to the steel industry to extend the utility of silicon iron. This is important in view of the danger which a nickel shortage would present for magnetic materials such as those needed by the Signal Corps, and by the communications industries.

Silicon steel has had a broad and intensive development as a "work-horse" for the electric power industry, where its behavior at high inductions has been of greatest interest. At the same time, its performance at low inductions has been disappointing, because of two handicaps: the rapid drop in permeability as the magnetizing force drops, and serious instability of permeability at low inductions—instability caused by lapse of time, particularly after previous magnetization at inductions higher than normal.

The paper indicates encouraging progress in removing one of these handicaps, through a combination of especially hard rolling of silicon steel sheet, together with closely controlled final heat treatment. This process evidently yields material with permeability declining much more slowly with decreasing field than that of normally fabricated silicon steel. Whether the other handicap is removed remains for examination. We would inquire if the author has data indicating improved stability of permeability with age after previous magnetization. If such data are not available, they will surely be needed before the industry can be confident that his type of silicon steel can be used in communication equipment.

In connection with Dr. Both's display of data, it is urged that new material constants should be avoided if possible, in the interest of clarity in conveying information. A new permeability variation constant δ has been defined in the text, and, rather inconsistently, interpretations of the same symbol but differing by a factor of 10 have been used in the tables. To correlate these data with previous literature, we offer Table IV extracted for the first three materials from a 1937 study of magnetic losses[1] and computed for the rest from the present paper.

In Table IV the fundamental definition of $\delta = (\mu\text{-}\mu_0)/\mu_0 H$ has been used, with the data of the present paper covering the range of field strengths 0.01 to 100 millioersteds. Obviously δ is the fractional increase in permeability per unit of field strength. For appraisal of high-permeability magnetic materials we have found it preferable to observe the variation of permeability as a function of induction B. The material constant λ in Table IV is the fractional increase in permeability per unit flux density B. It is related to δ by the equation $\lambda = \delta/\mu_0$. This latter constant is especially useful in calculating permeability variation as a function of voltage across a coil.

REFERENCE

1 STUDY OF MAGNETIC LOSSES AT LOW FLUX DENSITIES IN PERMALLOY SHEET, W. B. Ellwood, V. E. Legg. *Journal of Applied Physics*, New York, N. Y., vol. 8, 1937, p. 351.

R. A. Chegwidden (Bell Telephone Laboratories, Murray Hill, N. J.): The paper is of particular interest since it describes a type of 3 per cent silicon-iron having magnetic qualities approaching those of the higher priced and sometimes difficult-to-get 45–50 per cent nickel-iron alloys.

A sample of specially prepared 0.001-inch-thick material, which Dr. Both sent us, was found to be the most stable silicon-iron we have tested. Stability in this sense refers to the stability of its permeability at very low-flux densities with respect to mechanical shock and with time after demagnetization as described by Mr. Legg.

The 0.004-inch commercial grade samples mentioned by Mr. Dieterly were also very good in this respect, although not quite as stable as the sample from Dr. Both. This may be, as Mr. Dieterly suggests, because 0.004-inch and not 0.001-inch material was used.

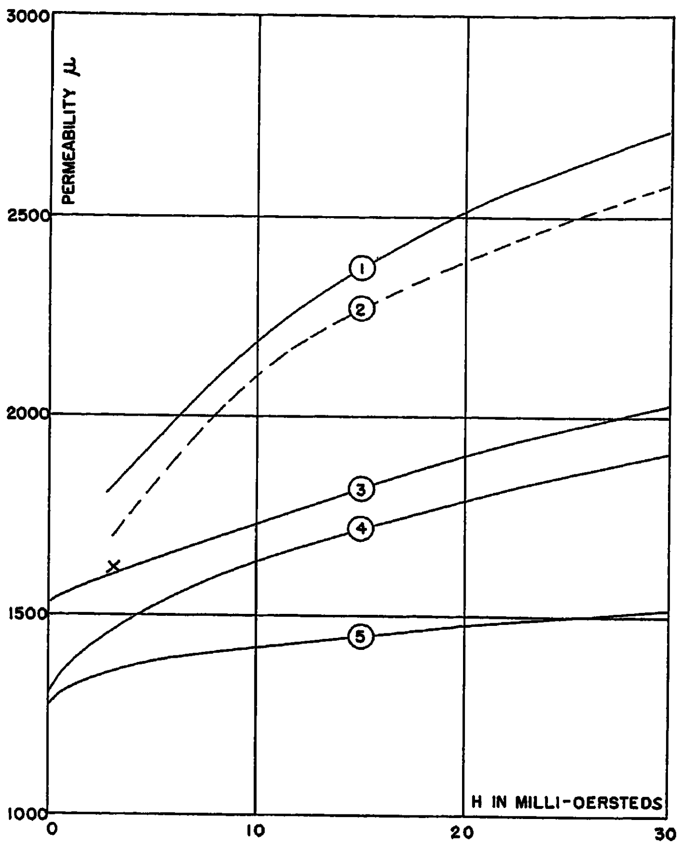
Some types of communication apparatus will work at very low power levels where the current in the windings also is extremely small. For such applications, it is customary to use nickel-iron alloys for the core material. The true initial permeability of the core material is an important design factor in this case. It was not found possible to use 0.014-inch thick silicon-iron in these applications because not only is magnetic stability a problem, but also the permeability tends to fall off so rapidly with decreasing flux density at very low flux densities that the indicated initial permeability is sometimes not very much greater than that of iron.

We are encouraged to learn from the tests of Dr. Both's material and the 0.004-inch commercial grade silicon-iron that in these thinner gauge materials substantial improvements have been made in magnetic stability and in the permeability at very low flux densities. Measurements of these materials using magnetizing forces of the order of 1.0 millioersted or less, however, still show the tendency of the permeability to fall at an increasing rate with decreasing magnetizing force. The true value of the initial permeability is thus uncertain. This behavior is not encountered in the use of the 45–50 per cent nickel-iron alloys which have practically constant permeability at these low magnetizing forces. The permeability of the silicon-iron alloys measured at magnetizing forces of a microoersted or less would be of interest.

Fig. 6. Permeability of silicon-iron materials 2 mils thick:

a. Armco TRAN-COR T-O material, according to data furnished by D. C. Dieterly: Curve 1—Demagnetized(no.5,371) Curve 2—After 10 hours drift (no. 5,006, corrected) Curve 4—Low temperature anneal (no. 5,372)

b. Experimental material, replotted from Fig. 3: Curve 3: 850 degrees centigrade anneal Curve 5: 750 degrees centigrade anneal



Eberhard Both: Mr. Dieterly points out correctly that, while the Armco materials, 14-mil-thick TRAN-COR 3X-O and 4-mil-thick TRAN-COR T-O, are most useful for high flux density applications only, the TRAN-COR T-O materials 2 mils and 1 mil thick have interesting properties for low flux density applications as well, and that the characteristics of the light-gauge materials approach those of the author's experimental material.

A comparison of these characteristics based on new and revised data furnished by Mr. Dieterly is given in Fig. 6 and Table V, where the curves labeled 1, 2, and 4 represent TRAN-COR T-O material 2 mils thick; and curves 3 and 5, two of the author's specimens of the same thickness. Curve 1 shows the TRAN-COR T-O material in the demagnetized state, and curve 2* after a 10-hour drift subsequent to demagnetization; curve 4 is a TRAN-COR sample deliberately annealed at a temperature below that recommended for 100 per cent relief of mechanical stresses. Curves 3 and 5 are replotted from Fig. 3; they represent specimens annealed at 850 and 750 degrees centigrade respectively and they were selected for coming closest to the permeability values of the TRAN-COR T-O samples.

Table V contains the numerical values for these curves. To represent the slope in the initial field region, a column for $\delta_{0.01-20}$-values has been added to those for $\delta_{0.01-100}$ and δ_{20-100} used in the paper. Comparing curves 1 and 2 with curve 3, and curve 4 with curve 5, it can be seen that the $\delta_{0.01-20}$-values of the experimental material are only about one-half of those for the TRAN-COR T-O 2 mils thick. While this is still a considerable difference, it is much smaller than the author was led to believe from the data at his disposal prior to Mr. Dieterly's communications.

The relatively good low flux density properties of the TRAN-COR T-O materials 2 mils thick may appear to be at variance with the author's statement that materials with low power losses have low initial permeability and high δ- values. As has been shown, the permeability and δ-values of the TRAN-COR T-O material 2-mil are not the best possible characteristics; furthermore, the power losses of this material are about 1.5 to 2 times higher than those of TRAN-COR 3X-O 14-mils and TRAN-COR T-O 4 mils thick*. The characteristics of 2-mil TRAN-COR T-O may therefore be said to constitute a compromise of intermediate properties for high and low flux densities rather than a combination of optimum properties for both flux ranges.

If optimum properties for communication transformers are required, it is necessary to accept a large increase in power losses, which are of no consequence for low flux density applications anyway. It is then possible to achieve characteristics equal to those shown by the author, in materials 4 and 14 mils thick, where the normal grain-oriented variety is so extremely poor, not in spite of, but as a consequence of its very excellence at high flux densities.

The author is aware of the pitfalls inherent in the testing procedures for establishing magnetic characteristics at extremely low flux levels. A complete description of these procedures is not possible here; however, it can be stated that: 1. The instruments used were calibrated individually for the frequency and sensitivity ranges in which they were used; 2. The complete circuit was calibrated by testing a linear inductor (Mo-Permalloy powder core) at the same levels of current and voltage employed in the silicon-iron core tests; and 3. The result of the test performed by Mr. Cheg-

Table V. Comparison of Characteristics Based on New and Revised Data

Curve	Material	Permeability at 0.01	20	100	$\delta_{.01-20}$	$\delta_{.01-100}$	δ_{20-100}
		Millioersteds			per cent per Millioersted	per cent per Millioersted	per cent per Millioersted

*Values furnished by Mr. Dieterly.

†Value estimated from corrected data on Armco catalogue specimen, furnished by Mr. Dieterly.

---

*Curve 2 is included here to correct an error which the author had copied from the Armco catalogue and which resulted in wrong values for the estimated initial permeability and δ used in Figs. 2 and 5 and in Table I. According to Mr. Dieterly, the permeability of 2 mil TRAN-COR T-O at $B = 5$ gausses is not 1,620 as shown in the Armco catalogue curve no. 5,006 (this point is marked by a cross in Fig. 6), but 1,695; consequently the estimate of the extrapolated initial permeability is revised from 1,000 to 1,500 and the $\delta_{0.01-100}$- value from 2.6 to 1.4 per cent per millioersted (see Table V).

*No way has yet been found to achieve the low power loss characteristics of 14-mil and 4-mil grain-oriented material in gauges of 2 mils or less; despite this handicap, however, these materials are extremely valuable for power applications at high frequencies, where eddy current losses are equal to or greater than the hysteresis losses.

widden on one of the author's specimens was well within the estimated accuracy limit of 2 per cent given in the paper. The author is therefore satisfied that his results are probably correct within this limit.

Mr. Dieterly and Mr. Chegwidden disagree quite considerably on the lowest field strength at which the permeability should be determined to permit a dependable extrapolation to $H = 0$; while the former feels that this can be achieved by testing down to 1 or perhaps 0.2 millioersted, the latter wants the range extended down to 1 microoersted, that is, to a value 200 times smaller than Mr. Dieterly's figure, and 10 times smaller than the author's. The author is more inclined to follow Mr. Chegwidden's suggestion, since any tests above the actual operating level of communication transformers may yield meaningless and misleading results.

If test specimens having 10 times the cross-section area of those used by the author in the present study are available, the permeability values at 1 microoersted can be determined with the same accuracy as those given now for 10 microoersteds.

Mr. Legg and Mr. Chegwidden are mainly concerned with the instability of the material resulting from lapse of time and other influences. The latter's statement that the experimental material was found to be the most stable silicon-iron tested at the Bell Laboratories is in agreement with observations made at the Signal Corps Engineering Laboratories and extending over several weeks, where the permeability of four samples was found to remain within 2 per cent of the value obtained immediately after demagnetization, if the cores were kept on the shelf without a magnetic shield, but undisturbed by mechanical shock or handling. Many further tests of this nature will be needed in order to ascertain the limitations and possibilities of this material.

The author has used the δ-values for the variation of permeability rather than Mr. Legg's λ-values, because they are more familiar to him. While Mr. Legg is correct in stating that numerically the δ-values as expressed in per cent per millioersted are smaller by a factor of 10 than those which would follow from using the equation for δ as given in the paper, the values as given do represent the correct slope. In the German specification, the slope is expressed in per mille per millioersted, or $(\mu-\mu_0)/\mu$ per oersted, which results numerically in the δ-values as used by Mr. Legg. However, the author preferred to base his slope values on the percentual variation of permeability rather than on the variation expressed in per milles, because the latter unit appears to be hardly used in the technical literature of this country.

An Automatic Transfer Function Measuring and Recording System

IN making frequency response tests of various devices, the phase and amplitude of the output must be measured when a signal having a known phase and amplitude is applied to the input. These data may be recorded in the form of a polar, or Nyquist, plot of amplitude with phase, frequency being varied as the parameter. If the input is set as the reference corresponding to a unit vector with its tip at the point (1,0) on the polar plot, then the locus of the vector representing the output of the device on the same polar plot will be the transfer function of the device throughout the range of frequencies being tested.

The method to be described eliminates some of the drawbacks of the "brute force" method of taking frequency response tests, which usually involves taking reams of oscillograms of the input and output wave forms and graphically measuring the phase and amplitude from the curves. A further difficulty lies in the need for having recorders with a dynamic response considerably better than that of the device under test, lest the recorder response give phase and amplitude errors. The system described here does not depend for its accuracy upon the dynamic characteristics of the recorder. A further advantage lies in the fact that the plot is made directly on a single sheet of paper, which simplifies the data reduction, handling, and storage problems considerably.

Operating Principles

Other authors[1] have described direct reading methods of obtaining frequency response tests whereby the output of the device to be tested is compared to a signal, the amplitude and phase of which may be adjusted to match the output exactly. An oscilloscope is used as the balance indicator. The advantage in the method described in this paper lies in the fact that the measuring and plotting is done by a recorder. Also, at very low frequencies, it is difficult to use an oscilloscope as a balance indicator.

Fig. 1 illustrates the general method of obtaining the transfer function. A sinusoidal test signal, $A \sin \omega t$, is applied to the device under test which has a transfer function, $g\epsilon^{j\theta}$ where g is the amplitude ratio and θ the phase shift. The output of the device will then be $gA \sin(\omega t+\theta)+C$, which can be represented by a vector having a magnitude gA making an angle θ with the input vector, plus a constant output term C. By suitable resolving means, the X and Y components of the output vector may be measured and used to position the two co-ordinates of a function plotter which traces the vector locus.

This method of resolving the X and Y components is accomplished by sampling the output wave at certain points in the cycle, these points being chosen so that they will be indicative of the X and Y components of the output vector. This sampling technique, has been used for measurements at power-line frequencies.[2]

This sampling is performed by means of switches synchronously driven from the signal generator shaft. The switches energize each axis at the proper intervals. The sampled points are the 0- and 180-degree points of the input wave for the Y co-ordinate, and 90 and 270 degrees for the X co-ordinate. Owing to the fact that the sine is negative in the 3rd and 4th quadrants, and the cosine is negative in the 2nd and 3rd quadrants, the output signal is reversed when the wave is sampled at these points. This reversal is indicated in the figure by the switches and the box labeled -1.

Fig. 2 shows a plot of the wave forms at the input and output of the device under test. The middle sine wave is the input, with the sampling points indicated. Directly above is shown the output wave form on the same time scale. The dotted portion shows the wave form as it would be without the periodic reversal; the

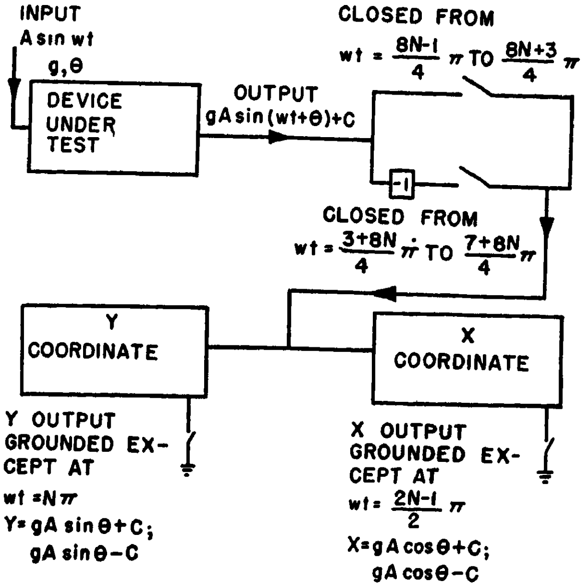

Fig. 1 (left). Block diagram showing principle of operation

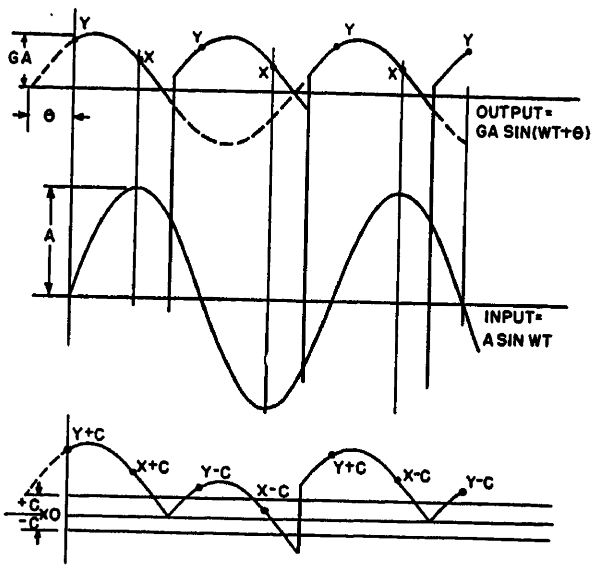

Fig. 2 (right). Wave form plots

solid portion shows the wave with reversals. The sampled points are indicated on the curves and designated as X for the points during which the X co-ordinate system is energized, and Y for the Y system. It is to be noted that for each axis two points are sampled per cycle.

It was mentioned previously that the output might contain a constant term C. This C might be any d-c component present in the output or a constant value of carrier in a carrier system. It might be caused by a zero shift present in the device or any static unbalance of the output transducer. To make use of the sampling technique for measuring the components of the vector, this constant term must be balanced out. This is accomplished by means of an adjustable suppression voltage in the measuring circuits.

The lower curve shows the effect of an error in this suppression adjustment. When the output of the device is reversed, it will also result in a reversal of the constant term C causing it to oscillate between $+C$ and $-C$ at the reversing frequency. Thus, the signals applied to the axes, which have this constant term added to them, will alternate between $X+C$ and $X-C$ for the X value, and $Y+C$ and $Y-C$ for the Y. This effect causes the point being plotted at a given frequency to appear as a rectangle instead of a point. Proper adjustment of the suppression control allows the area of this rectangle to be reduced to zero.

Table I shows the principle of this sampling technique. The first two columns show the expression for the output due to samples taken at 0 and 90 degrees without reversal. The vector sum of the X and Y components corresponding to the actual point plotted is $gA\, e^{j\theta}+\sqrt{2}Ce^{j\pi/4}$. The last two columns show the sampled points at 180 and 270 degrees with the output reversed. It can be seen that the components result in the same vector except that the constant term now has the opposite sign.

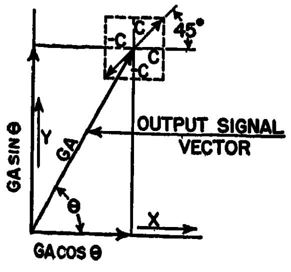
Fig. 3 shows a more complete block diagram of the system. The generator uses a closed-loop speed control servo to set and maintain the desired speed. Shaft rotation at this test speed is converted to pneumatic, positional, and electric sine waves by means of suitable transducers. This signal is then fed to the device under test.

The output of the device under test is converted to a 60-cycle modulated carrier signal by a suitable transducer, for example, a slide wire or a strain gauge. The reversing function described earlier is accomplished by reversing the supply voltage to the output transducer. The suppression potentiometer is also supplied from the same source as the output transducer, since the polarity of the suppression voltage must be reversed along with the output signal.

Each of the two co-ordinates includes a complete self-balancing system having an amplifier, balancing motor, and slide wire. Individual zero and span adjustments are provided for each axis, and serve the purpose of centering the plot and setting the proper scale factors. The output signal is connected to both systems; the sampling is performed by short-circuiting the balancing motors except during their sampling interval.

It is especially important to note that in the operation of the device the response of the recording system need not be fast, since the co-ordinates are required only to follow changes in the plotted point corresponding to the vector locus. This may be seen from a consideration of the fact that each co-ordinate is required only to balance to a single value at any one frequency, this point being the instantaneous value of the sine wave at the instant of sampling. Once a balance is reached by the system, no further movement of the co-ordinate drive system is required until the frequency is changed.

Table I. Development of the Polar Plot



Polarity	Output = $gA\sin(\omega t+\theta)+C$			
	Direct		Reverse	
Axis	Y	X	Y	X
Sample instant	$\omega t=0$	$\omega t=\pi/2$	$\omega t=\pi$	$\omega t=3\pi/2$
Quadrature components transmitted to recorder	$gA\sin\theta+C$	$gA\sin(\pi/2+\theta)+C$ $=gA\cos\theta+C$	$-[gA\sin(\pi+\theta)+C]$ $=gA\sin\theta-C$	$-[gA\sin(3\pi/2+\theta)+C]$ $=gA\cos\theta-C$
Vector sum	$(gA\cos\theta+C)+j(gA\sin\theta+C)$ $=gAe^{j\theta}+C\sqrt{2}e^{j\pi/4}$		$(gA\cos\theta-C)+j(gA\sin\theta-C)$ $=gAe^{j\theta}-C\sqrt{2}e^{j\pi/4}$	

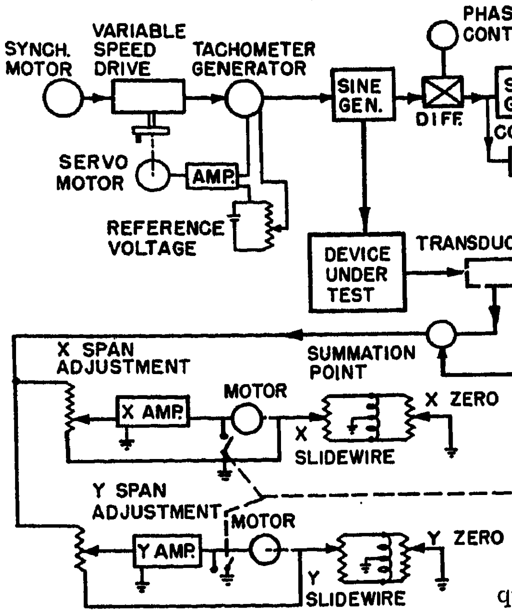


Fig. 3. System block diagram

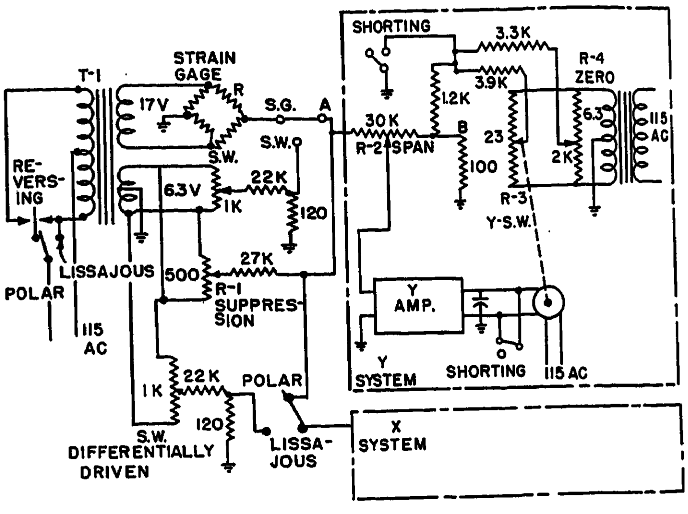

Fig. 5. Measuring circuit schematic

The rate of movement of the co-ordinates of a point is a function of the rate at which the frequency is varied. In practice, the frequency is varied manually in discrete steps, several cycles being allowed for a balance before the frequency is again changed.

The signal sampling interval is determined by the length of time that the short-circuiting switches remain open, and is influenced by two conflicting factors: the length of time required for motor drive and balancing, and the amount the instantaneous signal will vary during the sampled interval. It was found that about 6 degrees was a good compromise. For lower frequencies, a shorter interval can be used, since the sampled interval is then sufficiently long to obtain a balance in 1 or 2 cycles of the signal frequency. For higher signal frequencies, a somewhat longer period might be allowed, on the basis that the inertia of the motor will prevent any appreciable movement during 1 cycle.

Fig. 4 shows the entire system. The signal generator is in the lower left-hand corner. To the right of it is the control box which contains the operating controls as well as the electric circuits. In the top right-hand corner is the recorder, and adjacent to it the precision potentiometer, the d-c output potential of which determines the generator frequency.

Fig. 5 shows a schematic of the measuring circuits. Only the Y axis is shown in the diagram, but the X axis is identical in all respects. A 60-cycle suppressed carrier is used for all of the bridge and measuring circuits as well as for the amplifiers.

The use of a 60-cycle signal has the advantage that sufficient power is available to energize many types of output transducers, some of which require up to 1 watt. By using transformers having the center taps grounded, the impedances to ground are kept low, resulting in less trouble from electrostatic pickup. The use of the 60-cycle system has the disadvantage that signals must be properly phased. It also precludes the use of simple resistance-capacitance lead and filtering networks.

The strain-gauge output transducer and slide-wire signal transducer are energized from T-1, the primary supply to which is reversed to accomplish the signal reversal. The sampling switches short-circuit the amplifier windings of the balancing motors except during the sampling instant. It was also found necessary to short-circuit the voltage output of the slide wire of the axis not being sampled in order to prevent interaction between the two axis.

The bridge circuits use the principle of adding voltages through the use of summing resistors. The $3.3K$ and $3.9K$ act as summing resistances for the voltages at the slider of R-4 and R-3 respectively. Thus the voltage appearing at point B is the resultant of the slide wire and zero adjuster positions. The voltage which appears at point A is the resultant of the strain-gauge unbalance, and the position of the suppression potentiometer R-1.

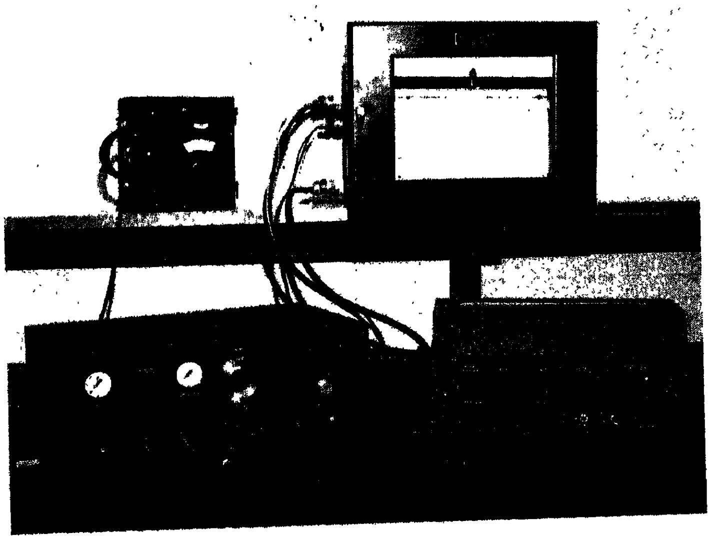

Fig. 4 (left). Entire system

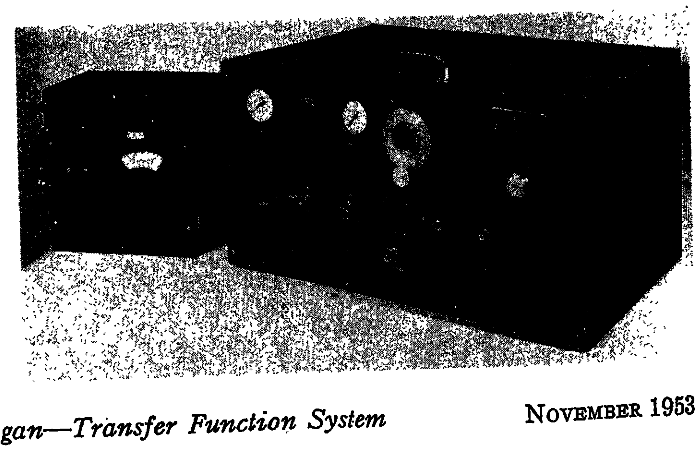

Fig. 6. Signal generator

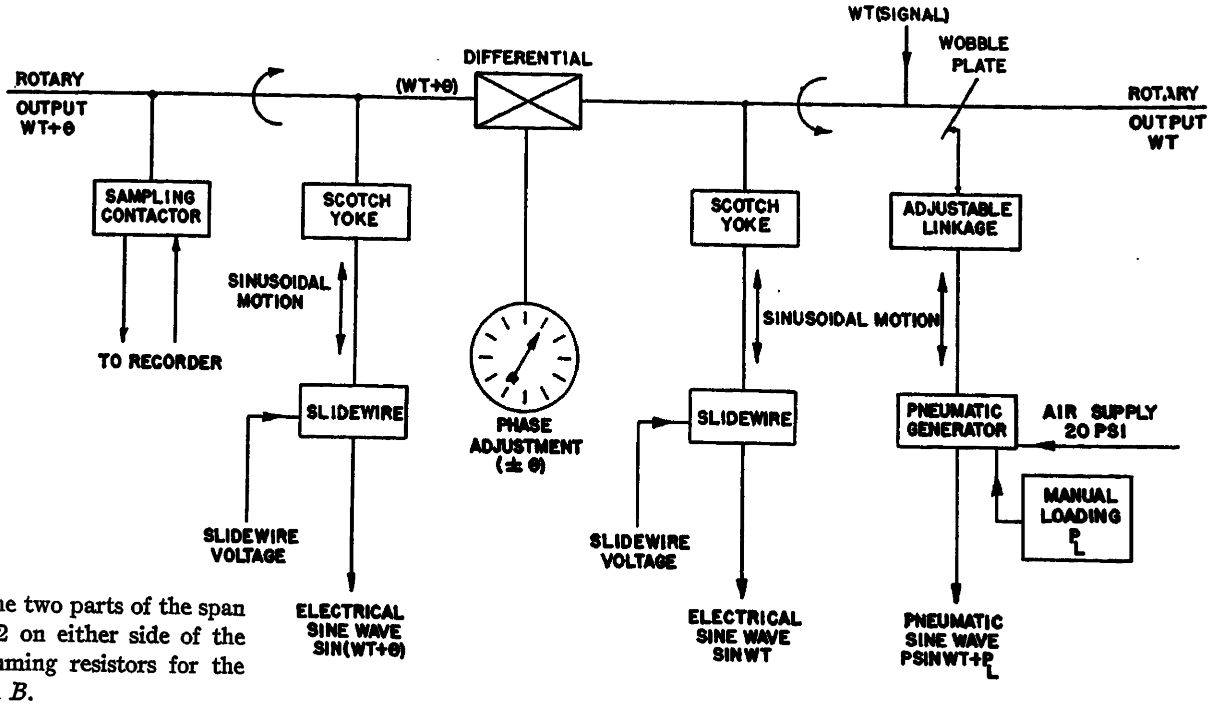
Fig. 7. Signal generator block diagram



In like manner, the two parts of the span potentiometer *R*-2 on either side of the slider act as summing resistors for the voltages at *A* and *B*.

For Lissajous operation, the two switches are thrown from "polar" to the "Lissajous." This connects the *X* system to the differentially driven reference slide wire, and cuts out the reversing switch in the primary of transformer *T*-1.

Signal Generator

The generator covers a frequency range from 1/30 cycle to 720 cycles per minute. It is capable of generating a wide variety of signals having good wave form and sufficient power output for most purposes. The desired frequency is set by a calibrated potentiometer and maintained by a speed servo. In addition to the test signals, reference and timing signals are provided. All controls and adjustments may be made from the front panel. Fig. 6 shows the generator and speed reference potentiometer.

Fig. 7 shows the block diagram of the generator. The main drive shaft rotating at the signal frequency is used to actuate all sinusoidal generating components. A wobble-plate sinusoidal cam activates the pneumatic generator through an adjustable linkage, as well as providing a motion sine wave suitable for testing low input-force devices such as pneumatic transmitters. Two scotch-yoke mechanisms, with a calibrated mechanical differential interposed between them, move the sliders of two linear slide wires. Also driven from the main shaft is the contactor which performs the quadrature sampling for polar operation.

For compactness the generator is arranged in two levels. The lower deck, Fig. 8, contains the main drive motor and speed control components. A 3,600-rpm synchronous motor drives a speed changer through a rubber-and-fabric timing belt. This stable speed changer consists of two disk-type variable speed drives in cascade, separated by a 6-to-1 gear reduction and further reduced at the output by a ratio of 12 to 1. A d-c tachometer generator develops a voltage proportional to the output speed, which is compared to a speed reference voltage from the precision portable potentiometer containing a standard cell. Any error voltage is applied to a d-c chopper-type amplifier to drive the speed change

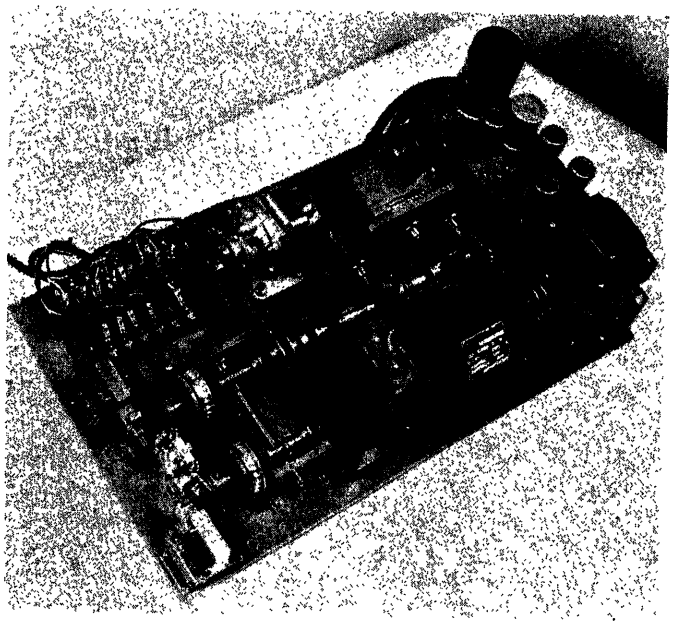


Fig. 8 (left). Lower deck

Fig. 9. Upper deck

motor so as to maintain the desired test speed. Adjustable limit switches prevent overranging of the speed changer.

The output rotation is fed through a gear box which gives a straight-through drive and also a 100-to-1 reduction. Either speed range may be selected by means of two solenoid-operated friction clutches controlled from the front panel. The driven members of the clutches are connected to the upper deck by means of a single timing belt. Extensive use in the drive unit of toothed timing belts eliminates many of the alignment and noise problems associated with gear trains.

The upper deck, Fig. 9, contains all of the signal-producing equipment. Driven directly from the drive pulley are the scotch yoke and sinusoidal cam, which in conjunction with their transducers generate the test signals. Between the generator elements and the reference and switching components is the differential gear which varies the relative phase. The reference and signal slide wires, which are standard Honeywell-Brown parts, are available in several resistances and are mounted so that they may be replaced quickly and easily. Also driven after the differential gear are the polarity reversing switches and the contactor unit. The contactor unit consists of four normally closed contacts which are opened periodically by a set of single-lobe cams driven at twice the test speed, since two points are sampled per cycle for each axis. Individual adjustments for duration and phase angle of contact opening are provided on the unit.

Pneumatic Sine Wave Generator

The pneumatic generator is a closed-loop device which produces an accurate sine wave with very little distortion. It is easily adjusted and provides a large range of signal amplitudes and mean pressure levels as well as having a high air-handling capacity. Supply pressure to the transmitter is 20 pounds per square inch (psi). The mean level of the output pressure may be set by means of a precision regulator from 1 psi to about 19 psi. The peak-to-peak amplitude of the sine wave signal may be varied from approximately 0.1 psi to about 15 psi. The signal amplitude is determined by the rotation of a control knob on the front panel of the drive unit. An adjustable linkage is also provided on the transmitter for setting the range of amplitudes.

Fig. 10 shows the air-handling capacity of the transmitter in the forward and reverse flow direction, which determines the pneumatic load that may be supplied from this generator. Frequency response tests have shown that the transmitter is flat to 300 cycles per minute (cpm) with a peak-to-peak amplitude of 1.2 psi at a mean level of 9 psi. These data were obtained when the transmitter was dead-ended into a strain-gauge pressure

transducer. For the same signal the transmitter is flat to 80 cpm when pipe-coupled into a 100-inch^3 volume.

Test Results

Fig. 11 shows an actual frequency response plot taken on a length of 400 feet of 3/16-inch inside-diameter tubing terminated in a 100-inch^3 volume. The frequencies corresponding to points on the curve are labelled and they cover the range from 0 to 50 cpm. The input to the tubing at all frequencies is shown on the plot as the point 3*i*. The plot shows a phase lag of 230 degrees and an amplitude ratio of 0.03 at a frequency of 50 cpm. Fig. 12 shows a similar test run using only the 400 feet of tubing dead-ended directly into the pressure transducer. In this case the plot indicates a phase shift of 200 degrees and an amplitude ratio of 0.13 at a frequency of 50 cpm.

The points indicated by 70 and 100 cpm on this plot illustrate the type of plot which results if the measured signal is not a good sine wave. In this respect the system provides a simple means of self-checking the wave form, if it is distorted at the instant of sampling. As the wave form becomes poorer, the recorder exhibits a tendency to wander and to draw large blocks instead of coming to a balance at a definite point. A further method of checking the wave form is to rotate the phase dial slowly as the recorder is plotting the balance point. If the wave form is good and the system is operating properly, the points will lie on a circle with its center at the origin.

Conclusion

This paper has described a flexible test station for frequency response measurement. It is capable of producing pneumatic, electric, and displacement sine waves in the low-frequency spectrum, and offers a quick means of obtaining a permanent, compact record of the frequency response characteristics of devices and systems. It has not only proved its usefulness in the laboratory for device and analogue testing but has also demonstrated its suitability and ruggedness in the field-testing of processes.

The data-handling and storage problems associated with graphic methods of frequency response measurements are eliminated and the recorder dynamic characteristics are by-passed by the sampling technique employed by this device. The 20,000-to-1 frequency range from 1/30 cpm to 720 cpm, plus the wide adjustability of signal size and level, provides a versatile transfer function measuring system. Considerable time-saving is achieved by being able to select the desired test frequency accurately and rapidly. Because the transfer function may be observed while the test is in progress, the operator is assured that he will not miss any significant points of the frequency response of the device.

Discussion

Page S. Buckley (E. I. du Pont de Nemours and Company, Orange, Texas): Although the determination of transfer-function data sometimes appears simple and straightforward in theory, in practice it is apt to be tedious and time consuming. This is because most of us must use such test equipment as oscilloscopes or oscillographs, laboriously pick off phase and amplitude, and plot it up on suitable graph paper. Any apparatus to mechanize or replace this procedure is welcome, and the authors have successfully developed such equipment.

This system is fairly elaborate and more expensive than conventional equipment for determining transfer-function data. This will probably be more than offset, in my opinion, by the time and labor saving features for three categories of users:

1. Research groups which have enough dynamic testing to provide a good load factor for the equipment.
2. Instrument or control equipment manufacturers who may wish to use dynamic tests for quality-control purposes.
3. Instrument departments in such manufacturing plants as chemical plants or oil refineries, where instruments and control devices get periodic overhauls and tests.

The design of this equipment appears to be basically sound and I have only two comments about it:

1. It has been our experience that there are several commercial variable-speed devices with adequate speed regulation, whose use would eliminate the need for a tachometer, d-c amplifier, and precision portable potentiometer.
2. The work we have done on dynamic testing of pneumatic instruments indicates the need for a transducer with a wider bandwidth and higher air capacity. Specifically, this reviewer suggests 0 to 10 cycles per second for loads of 10 standard cubic feet per minute or higher. This is needed to test pneumatically operated control valves, such as are used in the oil and chemical industries.

R. J. Ehret, E. F. Hochschild, J. M. Embree, and E. C. Grogan: We wish to thank Mr. Buckley for his thoughtful comments, which clearly point out the advantages of this method of taking transfer function measurements.

In reply to the two points which were raised by Mr. Buckley, we offer the following comments:

1. A closed-loop speed control system was chosen, not because the regulation was a problem, but rather because we desired an accurate and fast means of setting frequency. Furthermore, it is not necessary to depend upon any speed-changer dial calibration.
2. We agree with Mr. Buckley that for certain tests the pneumatic power requirements on a sine-wave generator are very high. For such tests, auxiliary equipment in the form of power amplifiers has been used. Even the suggested 10 cycles per second is not high enough to perform all testing; therefore other test equipment is used in the high-frequency spectrum.

Transmission Design of Intertoll Telephone Trunks

H. R. HUNTLEY
FELLOW AIEE

FOUR papers have already discussed such features of the nation-wide toll switching plan as the fundamental plant layout, numbering plan, toll switching, and automatic accounting equipments.[1–4] The present paper is intended to round out this coverage of the plan with a further discussion of the transmission features.

The Problem

In the new nation-wide toll switching plan using switching machines the layouts of toll circuits as well as the routings of traffic will be quite different from that of the earlier plans, which were based on manual switching. Individual calls can be switched so fast and so cheaply that switching is no longer a limiting factor, and circuits can be laid out and used in such a way as to obtain maximum economy with few, if any limitations from the switching standpoint.

An example of these changes is given in Fig. 1(A), which shows the circuit groups which would be used to handle a given (assumed) flow of traffic on a manual basis and in Fig. 1(B) the groups which would be used to handle the same traffic on a dial basis. In (A) there are 44 different circuit groups and in (B) there are 26 circuit groups. More specific ideas regarding the effects of these differences can be obtained by considering how calls between specific centers (for example, in Fig. 1, *A*1 to *B*1) would be routed in the two plans.

From the transmission standpoint the principal impact of the new plan is that the situation will be changed from one in which as much of the traffic as practicable was handled over direct circuits with a minimum of switched traffic (circuits in tandem) to one in which two or more (up to a maximum of eight) circuits will be used in tandem on many calls and in which different numbers and make-ups of circuits may be encountered on successive calls between the same two telephones, as a result of the alternate routings employed with machine switching. This means that the losses of circuits must be low to provide adequate transmission on all calls and to avoid large differences in transmission on successive calls between the same two places.

The ideal method in such a situation would be to operate all circuits at zero loss, since this would make the results independent of the number of circuits in tandem. However, the distances involved in the Bell System are so great that the propagation times, which affect echo, and the crosstalk between circuits require that even carrier circuits be operated at finite losses. Also, the plan must accommodate many voice frequency circuits on which the noise and singing conditions, as well as echo and crosstalk, may be more severe than on carrier circuits. The practical plan, therefore, is to:

1. Operate every circuit at the lowest loss practicable considering its length and the type of facilities used.
2. Assign circuits with different transmission capabilities in accordance with the parts they have to play in the operation of the over-all network.

The principal problem is to determine how low circuit losses can be made without getting into trouble as a result of one or more of the limitations mentioned above. This problem is complicated by the fact that the effects of these limitations are not directly proportional to circuit length or to the number of circuits in tandem. For example, if circuit *A* can be operated by itself at a loss of *X* decibels and circuit *B* can be operated by itself at a loss of *Y* decibels, the loss permissible when circuits *A* and *B* are switched together is less than $X+Y$. Ideally, therefore, each circuit should have a different loss in each different connection in which it is used. However, this is not practicable and a compromise must be adopted. This compromise provides that in some connections a particular circuit will operate at its lowest practical loss while in other connections higher losses will be employed to give over-all figures that will be adequate from the standpoint of echo, crosstalk, etc. The general procedure is as follows:

1. When a toll circuit is switched to another toll circuit at both ends work it at a loss which is called via net loss (VNL).
2. When the circuit is switched to another at one end only (the other end being at the point of origin or destination of the call) work it at a loss higher than VNL by an amount which we shall call *S*, *S* being a generic term derived from the fact that it may be associated with switching pads, usually called *S* pads.
3. When the circuit is used by itself (that is, the origin and destination of the calls are at the ends of the circuit) increase its loss by *S* again, that is, work it at VNL plus 2*S*. This is known as terminal net loss (TNL).

Via net loss is, of course, to be the lowest loss practicable referred to, and the next step is to establish methods of deriving VNL and of selecting the best value for *S*.

Since it would be a very complicated process to work simultaneously with all four of the limiting factors mentioned in the foregoing (echo, crosstalk, singing, and noise), the practical approach has been to select one of them as the basis of design and then check the results against the other three, modifying the final solution as necessary so that all four are kept under control. Since long experience indicates that echo is likely to be the most difficult and complex factor to control, it has been used as the starting point in the solution of the problem. As will be evident later, there are a large number of solutions possible from the echo standpoint, and the one which has been selected has been affected to a considerable extent by the other factors.

The next part of this paper is, therefore, devoted to an analysis of circuit design from the echo standpoint.

Determining Lowest Practicable Circuit Loss from Echo Standpoint

The over-all objective is to have practically no cases in which objectionable echo will be observed by customers.

If circuits could be precisely adjusted to the requirements in each different connection the probability of echo would be the same on all connections and the computations would have been carried out on the basis of a very small probability, say, 1 in 10,000. However, losses can be

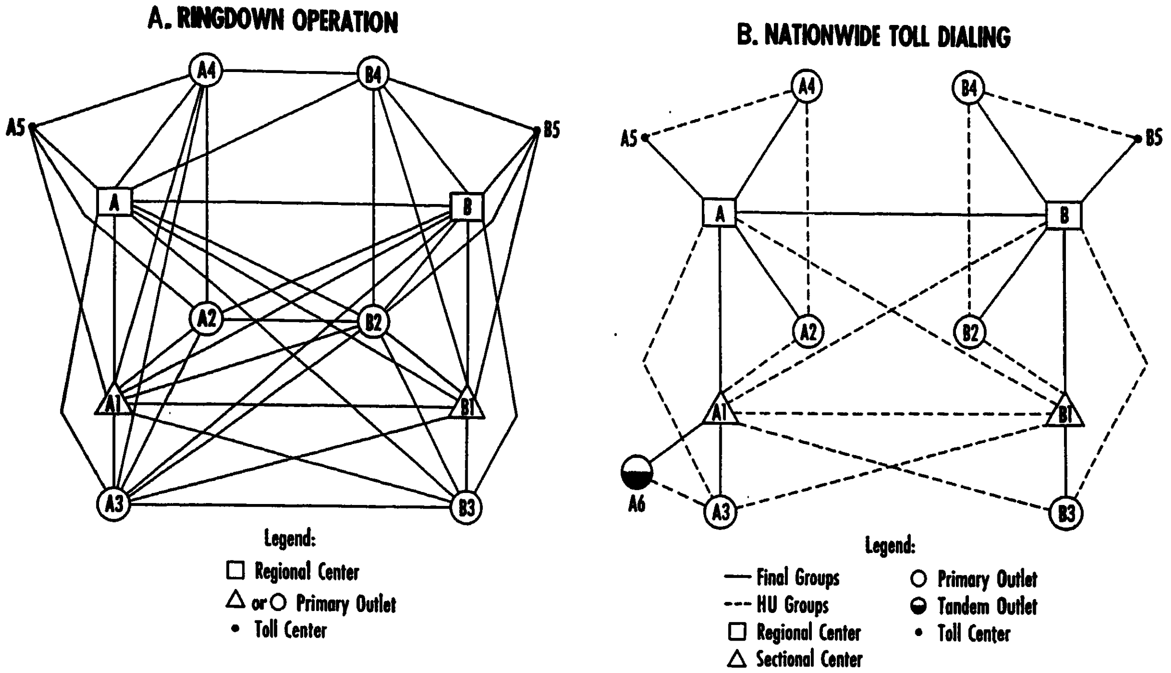
Paper 53-227, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 18, 1953; made available for printing April 22, 1953.

H. R. HUNTLEY is with the American Telephone and Telegraph Company, New York, N. Y.

Many persons took an active part in the preparation or in the development of the background data for this paper. The author wishes to mention, particularly, L. L. Bouton, who did much of the basic work on the mathematical concepts involved, on the simplification of these concepts for practical application, and on the re-evaluation of data required in these applications.

Fig. 1. Typical intertoll trunk networks



changed only in discrete steps S so that in a very large proportion of cases the losses will be higher than theoretically necessary. Hence it seems sensible to compute the theoretical losses on the more liberal basis of 1 in 100, relying on the excess loss in most connections to reduce the over-all probability to the very small value desired.

The echo problem with which we are concerned is illustrated in Figure 2. As shown there, part of the speech power which is being transmitted to the listener leaks across the hybrid, or 4-wire terminating set, at the listener's end and returns to the talker. This is known as talker echo. Actually, of course, some of the echo which returns to the talker can leak across the hybrid there and go back to the listener. This is known as listener echo. However, with modern plant listener echo will not be important if talker echo is adequately controlled.

Considering the effect of echo on the talker, if the elapsed time before the echo gets back to him is very short, it is just like hearing his own voice through the sidetone in his own set, and unless it is very loud he does not notice it. If, on the other hand, the elapsed time is long, it sounds to him very much like the familiar acoustical echoes arising from physical obstacles. In extreme cases he may get the impression that the distant party is trying to interrupt him.

The over-all effect of echo then depends on:

1. How loud the echo is, which in turn depends on how much loss there is in the echo path.

2. How long it is delayed before it gets back to the talker.

3. How easily the talker is annoyed by it (his tolerance to echo).

The factors involved are discussed in more detail in the following. For simplification, 4-wire circuits and 4-wire switching are assumed; 2-wire circuits and 2-wire switching are treated as variations and are discussed later.

Tolerance to Echo

People vary greatly in their reaction to echo of given magnitude and delay, and it is therefore necessary to treat them statistically, using the usual two statistical terms to describe a mass of data, that is, average and standard deviation.

Average means simply the familiar algebraic average of the data. No talker is average but it is possible to obtain the average of a lot of talkers. Standard deviation means a number which tells in general terms how the individuals spread out on both sides of the average. Usually 30 to 35 per cent will be between the average and 1 standard deviation below the average; 30 to 35 per cent will be between the average and 1 standard deviation above it. At least 45 per cent will be between the average and 2 standard deviations below it and at least 45 per cent will be between the average and 2 standard deviations above it. Very few, if any, will be outside of ±3 standard deviations.

Judgment tests under controlled conditions and with a number of observers (talkers), under conditions simulating connections to subscribers near the toll office, have given the following basic data on these effects: (These data are slightly different from some published earlier because of recent re-evaluations. Further studies are now under way and may indicate some further changes.)

An analysis of all the test data indicated that the observer judgments conformed fairly well with a normal law curve having a standard deviation (D_0) of 2.5. This means, for example, taking the 40-millisecond delay condition, that while on the average a 17.7-decibel loss was required in the echo path to make the echo just tolerable, some 30 to 35 per cent of observers could tolerate 2.5 decibels less loss. Another 30 to 35 per cent were sensitive enough to need 2.5 decibels more loss for satisfactory echo condition. Practically no observer was so sensitive as to require $3 \times 2.5 = 7.5$ decibels more than 17.7 decibels, and practically none was so tolerant that he could permit 7.5 decibels less.

Terminal Return Loss

As shown in Fig. 2, with 4-wire switching and 4-wire-type circuits, the only source of echo is lack of perfect balance between the balancing network of the 4-wire terminating set (hybrid coil or its equivalent) and the trunk, loop, and subscriber station connected at the customer side of the set at the distant terminal.

Table I. Results of Judgment Tests

Round-Trip Delay, Milliseconds	Loss in Echo Path Just Satisfactory to Average Observer, Decibels
0	1.4
20	11.1
40	17.7
60	22.7
80	27.2
100	30.9

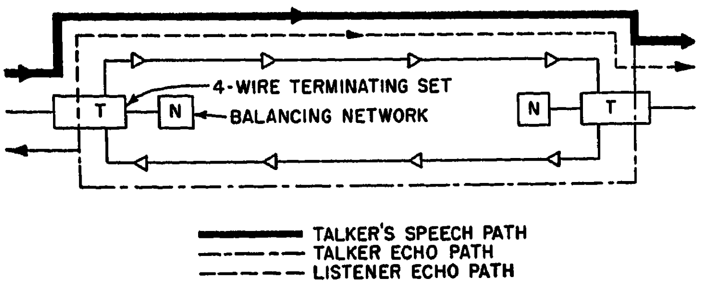


Fig. 2 (above). Echo paths

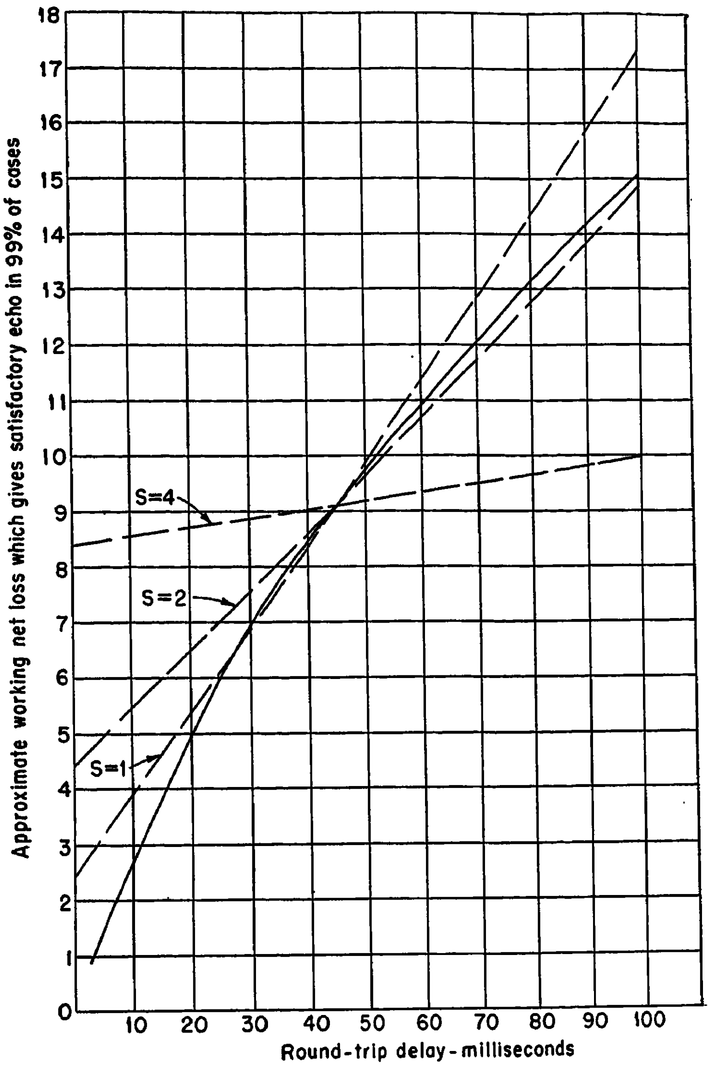

Fig. 3 (right). Approximate relationships between round-trip delay and permissible working 1-way loss for an intertoll trunk from echo standpoint for 4-wire circuits and 4-wire switching

The ratio of the amount of power reflected back into the hybrid coil to the amount which goes on toward the listener can be expressed as a loss in decibels. This terminal return loss in the echo range (approximately 500 to 2,500 cycles) has been found by tests and computations to have an average value of 11 decibels and a standard deviation $D_t=3$.

Round-Trip Circuit Loss

The round-trip circuit loss plus the terminal return loss is the total loss in the echo path. The round-trip circuit loss, that is, the over-all loss which the intertoll trunk (or trunks) inserts in the echo path, is the sum of the losses in the east-to-west and west-to-east directions. If the circuit regulation were perfect, this loss would simply be twice the nominal one-way loss of the trunks, which is the value sought.

However, regulation is not perfect, and to determine what the nominal loss should be, the deviations from it which are certain to occur in practice must be taken into account. A considerable amount of experience indicates that these deviations can be treated statistically and, considering some improvement in maintenance methods and procedures and a wider use of carrier systems with improved regulation, a standard deviation of $D_v=2$ decibels for round-trip losses seems a not unreasonable assumption for the next few years.

Relationship Between Working Echo Net Loss and Round-Trip Delay

All of the data needed are now assembled to solve the problem, which, as stated before, is to find what VNL to assign to a circuit of given length and on a given type of facility.

The first step mathematically is to combine the three statistical distributions discussed, that is, tolerance to echo, terminal return loss, and the variations in round-trip circuit loss.

The combined standard deviation (D_c) of the three sets of distributions is the square root of the sum of the squares of the standard deviations of the individual distributions. The first two distributions are independent of the number of links N (assuming 4-wire switching) but the distribution of circuit loss variations is a function of the number of links. The mathematical expression for the combination of these three standard deviations is

$$D_c^2=D_o^2+D_t^2+ND_v^2=2.5^2+3^2+N2^2$$

From this equation Table II can be constructed.

In line with the principles stated at the outset, the mathematics will be worked out on the basis that 99 calls out of 100 will be free from echo, then margins will be added. The mathematics are as follows:

1. To meet 99 per cent of the cases, 2.33 standard deviations must be used, or average round-trip loss = average echo tolerance—average return loss+2.33 standard deviations.

2. The average 1-way loss is the loss to be assigned and is one half the average round-trip loss.

Permissible average losses with several different numbers of links, based on this equation, are given in Table III. These data are for 4-wire circuits and 4-wire switching. It will be noted that for a given total round-trip delay the necessary increase in over-all loss for increasing numbers of links varies somewhat for different conditions but for the more severe cases it is about 0.4 decibel per link.

Because, as stated at the outset, the relationship between round-trip delay and permissible circuit loss is not linear, Table III cannot be used directly in selecting the working net loss of a circuit to be used in switched connections. An example will make this clear:

1. From Table III, the permissible loss of a circuit with 20 milliseconds round-trip delay is 5.0 decibels.

2. If this were used as the basis for designing the circuit, the loss of four such circuits in tandem would be 20.0 decibels whereas the table shows that four links with a total round-trip delay of 80 milliseconds could be operated at 14.6 decibels.

The problem then is to find the best method of determining VNL and *S*. As indicated earlier, this problem has a wide variety of solutions, among which the best can be selected on a judgment basis. The process is as follows:

1. In Fig. 3 a curve is shown giving the relation between working loss and round-trip delay for a single link, the information being taken from Table III.

2. With the plant as it will be in the reasonably near future the round-trip delay on any connection without an echo suppressor will not exceed about 45 milliseconds. This figure is based on a survey of geographical lengths, with some adjustment for the expected more extensive use of carrier and taking into account the rules (discussed later) for the use of echo suppressors.

3. Then starting at any arbitrarily selected value of S, a straight line can be drawn from $2S$ (since there is S at each end) plus 0.4 (required to be added per link for variations) and intersecting the curve at 45 milliseconds.

4. In Fig. 3, three such straight lines are drawn, for $S=1$, $S=2$ and $S=4$, which have slopes (in decibels per millisecond) about as follows:

S	Slope
1	0.15
2	0.10
4	0.016

5. From these data, equations for VNL and TNL for 4-wire circuits can be worked out in terms of round-trip delay d thus:

S	VNL	TNL = VNL + 2S
1	$0.15d+0.4$	$0.15d+2.4$
2	$0.10d+0.4$	$0.10d+4.4$
4	$0.016d+0.4$	$0.016d+8.4$

The slopes of the lines can be converted into factors called via net loss factors (VNLF) in terms of decibels per mile, by dividing twice the slope by the velocity of propagation in miles per millisecond. The product of VNLF and circuit length in miles plus 0.4 gives VNL.

As an example, for K carrier circuits with a velocity of propagation of 105,000 miles per second, the via net loss factor for $S=2$ would be $(2\times 0.10)\div 105=0.0019$.

For 2-wire circuits the local echo paths at the repeaters make it impracticable to establish a straightforward relationship between over-all delay and echo performance. The VNLF for such circuits are approximations based on judgment and experience.

8	6.9

Selection of VNLF and S

From the foregoing, it is evident that the values of S and VNLF are interrelated and that there is a wide variety of possible relationships.

Fig. 3 shows that, up to fairly long delays, the lower the value of S, the lower the over-all losses at which the circuits can be worked from the echo standpoint.

Since the lower delay calls are much more numerous than longer delay calls, it is desirable to use as low an S as is practicable. However, in selecting a value, the other factors which have been neglected to this point, crosstalk, singing, and noise, must now be taken into account and we must be sure that echo margin is now added. Each of these factors is now discussed separately.

SINGING

The more extensive use of carrier reduces the importance of singing because voice frequency circuits are becoming shorter, thus eliminating the difficult singing problems associated with multi-repeater-section 2-wire circuits. On the other hand, some of the conditions at circuit terminals may become more severe from the singing standpoint.

Studies indicate that over-all losses obtained with $S=2$ are adequate to care for singing under most conditions, but that if $S=1$ were adopted, singing would be more important. With $S=2$ the necessity for increasing circuit losses to avoid excessive danger of singing will probably be confined to a few open-wire circuits having large discrete irregularities.

NOISE

Noise is usually not a factor in the assignment of circuit losses. Carrier systems are so designed that under normal conditions the noise is low enough so that any desired loss can be used. If, in a specific case, noise in either carrier or voice frequency circuits is too high, the approach is to get rid of it by one or more of the means available.

ECHO MARGIN

Reference to Fig. 3 will indicate that for $S=2$ there is 2 decibels or more round-trip echo margin in all cases with round-trip delays less than the order of 30 or so milliseconds. With $S=1$ there is little margin and with $S=4$ there is excessive margin.

There will be very few connections with delays greater than about 30 milliseconds, which is roughly 1,500 miles of carrier, without echo suppressors. While the effect of the margin on probability of observing echo is difficult to compute quantitatively, it is estimated that with $S=2$ this probability will be very small. Additional margin is also provided by the fact that on many connections the connecting trunk loss at the talker's end is greater than the loss used in the tests for establishing the echo tolerance curve.

CROSSTALK

Analysis of many situations indicates, again, that with $S=2$, the losses are about as low as are practicable in general from the crosstalk standpoint. With $S=1$, they would be too low in many cases, and with $S=4$, they would be unnecessarily high.

With $S=2$, there may be a few cases where specific attention to crosstalk will be needed, particularly in open wire.

FINAL SELECTION

From the consideration of factors like the foregoing the value of 2 decibels has been selected for S on a judgment basis.

Provision of S

The loss S can be provided in any of the following ways as appropriate (see Fig. 4):

1. As a switchable loss pad in the intertoll trunks.

2. As a fixed loss pad in the toll connecting trunk.

3. As part of the conductor loss of toll connecting trunks. This can be done only if the structural return loss of the connecting trunks against the balancing network is reasonably good.

4. If there is to be no switching to other intertoll trunks or to connecting trunks with more than a 2-decibel loss, S may be provided simply by increasing the circuit loss by 2 decibels.

Via Net Loss Factors

Table IV lists typical VNLF's of Bell System intertoll trunk facilities for the condition $S=2$.

Typical losses at which circuits would be worked with $S=2$ and with the VNLF's tabulated in Table IV are given in Table V. The advantages of high velocity, 4-wire, circuits, carrier and radio, are obvious from these tables.

Echo Suppressors

Even if the intertoll trunk plant of the Bell System were all carrier, the length of some connections would be so great that some method of controlling echo other than simply increasing circuit loss would be desirable. Lower losses can be obtained on such connections through the use of the echo suppressor, an electronic device which under control of the talker's speech currents places a high loss in the return path at the right time to intercept the return echo currents.

Table IV. Typical Via Net Loss Factors

Facility	VNLF, Decibels per Mile 2-Wire Circuits	VNLF, Decibels per Mile 4-Wire Circuits

O. W. carrier		0.0017
K or *N* carrier		0.0019
L carrier		0.0015
Radio		0.0014

Echo suppressors perform very well so long as not many circuits equipped with them are connected in tandem and there is not too much time delay between them. With manual operation the switching is so limited that the chances of connecting circuits with echo suppressors in tandem are small and it has been practicable to apply echo suppressors on the basis of round-trip delay of the individual circuits. However, with dial operation it will be possible to establish connections which are long enough to require an echo suppressor but which are composed of circuits each too short to require an echo suppressor based on its round-trip delay. For example, an echo suppressor would not normally be used on a 500-mile carrier circuit, but if eight such circuits were connected in tandem giving a total length of 4,000 miles, an echo suppressor would be imperative, if over-all loss is not to be excessive.

It is not practicable to take care of this problem merely by reducing the delay time at which an echo suppressor is applied, since if this were done it is conceivable that eight circuits each with an echo suppressor might be connected in

Table V. Typical Losses

Type and Length of Trunk	VNL, Decibels	TNL, Decibels
50-mile *N1* carrier	0.5	4.5
50-mile 2-wire *H-88*	1.9	5.9
200-mile 4-wire *H-44*	2.4	6.4
500-mile *K* carrier	1.4	5.4

tandem. It has been necessary, therefore, to establish more or less arbitrary rules to insure at least one echo suppressor on long connections and to make it very improbable that more than two will be encountered. In general, these rules specify that echo suppressors will be placed on:

1. All RC-NC circuits.
2. All RC-RC circuits.
3. On high-usage group circuits when the desired losses cannot be met without them.

Our ideas as to when suppressors of item 3 will be required may change with the trend from voice-frequency towards high velocity carrier circuits. Experience will be a valuable guide, for it is not likely that an intolerable situation will build up overnight and without casting some shadow of coming echo; and the echo suppressor, being a discrete equipment unit, can be installed after needed without appreciable lost motion or additional cost.

Allocation of Facilities

If the intertoll plant were homogeneous the over-all problem would be solved at this point by designing each circuit in accordance with the preceding. But the plant is not homogeneous; it consists of everything from loaded voice-frequency circuits to circuits on microwave radio with VNLF's ranging from 0.03 to 0.0014. It is therefore necessary to allocate these facilities among different circuit groups in such a way that as far as practicable the higher performance facilities are used in the more demanding parts of the network.

As an aid to allocating facilities, charts like Fig. 5 are used. This figure shows ranges of losses within which circuits in different parts of the network are expected to fall. The losses shown there are exclusive of S, which must be added, as indicated before, at both ends of each connection. It should be emphasized that these losses are not limits in the usual sense, neither are they attempts to divide up over-all losses among circuits. They simply help in allocating facilities in the nonhomogeneous plant among different circuit groups. As the use of carrier is extended, the plant will become more homogeneous and the need for such charts will gradually disappear.

Fortunately, from the transmission standpoint, while the machines will set up a wide variety of connections, the routing patterns will be rigidly controlled. Thus, it is practicable to know for each circuit group the maximum number of other circuits with which it can be used in tandem. The lower velocity circuits, 2-wire circuits, narrow-band circuits, etc., can, within practical limits, be allocated to groups which have relatively easy requirements.

Two-Wire Switching and Other Considerations

Present views are that even the ultimate plan will involve 2-wire switching at many points, mainly at the smaller switching points where the amount of traffic will not support the cost of complete automatic alternate routing features. This will cause some additional complication, for each such point introduces another source of echo, that which occurs because the capacitance and resistance of the office cabling reduces the balance obtainable when two intertoll trunks are switched together. The effect of such switching on VNL's can be cared for by adding appropriate loss increments which will be small if a careful job of impedance matching is done and if the distances from the toll terminal equipment to the switches is held within bounds.

No increment is added if the return loss for about 84 per cent of the circuits in the group is 24 decibels or more. These increments increase to about 0.2 decibel for a return loss of 20 decibels, 0.4 decibel for 18 decibels, and so on. They are added to VNL of circuits between a 2-wire switching point and a 4-wire switching point, and of circuits between two 2-wire switching points. Impedance matching is usually accomplished by adding capacitance across the compromise network and in some cases across the shorter cable runs in an office.

All circuit losses referred to in this paper are 1,000-cycle values, that is, no allowance is made for the effects of noise and frequency distortion. Careful design, layout, and co-ordination of individual transmission systems are depended on to keep noise within proper bounds; and all new carrier systems going into the plant have transmitted bands wide enough to require no assignment of distortion transmission impairment (DTI). Circuits having excessive noise and those circuits with large DTI's are earmarked for improvement by any means that may come along. But beyond this, frequency distortion does not enter into VNL calculations since it cannot be offset by reducing circuit losses without encountering trouble from the echo or other standpoint.

While only circuit design is considered in this paper, it is evident that the success of the whole plan also depends on how closely circuit losses are maintained. This is important from two aspects:

1. The expected variations determine the allowance which must be made in the assigned loss. As indicated previously, it is expected that an allowance of 0.4 decibel per link will be adequate for the near future and it is hoped that as time goes on this figure can be reduced.
2. A more important factor is that unless circuit losses are maintained fairly precisely, large positive or negative excess losses can be accumulated on multiswitched connections. Avoidance of such large excesses is particularly important with dial operation since detection and avoidance of unsatisfactory transmission conditions by operators will be much less effective.

The maintenance problem is at least as complex and difficult as the design problem, but it is beyond the scope of this paper.

Summary

For the particular conditions in the Bell System, an equation has been set up to give adequate approximations of the lowest practicable loss for practically all intertoll trunks as follows

$$\text{VNL} = \text{VNLF} \times L + A + B$$

where

VNL = Via net loss (decibels) of the trunk
VNLF = Via net loss factor, that is, a factor which depends on and is appropriate to the type of facilities used in the trunk
L = Length in miles
A = Design allowance for expected variations of circuit loss in service, 0.4 decibel
B = Amount to be added if 2-wire switching is used; the magnitude depends on the passive return loss obtainable on such connections at the 2-wire switching office

At each end of the connection a loss of 2 decibels ($S=2$) is added by appropriate means, as discussed earlier.

Conclusion

Let it be emphasized that this discussion has been largely of planning for the future in all that has preceded, for the switching plan as outlined is growing, and it will be a couple of years before much complex automatic alternate routing is accomplished. It would be surprising if the project should escape growing pains and change of ideas as the plan develops. The author is confident, however, that the plan is sound economically and transmission-wise; and flexible enough to adapt itself to further developments and experience.

Discussion

R. C. Crawshaw (New York Telephone Company, Albany, New York): This discussion is not so much intended to be a direct comment on the material in Mr. Huntley's paper, but more to bring out its application to a going telephone plant, a matter that is of very practical interest in relation to the subject.

It is desirable at the outset to emphasize one point but briefly touched upon in the paper. The development of the national toll-switching plan employs an entirely new concept of switching with new switching instrumentalities at the hub of things. Of necessity, these will quite completely displace the older switching equipment. In this respect the switching end of the business ultimately gets an almost entirely new start—a clean break, as it were—except perhaps in a minor way at the outer edges.

On the other hand, the transmission system is not concentrated in the form of equipment and plant investments within a few building locations, as is the switching equipment. It is obviously impractical to take the replacement approach, since it consists of wire lines, cables (aerial, underground and buried), repeater or amplifier stations, radio system and coaxial cables, etc., scattered over the country covering tremendous route mileage. It is thus harder to reach and to change to conform to the new strains put on it to meet the more exacting transmission requirements Mr. Huntley has described. As a very simple example of a most complex problem, the desired transmission results can be upset by a poorly located loading point buried under the plains of Missouri or in the rugged terrain of New York's Catskill Mountains. This coil may have been adequately located to meet the structural or electrical circuit balances and permit the repeater gains and echo control required under the old switching plan, but it might not be adequate under the new one.

From the transmission viewpoint, therefore, it was of considerable importance to know that the large investments in existing plant built up over many years could with a minimum of expense be fitted in or adapted.

Mr. Huntley has given a clue to one part of the threefold answer to this very practical problem. In this switching plan some circuits will not be required to meet maximum switching demands. As described in the Minneapolis symposium on switching, these are the so-called high usage groups and circuits for certain other uses, as opposed to the final groups. Judicious assigment of facilities and routing of message traffic results in preserving the more flexible ones for final group use. This requires much study and day-to-day attention.

The second part of the answer lies in our advance planning. New instrumentalities, known to be in the development stage, such as *N* carrier systems, were fitted into current route relief plans long before actual availability. In some cases circuits to provide for current growth were temporarily misrouted to stall off relief on a given route until new facilities would be available that would more adequately meet these future transmission requirements than those immediately at hand. This was done on backbone routes destined to carry the important final groups on the switching plan, with the most important ones getting first attention. An example of this was in respect to the important long-haul routes between Buffalo, Fredonia repeater station, and Jamestown in New York State, where by careful planning and facility matching, some new requirements during the last few years were met by using roundabout routes until an *N* carrier development could be made available to meet both current and future demands.

The third part of this answer lies in the application of more exacting maintenance requirements on all toll facilities. Procedures to do this have been adopted and are working out very well. Time does not permit a detailed review of this other very practical side of the transmission problem.

It perhaps suffices to say that the over-all result of applying these new transmission concepts to the telephone plant has been good. What looked like another case of a good theory but hard to practice is turning out to be sound in both theory and practice. Practically all of the existing intercity plant is being put to useful purpose by advance planning and careful study.

Generator Stator Copper Temperature Indicator

A. L. BROWNLEE
ASSOCIATE MEMBER AIEE

H. E. BROWN
ASSOCIATE MEMBER AIEE

A MEANS of measuring the copper temperature of a high-voltage generator conductor is described. A temperature potentiometer measures the temperature drop through the insulation. The temperature drop through the insulation added to the temperature of the outer surface of the insulation is the temperature of the copper.

The resistance temperature detector (RTD) is commonly used as the temperature guide for operation of the stators of large high-voltage generators. These detectors indicate the temperature at their location in the stator, usually between stator conductors or in the bottom of the slot. In either case they are in contact with the outer surface of the conductor insulation and measure the average surface temperature and not the copper conductor temperature. To obtain the copper temperature, the temperature drop through the insulation must be added to the temperature of the RTD.

The temperature drop through the insulation is variable, depending on the generator load, iron temperature, and machine cooling. It can be estimated from data on pilot generators of similar design but preferably should be measured.

A temperature potentiometer is used to measure the drop through the insulation. Fig. 1 shows a temperature potentiometer in which two thermal insulators are in contact. T_c, T_1, and T_2 are temperatures at surfaces indicated; R and r are corresponding thermal resistances. When there is no heat flow through the insulation $T_c = T_1 = T_2$. When there is a difference in temperature between T_c and T_2, heat flows through the insulation and the following relationship holds: $T_c = R/r\ (T_1 - T_2) + T_1$. With the ratio of thermal resistances R/r

Paper 53-294, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 16, 1953; made available for printing April 30, 1953.

A. L. Brownlee and H. E. Brown are with the Commonwealth Edison Company, Chicago, Ill.

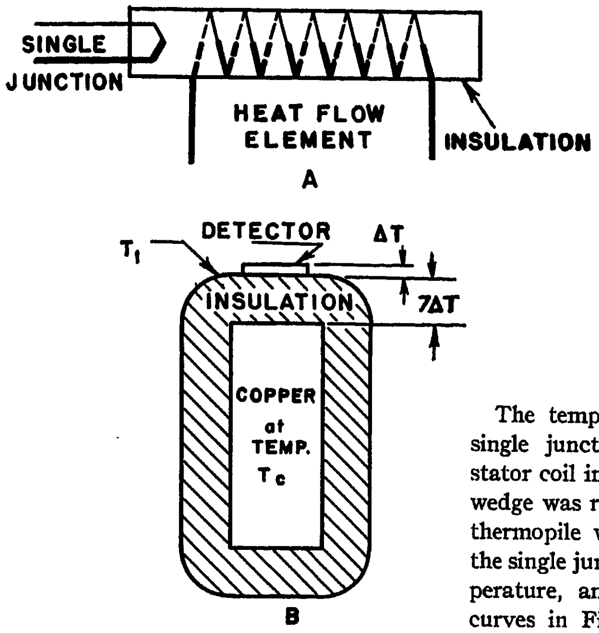

Fig. 2. Thermal electric conductor temperature detector and method of mounting

chosen equal to n, a whole number, the equation reduces to $T_c = n\ (T_1 - T_2) + T_1$.

If a thermopile of n couples is formed with one set of junctions at T_1 and the other set at T_2, an electromotive force is produced that is proportional to $n\ (T_1 - T_2)$. A single thermal junction at T_1, in conjunction with a compensated junction at the measuring instrument, produces an electromotive force proportional to T_1. The thermpile connected in series with the single junction and the compensated junction at the instrument produces an electromotive force proportional to $n(T_1 - T_2) + T_1$ or T_c.

This temperature potentiometer is the method used in this device. T_c is the temperature of the copper, which cannot be measured directly but is the quantity to be determined. T_1 is the temperature of the exterior of the insulation and is measured. T_2 is the temperature on the remote side of the thermopile and in combination with T_1 establishes the temperature drop through the insulation.

A thermopile and single junction were mounted on a strip of pressed mica 0.030 inch thick, 2 inches long, and $^1/_2$ inch wide with thermal resistance r, and installed in the slot wedge of a 30,000-kw 9,000-volt 25-cycle generator. The ratio R/r as determined by test was seven. Seven thermocouples were used in the thermopile, with the additional single junction for measurement of the surface temperature. The construction of the thermopile and the single junction is shown in Fig. 2(A) and its position on the stator coil is shown in Fig. 2(B).

The temperature, as indicated by the single junction, on the surface of the stator coil insulation in contact with slot wedge was recorded. The output of the thermopile was added to the output of the single junction to give the copper temperature, and was also recorded. The curves in Fig. 3 are plotted from data recorded with the generator in service carrying load. These curves show the variation in temperature of the surface of the insulation and the copper for various loads on the machine.

Laboratory tests were made to check the time rate of response and the expected accuracy of the detector. An armature coil removed from a 60-cycle 12,000-volt generator was used for these tests. The copper temperature was measured by a thermocouple attached to the copper and the thermopile with a thermal junction for surface temperature was taped in contact with the outer surface of the insulation. In Fig. 4 the temperature of the copper, curve A the copper temperature as indicated by the thermopile, curve B, and the temperature of the surface of the insulation, curve C, are plotted against time. In a 40-degree rise in an hour, the indicated copper temperature approached true temperature within 2 degrees, the indicated temperature lagged behind the true temperature a maximum of 8 degrees. When the 8-degree lag occurred, the indication lagged the true temperature 10 minutes in time. In this test five couples were used in the thermopile. The curves show that the temperature drop through the insulation as indicated by the thermal pile was too small. This means that the ratio of R/r was greater than five. The error could have been reduced by slightly modifying the thermopile.

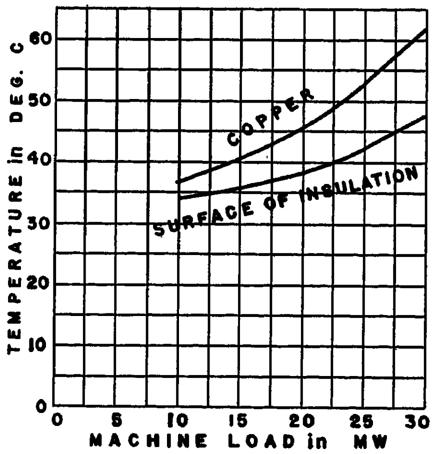

Fig. 3. Copper and surface insulation temperatures of stator winding as a function of machine loading

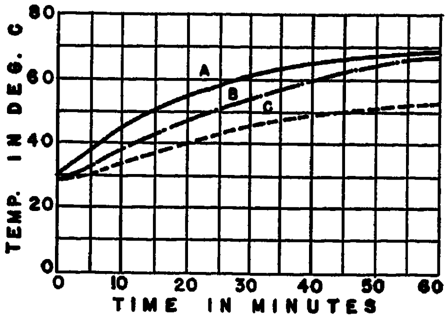
Fig. 4 (rigt). Conductor thermal electric temperature detector response as a function of time



$T_c = R/r\ (T_1 - T_2) + T_1$ is the equation of a straight line and assumes the temperature distribution to be uniform throughout the insulation. To check the distribution, thermal junctions were embedded in the insulation of an armature coil. The conductor was heated by circulating current. The curves of Fig. 5 show this distribution. Curve A is the temperature measured through the insulation on the top edge of the coil. Curve B is the temperature measured at the same junctions after copper plates had been clamped to the two sides of the coil to increase side surface cooling. The increased cooling lowered the insulation and conductor temperature with little change in the temperature distribution.

The temperature distribution as shown by the curves of Fig. 5 is not uniform. A detector installed on this edge of the coil would indicate a lower temperature than the true temperature of the copper if the ratio R/r is determined from the thermal resistances of the insulation and the thermal pile. However, if the ratio is corrected for the unequal temperature distribution the conductor temperature can be indicated with negligible error.

No information is available on the change in thermal resistance of armature insulation with age. From examination of the slot portion of many coils removed from generators after many years of service, no large change is expected in the ratio of R/r where the insulation in the thermopile is similar to the coil insulation. The change in the ratio R/r only

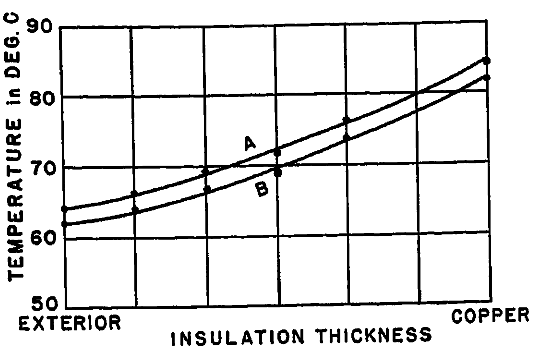


Fig. 5 (left). Temperature distribution in coil insulation

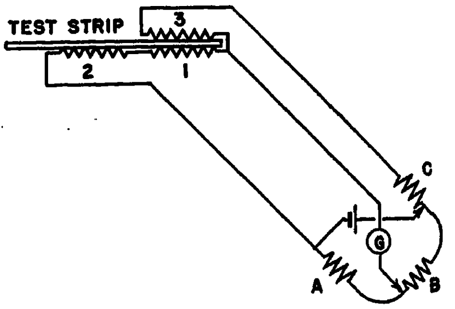
Fig. 6 (right). Resistance conductor temperature detector with measuring circuit



affects the term $R/r\ (T_1-T_2)$ which is of the order of 20 degrees centigrade maximum.

The resistance temperature detector method now generally used can be modified to give copper temperature rather than the exterior of the insulation. The measurement is independent of the lead resistance, provided that the resistances of the leads are equal. In the modification, equal resistances are added in the exploring coil leads. These resistances are mounted on opposite sides of a test strip of thermal resistance r. The measuring circuit and details of the detecting device are shown in Fig. 6. Resistors 1, 2, and 3 are all copper resistors. Resistors 1 and 2 are mounted on the side of the strip that is placed adjacent to the exterior of the insulation of the stator coil. Resistor 3 is mounted on the opposite side of the thermal strip. Resistor 1 is the conventional exploring coil, for instance, 10 ohms at 25 degrees centigrade. Resistors 2 and 3 are equal to $10R/r$ at 25 degrees centigrade, where R/r is the ratio of the thermal resistances of the stator coil insulation to the thermal resistance of the detector strip.

Assume that the temperature difference across the strip is ΔT and that the temperature of the exterior of the insulation is T_1 degrees centigrade. The resistances of 1 and 2 are $10+0.04(T_1-25)$ and $10R/r+0.04R/r\ (T_1-25)$ respectively. The resistance of resistor 3 is $10R/r+0.04R/r\ (T_1-\Delta T-25)$. The resistance required in C for balance is therefore

$$\begin{aligned}C=10+0.04(T_1-25)+10R/r+\\ 0.04R/r(T_1-25)-[10R/r+\\ 0.04R/r(T_1-\Delta T-25)]\\ =10+0.04(T_1-25)+0.04R/r\Delta T\\ =10+0.04(T_1+R/r\Delta T-25)\end{aligned}$$

The bridge will therefore indicate a temperature R/r times the differential across the strip higher than T_1. This is the temperature of the copper.

◆

Discussion

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): As indicated in another discussion,[1] great attention should be given to the temperature of the conductors themselves in determining allowable loads. Information is needed on average conductor temperatures in connection with the movement of the coils in the slots, and is needed on hottest-spot conductor temperatures in connection with the allowable total temperature for the insulation.

With the advent of hydrogen cooling, the matter of determining the conductor temperatures accurately has assumed increased importance. This is due to the fact that with hydrogen-cooled generators, especially at elevated pressures, a large portion of the temperature rise between the ambient and conductor occurs across the insulation of the armature coil. For air-cooled machines, the thermal drop across the armature coil insulation is relatively small compared to the total temperature rise.

The manufacturers have been aware of this situation for some time. It is gratifying to learn that they are conducting investigations to obtain more information on the actual total temperatures of the conductors in generators.

The authors have developed some ingenious schemes for obtaining more accurate ideas of conductor temperatures of generators after they go into service. They indicate, however, that the applications of their methods require care in order to avoid erroneous conclusions. It would be of interest to see what others find in trial use of the authors' scheme. Also, it would be of interest to see how results obtained by the authors' scheme methods compare to the findings of the manufacturers based on the methods used in the manufacturers' present investigations.

Correction of Frequency Errors in Wattmeters

JAMES ROBERT FREEMAN
ASSOCIATE MEMBER AIEE

Synopsis: Wattmeter readings taken at low power factors or at higher frequencies should be corrected for frequency errors to insure the accuracy of which the instrument is capable. In addition to the error caused by the voltage circuit self-reactance, there exists an error due to the mutual reactance between the two circuits of a wattmeter. A practical method of correcting wattmeter readings for this error is presented and its use demonstrated. Wattmeter readings which have been corrected for the mutual reactance error in this way may be corrected for the voltage circuit self-reactance error by using the customary tables or correction factors in the conventional manner. Curves are shown of the two frequency errors as functions of the frequency and the deflection for a typical commercial low power-factor wattmeter.

ELECTRODYNAMOMETER wattmeters are generally accepted as the most satisfactory type of indicating instruments for the measurement of power at low frequencies. These instruments may have accuracies to within 0.1 per cent of full-scale deflection when used within reasonable limits of frequency and power factor. Most portable types of commercial precision electrodyanamometer wattmeters have a guaranteed limit of error of 0.25 per cent of full-scale deflection on frequencies up to 133 cycles per second, but because of inherent errors this accuracy is not maintained at higher frequencies or with very low power factors. The inherent errors referred to may be attributed to two things: the self-reactance of the voltage circuit, including distributed capacitance; and the mutual reactance between the voltage coil and the current windings. The existence of eddy currents within an instrument will also cause an error in indication. Experiments have revealed this error to vary at a rate slightly higher than the first power of the frequency. The error may be determined by a method based on bridge measurements.[1] The results of such measurements on a particular commercial wattmeter have shown that the error is 0.4 per cent of full-scale deflection at 1,200 cycles per second, and is proportional to the 1.3 power of the frequency.

The error caused by the voltage circuit self-reactance is well understood, and correction tables are available which give factors by which wattmeter readings may be multiplied to correct for this error.[2,3] For measurements at frequencies below about 600 cycles per second, these corrections are usually sufficient to insure the accuracy of which a wattmeter is capable. At higher frequencies, however, the error caused by the mutual reactance may be significant also, and it then becomes necessary to have a correction for it. At these higher frequencies attention should be given to this problem.

Effect of Frequency

Not considering the effect of eddy currents, the indication of a wattmeter at a particular frequency depends only upon the product of the currents in the two wattmeter circuits and the cosine of the phase angle between them. Fig. 1 is a schematic diagram of an electrodynamometer wattmeter and Fig. 2 is a phasor diagram which interprets the wattmeter operation on alternating current. The true power being measured is

$$P=EI\cos\theta \tag{1}$$

where

E = the voltage impressed across the voltage circuit
I = the current in the current circuit
θ = the phase angle between E and I. θ is taken negative for lagging power factors and positive for leading

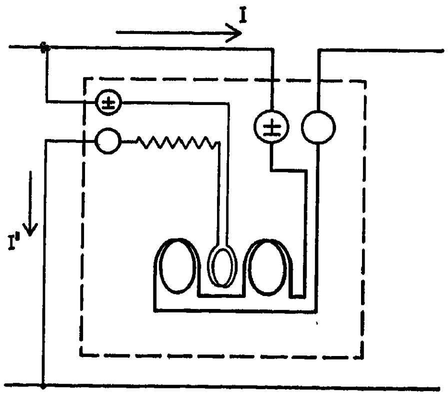

Fig. 1. Schematic diagram showing the two electric circuits of an electrodynamometer wattmeter

The effect of the mutual reactance between the two wattmeter circuits is to induce a voltage into the voltage circuit. This voltage is represented by the phasor $I\omega M$ and is in quadrature with the current I. Therefore the impressed voltage is given by the phasor equation

$$E\underline{/\theta}=I'Z\underline{/\bar{\theta}}+I\omega M\underline{/-90^\circ} \tag{2}$$

where

I' = the current in the voltage circuit
Z = the self-impedance of the voltage circuit

With direct current

$$E=I'R \tag{3}$$

and if a wattmeter reads correctly on direct current, it is apparent that the instrument is calibrated so as to make the voltage measured by the instrument equal to $I'R$.

With alternating current, the current flowing through the voltage circuit will lag the impressed voltage by the angle α which is the phase angle of the voltage circuit impedance. Therefore from Fig. 2 the wattmeter indication with alternating

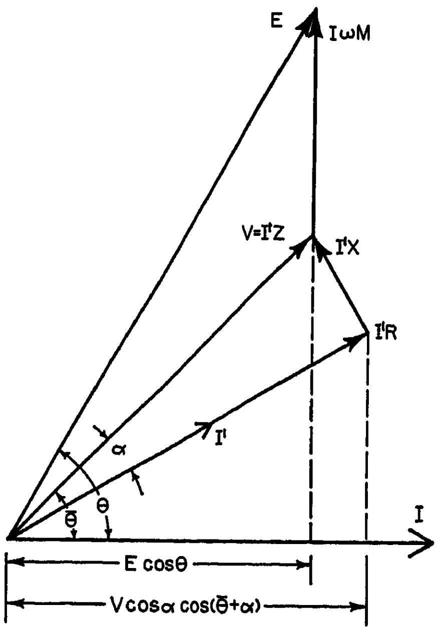

Fig. 2. Voltage phasor diagram which indicates the operation of a wattmeter on alternating current

Paper 53-295, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted June 12, 1952; made available for printing April 29, 1953.

JAMES ROBERT FREEMAN, formerly with the University of California, is with the Massachusetts Institute of Technology, Cambridge, Mass.

The author wishes to acknowledge the assistance and instruction received from Wilson S. Pritchett during the preparation of this paper. Acknowledgement is also made to Prof. Charles F. Dalziel, under whose supervision the early investigations of this problem were carried out.

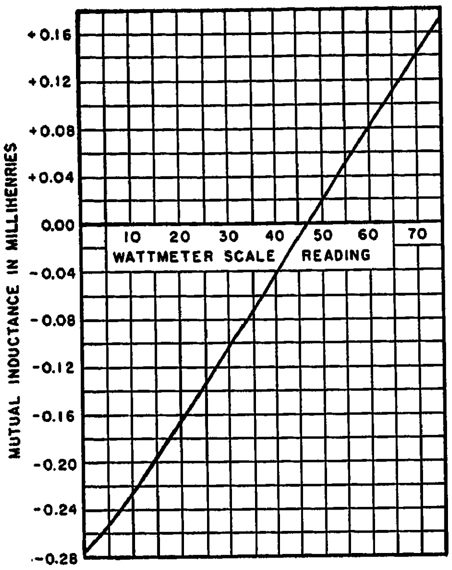

Fig. 3. Curve showing the value of the mutual inductance between the two circuits of a Weston model 310 low power-factor wattmeter as a function of the wattmeter deflection. Current windings connected in multiple (5-ampere connection). For the series connection (2.5 amperes) the values of mutual inductance are to be multiplied by 2. The wattmeter voltage circuit is connected uncompensated for voltage circuit loss to minimize the mutual inductance

current is

$$W=II'R\cos(\bar{\theta}+\alpha) \qquad (4)$$

The projections $E\cos\theta$ and $I'R\cos(\bar{\theta}+\alpha)$ on the reference phasor I show the relative difference between the true power component of voltage and the one observed by the wattmeter. Multiplying equation 2 by the phasor quantity $\cos\alpha\underline{/\alpha}$ gives

$$E\cos\alpha\underline{/\theta+\alpha} = I'R\underline{/\bar{\theta}+\alpha}+I\omega M\cos\alpha\underline{/\alpha-90^\circ} \qquad (5)$$

The projection of equation 5 upon the reference phasor I is

$$E\cos\alpha\cos(\theta+\alpha)=I'R\cos(\bar{\theta}+\alpha)+ I\omega M\cos\alpha\cos(\alpha-90^\circ) \qquad (6)$$

Therefore

$$I'R\cos(\bar{\theta}+\alpha)=E\cos\alpha\cos(\theta+\alpha)- I\omega M\cos\alpha\sin\alpha \qquad (7)$$

Multiplying equation 7 by I and comparing with equation 4 shows the wattmeter indication to be

$$W=EI\cos\alpha\cos(\theta+\alpha)-I^2\omega M\sin\alpha\cos\alpha \qquad (8)$$

Equation 8 is an expression for the indication of a wattmeter on alternating current in which the effect of the mutual reactance has been isolated as an independent term. From equation 8 and Fig. 2 it can be seen that without mutual reactance the wattmeter indication would be

$$W'=EI\cos\alpha\cos(\theta+\alpha) \qquad (9)$$

Correction for Voltage Circuit Self-Reactance

If the effect of the mutual reactance is insignificant, or if the value of the wattmeter reading W has been adjusted to correct for the effect of the mutual reactance, comparison of equations 1 and 9 reveals that by multiplying W' in equation 9 by

$$\cos\theta/\cos\alpha\cos(\theta+\alpha) \qquad (10)$$

the value of the true power, as given in equation 1, is obtained. The values of $\cos\theta/\cos(\theta+\alpha)$ can be found by entering tables with the values of α and $\cos(\theta+\alpha)$.[2,3]

Correction for Mutual Reactance Between Current Windings and Voltage Coil

For measurements where the effect of the mutual reactance should not be ignored, it is possible to correct wattmeter readings for this error by adding a correction term ΔW, to the wattmeter reading W, which gives an adjusted reading

$$W'=W+\Delta W \qquad (11)$$

If W' is the wattmeter reading corrected for the effect of the mutual reactance (equation 9), then from equation 8 it follows that

$$\Delta W=I^2\omega M\sin\alpha\cos\alpha \qquad (12)$$

As shown in the Appendix, the expression for ΔW may be simplified to the form

$$\Delta W=0.11fMI^2\alpha \qquad (13)$$

where

f = the frequency in cycles per second
M = the mutual inductance between the current windings and the voltage coil expressed in henrys. M may be either positive or negative
I = the current being measured by the current circuit expressed in amperes
α = the phase angle of the voltage circuit self-impedance expressed in decimal parts of a degree

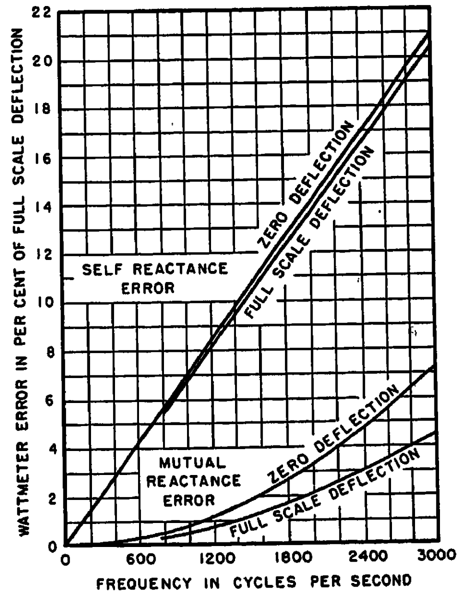

Fig. 4. Curves of the frequency errors as a function of frequency for a Weston model 310 low power-factor wattmeter when used on the 75-volt range with rated voltage and current. Rating: 75 volts, 2.5/5 amperes, 37.5/75 watts

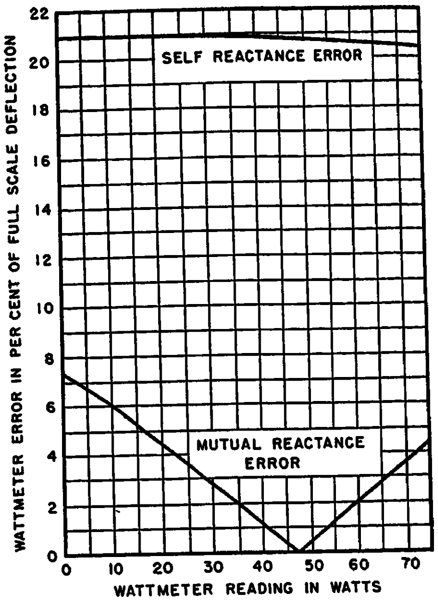

Fig. 5. Curves of the frequency errors at 3,000 cycles per second as a function of wattmeter reading for a Weston model 310 low power-factor wattmeter when used on the 75-volt range with rated voltage and current. Rating: 75 volts, 2.5/5 amperes, 37.5/75 watts. For 2.5-ampere connection wattmeter reading is divided by 2

Applying the Correction

In applying the correction for the mutual reactance, it is obvious that one must first know the value of the mutual inductance M. The value of the mutual inductance depends upon the orientation of the voltage coil with respect to the current windings. This means that the value varies with the indication of the wattmeter. When an instrument is connected for up-scale deflection, M is negative at the lower end of the scale and positive at the upper end, having a value of zero somewhere near mid-scale.

The mutual reactance between the two

circuits of a wattmeter may be determined by measuring the voltage induced in one circuit by a known current flowing through the other circuit. If this is done for several positions of the pointer, a curve such as the one in Fig. 3 can be drawn. The voltage should be measured with a high impedance device such as a vacuum-tube voltmeter or an oscilloscope. Fig. 3 is a curve of the mutual inductance versus wattmeter deflection for a Weston model *310* low power-factor wattmeter.

As an example of the use of equation 13 and the curve in Fig. 3, consider this wattmeter to be used at a frequency of 1,200 cycles per second. Assume the wattmeter reading to be $W=22.5$ watts, and the current measured to be $I=4.97$ amperes. For this wattmeter, $\alpha=1.13$ degrees at 1,200 cycles per second. From the curve of Fig. 3, $M=-0.15$ millihenry. Setting these values into equation 13 gives $\Delta W=-0.6$ watt. Therefor the wattmeter reading corrected for the effect of mutual reactance is $W'=21.9$ watts. If the correction for the mutual reactance were not applied, an error in the reading of 2.7 per cent would exist due to this effect. This error of 0.6 watt would be three times that of the guaranteed limit of error for the instrument.

Comparison of Frequency Errors

Figs. 4 and 5 are curves of the frequency errors for a Weston model *310* low power-factor wattmeter when used on the 75-volt range with rated voltage and current. Fig. 4 shows how the two errors vary with frequency. The mutual reactance error varies as the square of the frequency. This is so because ΔW is proportional to the frequency times α, α itself being proportional to the frequency since it is a small impedance angle. The fact that the mutual reactance error is proportional to the square of the frequency, whereas the error caused by the voltage circuit self-reactance is proportional only to the first power of the frequency, emphasizes the importance of correcting for the mutual reactance error when measurements are made at higher frequencies.

The curves of Fig. 5 show how the two frequency errors vary with the wattmeter deflection with rated voltage and current applied at 3,000 cycles per second.

Conclusions

1. The error in indication caused by the mutual reactance between the two circuits of a wattmeter is proportional to the square of the frequency and is given by equation 13.

2. The mutual reactance error may be corrected for by use of the correction term ΔW as given in equation 13. Wattmeter readings corrected for the mutual reactance error in this way may then be corrected for the voltage circuit self-reactance error by the usual methods.

Appendix. Simplification of Correction Term for Mutual Reactance Error

Equation 12 is an exact expression for the error due to the mutual reactance between the two circuits of a wattmeter

$$\Delta W=I^2\omega M\sin\alpha\cos\alpha \qquad (12)$$

Since

$$\omega=2\pi f \qquad (14)$$

and

$$2\sin\alpha\cos\alpha=\sin 2\alpha \qquad (15)$$

equation 12 may be written

$$\Delta W=\pi fMI^2\sin 2\alpha \qquad (16)$$

Furthermore, since α is a small angle

$$\sin 2\alpha=(\pi/180°)2\alpha \qquad (17)$$

where α is expressed in decimal parts of a degree. Substituting equation 17 into equation 16 gives

$$\Delta W=(\pi^2/90)fMI^2\alpha \qquad (18)$$

Therefore

$$\Delta W=0.11fMI^2\alpha \qquad (13)$$

Discussion

R. F. Estoppey (Weston Electrical Instrument Corporation, Newark, N. J.): Mr. Freeman has presented an accurate picture of the self-reactance and mutual-reactance errors that occur in wattmeters. In the early part of the paper it was indicated that the effect of eddy currents would be neglected but it is believed that further mention should be made of this error.

The effect of eddy currents in the metal parts surrounding the moving element causes the field coil flux to lag the field coil current by a small angle. Tests on the Weston model 310 low power-factor wattmeter cited in the paper indicate that this angle is approximately 0.4 degree at 1,200 cycles. At rated voltage and current which corresponds to 20 per cent power factor, this angle will cause an error of 3.5 per cent of full-scale deflection.

From the curves of Fig. 4 it can be seen that the mutual-reactance error is approximately 1 per cent at 1,200 cycles and the self-reactance error is approximately 8 per cent at 1,200 cycles. Since the error due to the eddy currents is appreciable, it is felt that this error should be considered if the curves of Fig. 4 are used to correct wattmeter indications.

Since the self-reactance error causes the moving coil current to lag the applied voltage and the eddy current error causes the field coil flux to lag the field coil current, the effect of these angles is to cancel each other and if they were equal there would be no error from these two sources. The combined error, due to these two causes, then becomes the difference between 8 per cent and 3.5 per cent, or 4.5 per cent.

The Weston model *310*, form *2* low power-factor wattmeter, chosen for this study, was designed for 60-cycle use. At this frequency, and up to 125 cycles, the compensation for the power taken by the potential system simplifies the taking of accurate readings under a variety of conditions. This compensation consists of an additional winding on the field coils, turn for turn with main winding, and connected in series with the moving coil; it can be connected in at will by means of a switch so that the user of the instrument may use the compensation feature or omit it.

The compensating winding is closely coupled with the field coils, both inductively and capacitively, and adds additional mutual-inductance error when the instrument is used with potential circuit compensation.

Due to the capacitive coupling between windings, part of the main moving coil current can flow from the compensating winding directly into the field coil winding. This causes an error in indication which cannot be evaluated simply and which cannot be eliminated completely since the compensation selector switch removes only one side of the winding from the circuit, leaving the other side to complete the circuit.

The Weston model *310* low power-factor wattmeter can be supplied without the extra winding on the field coil for potential circuit power compensation, and compensated for high-frequency use by means of a capacitor across a portion of series resistance. An equation for obtaining the value of the capacitance for compensation of the inductance errors both fixed and mutual, is given in the section "Wattmeter Compensation" of a paper by John H. Miller.[1] In actual practice the capacitor is made smaller than the calculated value to a point where the self-reactance error is equal to the eddy current error. In addition, the capacitor reduces the mutual reactance error to a negligible value up to 1,000 cycles. Above this frequency, any compensation becomes much more difficult and usually the accuracy is impaired.

Wilson Pritchett (University of California, Berkeley, Calif.): In low power-factor measurements the self-reactance correction becomes a term which may also be added to the wattmeter reading. It is convenient to use instead of the phase angle α the ratio of the reactance to the resistance Q of the voltage circuit. Both corrections in terms of Q are $2\pi fMQI^2$ and EIQ. The first due to the mutual reactance is valid for all power factors, and the second is accurate to within 2 per cent for power factors less than 0.2. Both depend upon $Q^2/2$ being negligible compared to unity. This is implied by equation 17 in the paper. This approximation is true for conventional wattmeters up to more than 10 kc where other factors tend to prevent use of such wattmeters for power measurement. The sign of Q is positive for leading power-factor loads, and the sign and magnitude of M depend upon the data of Fig. 3.

A practical method not involving breaking the seal for obtaining these data employs direct current to produce the deflection and alternating current to measure the mutual inductance. Appropriate a-c and d-c sources are connected in series with the current coils, a rheostat, and two ammeters. One of these is a d-c type and the other is a true rms type such as the electrodynamic ammeter. The square root of the difference between the squares of the two readings gives the a-c component to be used in computing M. The vacuum-tube voltmeter is connected to the voltage circuit terminals which are energized by a d-c source in series with a high a-c impedance element. Use of a conventional 32-henry choke coil rated at 40 milliamperes with 60-cycle current has given results hardly distinguishable from those obtained by deflecting the pointer manually.

The a-c and d-c supplies for the current circuit should mutually afford a low impedance path for the current of the other. This direct current, if not obtained from a battery, should have a ripple component low compared to the alternating current. The d-c supply for the voltage circuit must either be a battery or must be free from ripple or noise. Grounding the watt-meter terminals marked with the ± symbols helps to eliminate the effect of stray electric fields.

The voltage readings should be corrected for scale error of the vacuum-tube voltmeter and for the loading effect of the choke coil and battery. The latter correction is determined on a percentage basis by making the measurement at zero deflection both with and without the choke and the power supply connected. The resulting mutual inductance curve for uniformly spaced scale divisions is a straight line.

Use of the compensating winding adds a fixed amount of negative mutual inductance to the data. This fixed mutual inductance is four times as much for the series connection as it is for the parallel connection. In low-current wattmeters the fixed mutual inductance of the compensating winding is not only large but it is a much larger proportion of the total mutual inductance than it is in high-current wattmeters. For example, in a 30-watt 1.0/2.0-ampere 75/150-volt instrument with series-connected coils, the fixed mutual inductance is −4.5 millihenrys compared to a maximum of −1.3 millihenrys for the variable mutual inductance. Corresponding values for a 600-watt 20/40-ampere 75/150-volt instrument with parallel coils are −0.003 millihenry and −0.033 millihenry. In the first instrument the fixed component is over three times as large as the maximum value of the variable component. In the second it is less than one-tenth as large.

Fig. 1 shows the connection for power flowing toward the right. After the frequency corrections are applied the true power obtained includes that consumed by the current coils. Changing the connection of the upper voltage terminal from the left to the right of the current circuit causes the power consumed by the voltage circuit to be included instead. Since readings of current in the current coils and voltage across the voltage circuit (both corrected for frequency) are needed (see equations 13, 9, and 1), the power consumed by either the voltmeter or the ammeter is included also. Computation and then subtraction of the appropriate quantities is required as a final step in determining the true power consumed by the load.

James Robert Freeman: The method proposed by Prof. Pritchett of measuring the mutual reactance at several pointer positions without breaking the manufacturer's seal is an excellent one. The ability to do this is of great value to the user of a commercial instrument since the breaking of an instrument seal should be avoided in order to insure confidence in the instrument and not jeopardize a manufacturer's warranty.

Concerning the use of the Q of the voltage circuit instead of the voltage circuit impedance angle α, both equation 13 of the paper and $2\pi fMQI^2$ are equally satisfactory for the mutual reactance error correction. If the prepared tables for the self-reactance error referred to in the paper are not available, it would seem that the use of the term containing Q would be more convenient. Prof. Pritchett states that the sign of Q is positive for leading power-factor loads. The sign of Q is independent of the power factor since it is the tangent of the impedance angle of the voltage circuit. The exact correction for the self-reactance error is $EIQ \sin \theta$ and the sign associated with the correction is obtained from the sign of the angle θ. Therefore the self-reactance correction term is positive for leading power factors and negative for lagging. The mutual reactance correction term is not dependent on the power factor.

Dielectric Breakdown of Sulfur Hexafluoride in Nonuniform Fields

C. N. WORKS
MEMBER AIEE

T. W. DAKIN
ASSOCIATE MEMBER AIEE

THIS PAPER PRESENTS some of the anomalies in the dielectric breakdown of sulfur hexafluoride SF_6 as functions of pressure and electrode separation in a nonuniform field. The nonuniform field, although difficult to analyze, is of considerable importance from the engineering viewpoint as it is the condition most generally encountered in electrical apparatus. At atmospheric pressure, sulfur hexafluoride has unexpectedly high 60-cycle breakdown voltage for large gaps. In this case, the presence of corona precedes sparkover. This was termed "corona-stabilized breakdown" in a recent paper by Camilli, Gordon, and Plump.[1] This phenomenon will be explained by showing the effect of electrode spacing on the position of the maximum which occurs in the curve of sparkover voltage versus gas pressure. The d-c 60-cycle and impulse-breakdown voltage, as well as corona-onset voltage, will be discussed. The time required for corona stabilization to occur will be indicated.

Effect of Gap Length on 60-Cycle Breakdown

Fig. 1 shows the 60-cycle sparkover voltage of sulfur hexafluoride at 1 atmosphere pressure as a function of electrode spacing. The capacitor plates form an electrode configuration which approaches uniform field conditions. Therefore, this curve serves as a reference. These capacitor plates were 7 inches square, with corners rounded and 1/2-inch-diameter rods welded to the edge. The other electrode configurations produce very nonuniform fields. All these curves cross the capacitor plate curve for spacings of $2^1/_4$ inches or less. It is unusual that as the electrode spacing is increased,

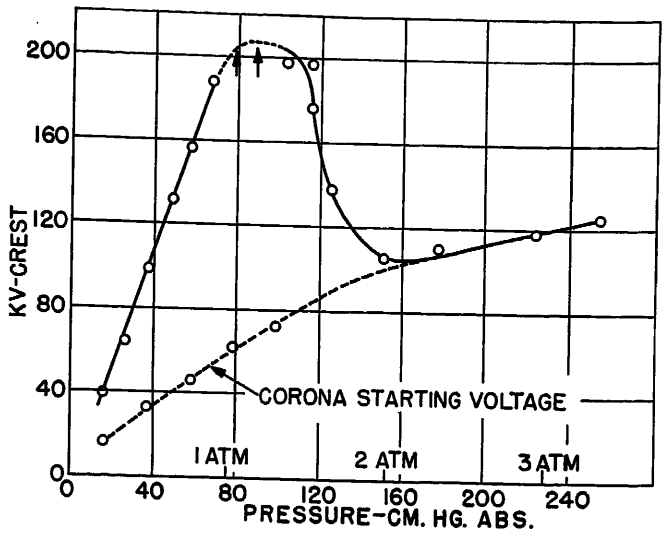

Fig. 2. Positive d-c sparkover voltage of sulfur hexafluoride for a 2-inch gap between 1/2-inch-square rods in 12-inch-diameter steel tank, as a function of pressure

instead of the sparkover voltage levelling off, it may increase at a more rapid rate with spacing, causing an inflection in the curve. Sparkover is preceded by the presence of strong corona which led to the term "corona-stabilized breakdown."

Effect of Pressure on Positive D-C Breakdown

In order to obtain better understanding of the a-c breakdown, the d-c dielectric breakdown was investigated. Fig. 2 shows the positive d-c breakdown voltage of sulfur hexafluoride as a function of pressure for a 2-inch gap between square rods in a steel tank. The grounded tank wall sets up an unsymmetric field. The sparkover voltage passes through a pronounced maximum, and then, at sufficiently high pressure, increases again. This maximum occurs in a region where corona precedes sparkover. The curve of corona-onset voltage increases linearly with pressure. At the higher pressures, sparkover occurs coincident with corona.

Breakdown Mechanisms

The conditions necessary to produce a maximum in the sparkover voltage are a divergent field and a gas with electron-attaching molecules. Such maxima do not occur in gases such as pure nitrogen or helium.[2] Curves showing a maximum in the positive d-c sparkover voltage of sulfur hexafluoride may be found in the literature. Pollock and Cooper[3] investigated a 3-millimeter gap between a point and plane. Results for a 1-centimeter gap were reported by Foord.[2] In the references cited, there is considerable discussion of the mechanisms which may produce such a maximum in the sparkover curve. However, as a background for discussing the experimental results, the following breakdown processes are postulated:

1. In a divergent field, such as is formed by a point-to-plane electrode system, the positive point attracts electrons from weaker parts of the field which, in gases, produces streamers which form long stems with few branches, because electrons are attracted to the advancing streamer tip.
2. With the point negative, the streamers therefrom repel electrons, forming numerous weak short branches, scattered in all directions.

Breakdown from a positive point, therefore, occurs at lower voltage than from a negative point. However, some tests on small gaps[3] have shown an exception to this.

For the point positive, stable corona discharge can occur at low pressures, because the field, due to the space charge at the tip of a positive streamer, is not sufficient to propagate the streamer across the gap. In gases containing electronega-

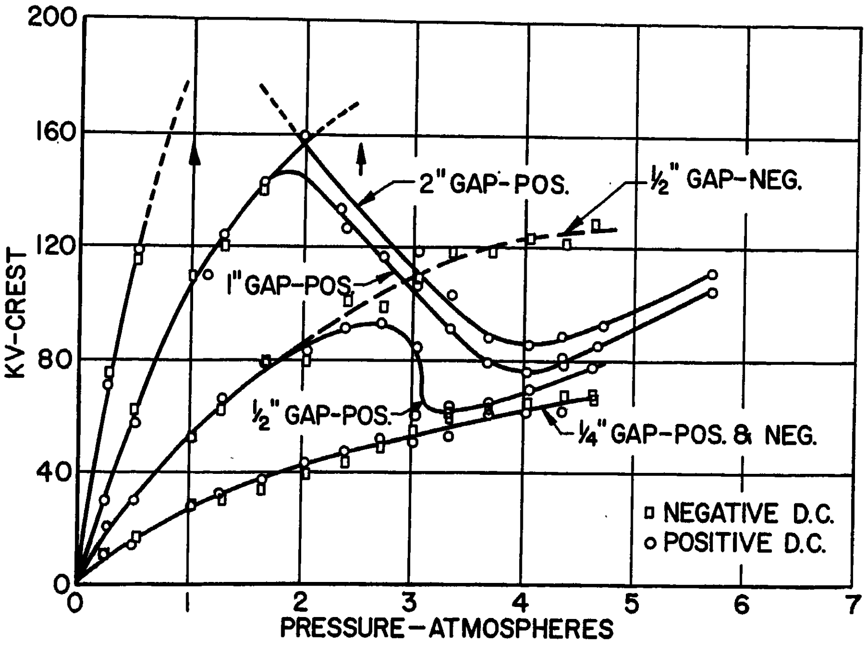

Fig. 3. D-c sparkover voltage of sulfur hexafluoride for several gaps between 1/16-inch-diameter hemispherical point and a 6-inch-diameter plane in 12-inch-diameter steel tank, as a function of pressure

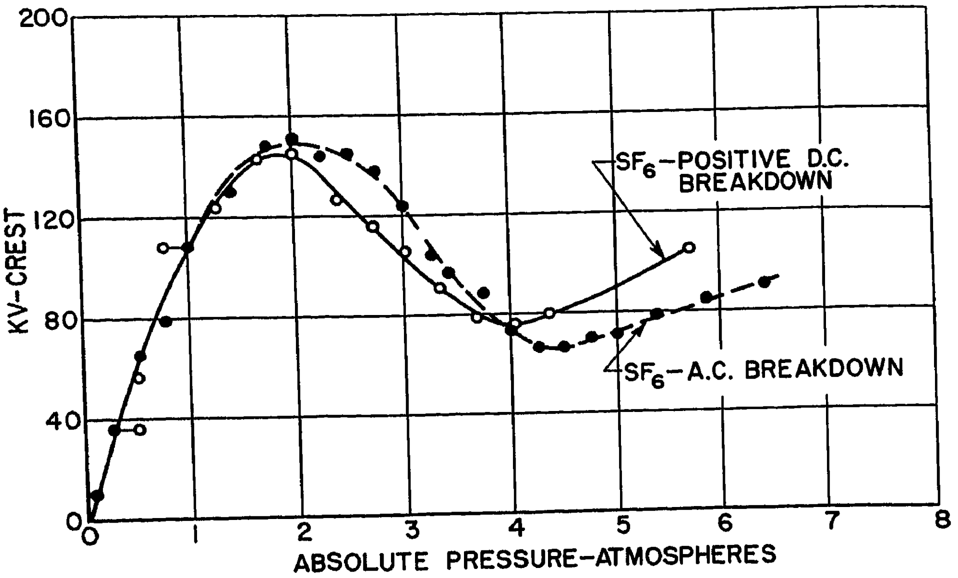

Fig. 4. Sparkover voltage of sulfur hexafluoride for 1-inch gap between a 1/16-inch-diameter hemispherical point and a 6-inch-diameter plane in 12-inch-diameter steel tank, as a function of pressure

tive atoms, such as sulfur hexafluoride, this space charge is reduced in the streamer by the capture of electrons to form negative ions. Photons formed by radiation from the streamer initiate other streamers which diffuse around the point, forming a continuous corona discharge which effectively rounds off the point and makes the applied field less divergent.

In the low-pressure region, increasing the pressure increases breakdown voltage as expected. Coincident with this, a countereffect occurs, which leads to a breakdown maximum, followed by decreasing breakdown voltage until stable corona no longer exists. This countereffect proceeds as follows: As the pressure is increased, the number of positive and negative ions in the streamers both increase, but since the number of positive ions probably exceeds the negative ions by a certain ratio, the net positive charge increases. Thus the gradient at the streamer tip increases with pressure. This is further enhanced by the decrease in diffusion of ions, which narrows the streamer. At the same time, further out in the gap, the absorption coefficient of the gas for photons formed in the streamers increases. Therefore, the extent of individual streamers from the tip across the gap is increased until all the streamers initiating at the point completely cross the gap, producing breakdown coincident with corona. The breakdown mechanism is further complicated by the fact that these positive streamers do not in all cases cross the gap by the shortest possible path. Curved sparks[2,4] have been observed to occur in electronegative gases. These sparks appear to bend around the region occupied by corona. As the pressure is increased, this region is reduced, due to less diffusion. Thus, the path which the curved sparks must travel to cross the gap is shortened. The breakdown depends on the field configuration, which includes the effects of space charges as well as the electrodes. Also, it should be pointed out that a weaker field, acting through a greater distance, can accelerate particles to sufficient energy to initiate breakdown over a circuitous path, as indicated by the curved sparks.

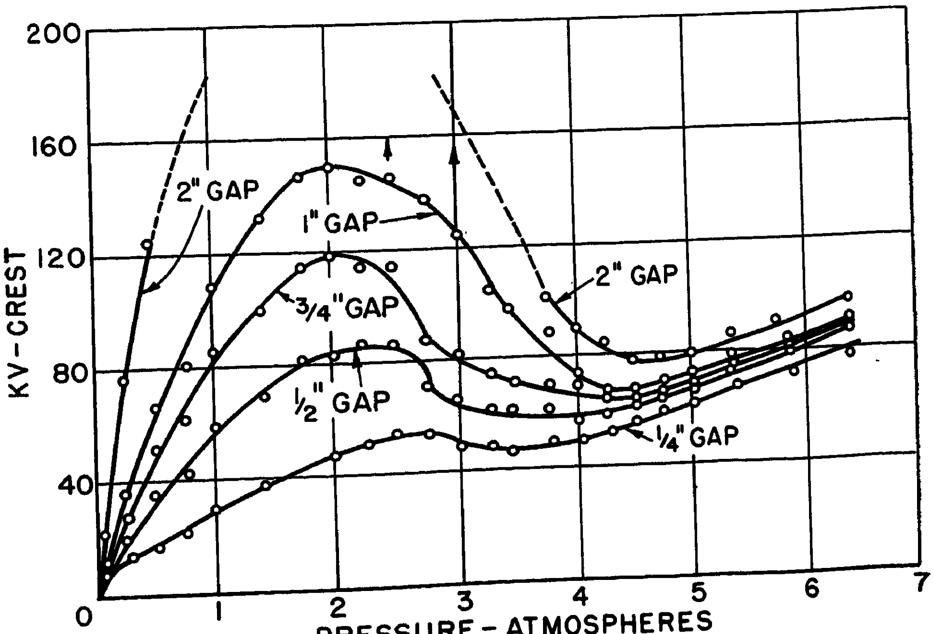

Fig. 5. A-c sparkover voltage for several gaps between 1/16-inch-diameter hemispherical point and 6-inch-diameter plane in 12-inch-diameter steel tank, as a function of pressure

Effect of Electrode Spacing on the Pressure at which Maximum Sparkover Voltage Occurs

The unusual behavior of the 60-cycle sparkover voltage with electrode spacing which we noted in Fig. 1 raises the question: Could such behavior be related to the occurrence of a maximum in the curve of positive d-c sparkover voltage as a function of pressure? To answer this question, Figs. 3 through 6 deal with the sparkover voltage between a rather sharp point and a plane. The sharp-pointed electrode is a 1/16-inch-diameter steel rod with a hemispherical tip.

In Fig. 3, the positive d-c sparkover voltage as a function of pressure was obtained for several gaps to show the effect of electrode separation on the position of the maximum in these curves. As the electrode spacing is increased, this maximum shifts toward lower pressure, and the maximum for larger gaps is broader, encompassing the curves for the small gaps.

Although each succeeding gap is double the former, at higher pressures there is very little increase in the positive sparkover voltage with increase in electrode spacing. Above a certain pressure, the negative strength, indicated by the squares, is much higher than the positive. For example, the negative strength of a 1/2-inch gap at 4 atmospheres pressure is nearly double the positive.

Pollock and Cooper[3] found that, after the maximum was reached, the breakdown voltage dropped off very abruptly, and stated that this was in agreement with

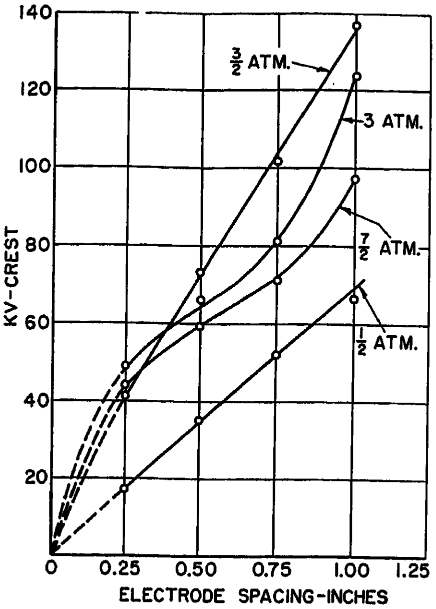

Fig. 6. A-c sparkover voltage of sulfur hexafluoride as a function of electrode spacing between 1/16-inch-diameter hemispherical point and 6-inch-diameter plane, at several pressures

theory. It was found that this is not generally the case. For the 1/2-inch gap in Fig. 3, the positive d-c sparkover voltage decreases very abruptly, whereas, for the 1-inch gap, and especially the 2-inch gap, the decrease is gradual. Also Foord[2] shows the sparkover voltage decreasing slowly over a considerable pressure range. Observation of the curved sparks, mentioned previously, showed that the longer gaps are more productive of curved sparks. Thus, experiment indicates that when breakdown proceeds across the shortest path between electrodes, an abrupt decrease in sparkover voltage may be expected, but when breakdown takes place over a devious route, as indicated by curved sparks, a gradual decrease in sparkover voltage is possible. The performance of a gap is determined more by the divergence of the field than the gap spacing.

As an example, if the curve for a 1-centimeter gap between a very sharp point and a plane, as obtained by Foord,[2] is compared to the curves of Fig. 3, its shape is more nearly like that of the curve for the 1- or 2-inch gap. The breakdown values obtained by Foord are of the same order of magnitude as those for the 1/2-inch gap, Fig. 3. Also, Pollock and Cooper[3] obtained a curve for a 3-millimeter gap between a point of 1/4-millimeter radius and a plane, similar in shape to that for the 1/2-inch gap in Fig. 3. The values of breakdown voltage approach those of the 1/4-inch gap for Fig. 3. The 1/4-inch gap in this figure appears to be approaching uniform field conditions again. However, it is possible that if this curve were continued to pressures of 7 or 8 atmospheres, a maximum might appear.

Comparison of Positive D-C and 60-Cycle Sparkover Voltage

To determine if there is any relationship between the positive d-c and the 60-cycle breakdown voltages, these parameters were plotted as a function of pressure, as shown in Fig. 4. The 60-cycle curve shown by the broken line, although somewhat broader than the other, has closely the same shape and nearly identical values. The curves of Fig. 5 which show the 60-cycle sparkover voltage of gaps from 1/4 to 2 inches as a function of pressure are similar to those for the positive d-c sparkover voltage, except the maxima shown here are somewhat broader than in the former case.

If a pressure in the region of the maxima in the curves of Fig. 5 is selected; for example, 3 atmospheres, and the sparkover voltage as a function of electrode spacing is plotted, the curve labeled 3 atmospheres in Fig. 6 is obtained. This curve has the same shape as the curve for the electrode configuration for 1/2-inch diameter sphere-to-plane shown in Fig. 1. The curve for a pressure of 7/2 atmospheres, Fig. 6, also has an inflection in it. The other curves in this figure are nearly linear. They are similar in appearance to the curves in Fig. 1 for rod-to-rod and rod-to-plane electrode configurations. The curves in Fig. 6 are for several pressures, whereas the curves of Fig. 1 are for several electrode configurations. However, changing the electrode configuration alters the sparkover-voltage versus pressure characteristic. For the larger gaps, the 60-cycle breakdown voltage increases very rapidly with gap length, even to the extent of producing an inflection in the curve at certain pressures. This shows that the unusually great 60-cycle sparkover voltage of sulfur hexafluoride for large gaps in a divergent field is related to the maxima which occur in the sparkover-voltage versus pressure characteristic.

Divergent Fields in Apparatus

As stated previously, a sharp-pointed electrode was used to obtain the data shown in Figs. 3 through 6. Even sharper points were used in the literature cited. Such electrodes were chosen to give fields that could be analyzed. The question may be raised that such electrodes are not representative of divergent fields which may occur in practice. In answer to this possible objection, Fig. 7 is presented, which shows the breakdown voltage between a 1/2-inch square rod and a plane as a function of pressure. Such an electrode arrangement has been used in engineering tests. It should be pointed out that these curves have not only the same shape as the ones referred to previously, but also nearly the same values of sparkover voltage. In the case of Fig. 1, which introduced us to the phenomenon of corona-stabilized breakdown, all electrodes were those which are often used in engineering tests. Therefore, the phenomena which have been described may take place to a considerable

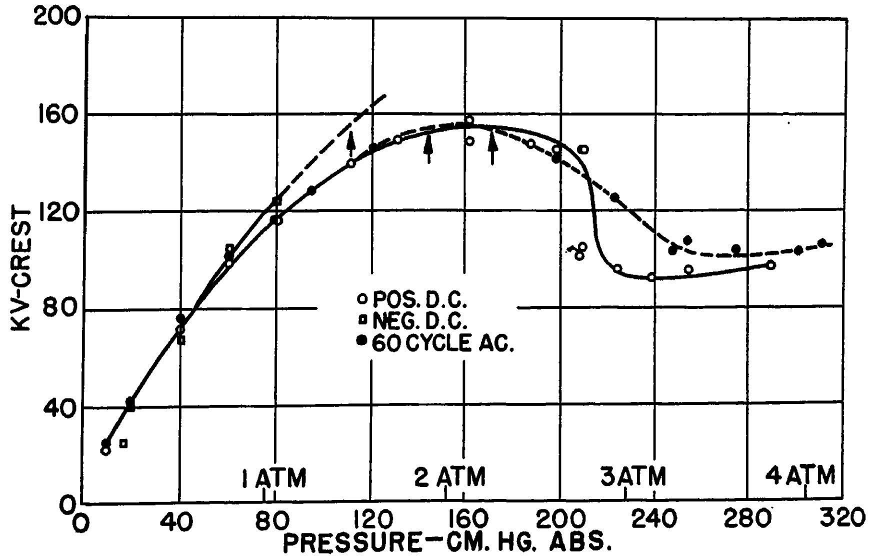

Fig. 7. Sparkover voltage of sulfur hexafluoride for a 1-inch gap between 1/2-inch-square rod and 6-inch-diameter plane in a 12-inch-diameter steel tank, as a function of pressure

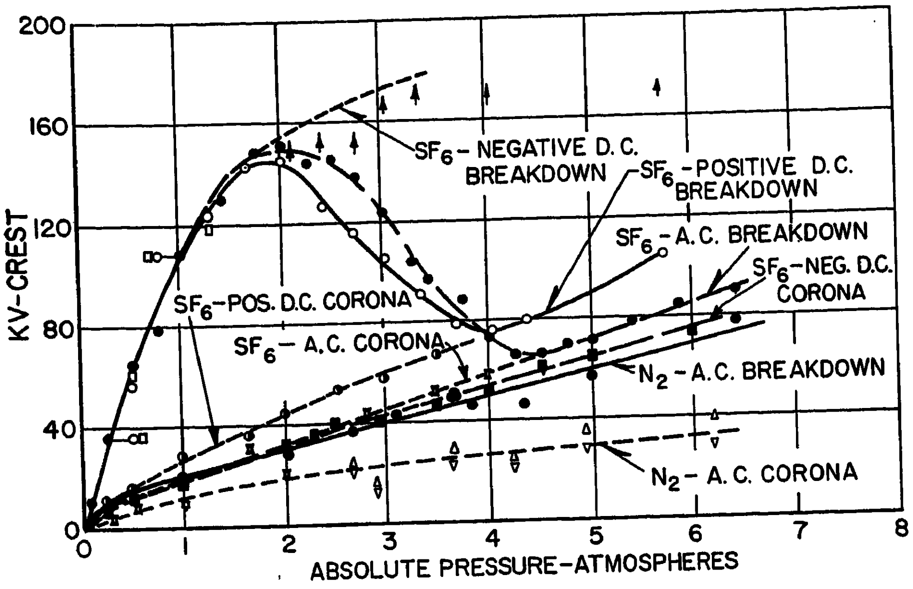

Fig. 8. Sparkover and corona onset voltages of sulfur hexafluoride and nitrogen for a 1-inch gap between 1/16-inch-diameter hemispherical point and 6-inch-diameter plane in a 12-inch-diameter steel tank, as a function of pressure

degree wherever a divergent field exists in electric apparatus.

Relative Strength and Corona Onset in Sulfur Hexafluoride and Nitrogen

In Fig. 8, the sparkover voltage of sulfur hexafluoride as a function of pressure is compared with that of nitrogen. Where a maximum occurs in the 60-cycle strength of sulfur hexafluoride, breakdown voltages of five or more times that of nitrogen may be obtained. However, it should be remembered that such breakdown is preceded by violent corona. The corona-onset point in sulfur hexafluoride is of the same order as the breakdown voltage of nitrogen. To take advantage of the high breakdown voltage of sulfur hexafluoride at this pressure, all solid insulation in the field must be capable of withstanding violent corona. Generally, it is more common to design apparatus to operate without the presence of corona. In this case, at a pressure of slightly more than 4 atmospheres, the 60-cycle corona-onset point for sulfur hexafluoride is about $2^1/_2$ times that of nitrogen. In a uniform field, the sparkover voltage of sulfur hexafluoride is about $2^1/_2$ times that of nitrogen at 1 atmosphere, and it is much greater than for the divergent fields. Also, it has been noted that with sharper points the ratio of corona onset voltage in sulfur hexafluoride to that in nitrogen is lower. Therefore, nonuniform fields should be avoided, or the divergence of the field limited to the minimum consistent with other design requirements.

Where divergent fields exist, the corona-onset voltage is of as great importance as the breakdown voltage. The corona-onset voltage becomes coincident with breakdown for both 60-cycle and positive d-c, beyond a critical pressure which depends on field configuration. For the round-end rod electrode of Fig. 8, this occurs at about 4 atmospheres, as compared with 2 atmospheres for the square-ended rods of Fig. 2. However, negative d-c corona occurs at a somewhat lower voltage for the electrode in Fig. 8, than does the positive. This may be the reason why the 60-cycle sparkover at the higher pressures is lower than that for positive d-c, since the ionization caused by corona occurring on the negative portion of the cycle lowers the breakdown voltage in the same manner as irradiation by X rays.[3]

Impulse Breakdown

The positive impulse-breakdown voltage of sulfur hexafluoride for a 2-inch gap between rods for a $1^1/_2$x40-microsecond wave is shown in Fig. 9. At about 1-atmosphere pressure, a slight maximum occurs in this curve. This maximum is about half the value of the positive d-c maximum breakdown voltage. When 60-cycle voltage was suddenly applied to this rod gap by a high-voltage switch, the breakdown voltage was not decreased. Therefore, the time required for the space charge around the positive electrode to build up is much less than 1 cycle, but greater than several microseconds, as indicated by the impulse curve. After reaching this maximum, the impulse sparkover voltage decreases only slightly, and then increases with increasing pressure, giving higher values than positive direct current. This seems to indicate that, in the absence of corona, an appreciable time is required for the propagation of positive streamers across the gap to initiate breakdown.

Summary

The occurrence of a maximum in the curve of positive d-c sparkover voltage as a function of pressure as reported in

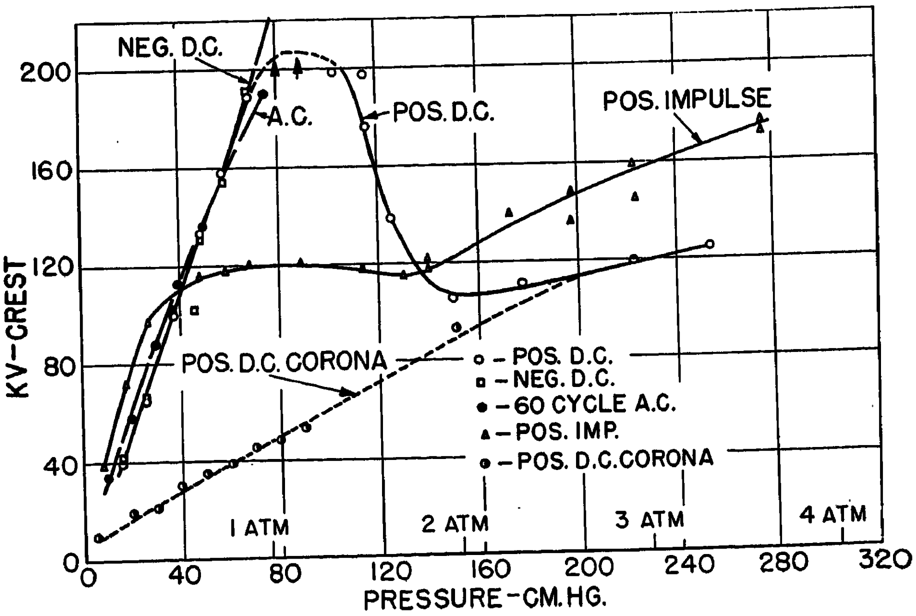

Fig. 9. Sparkover and corona onset voltages of sulfur hexafluoride for a 2-inch gap between 1/2-inch square rods in 12-inch-diameter steel tank, as a function of pressure

the literature was verified for longer gaps. The variation of the 60-cycle sparkover voltage with pressure was found to be very similar to that for positive d-c. The unusually rapid increase in sparkover voltage with increasing electrode spacing was explained by showing the effect of electrode separation on the position of the maximum in the curve of sparkover voltage as a function of pressure. Although positive d-c, negative d-c, and 60-cycle breakdown voltage may increase rapidly with gap spacing over a wide range of pressure, at the higher pressures, the positive d-c and 60-cycle sparkover voltages were found to increase slowly with electrode separation. A situation might well occur in which a considerable increase in electrode separation would not yield any appreciable increase in breakdown voltage. The negative d-c sparkover voltage beyond a critical pressure, which depends on field configuration, was greater than that for positive d-c as predicted by theory. It was shown that, after the maximum was reached, the rate of decrease of breakdown voltage with pressure was a function of field configuration. Although the sharpness of the positive electrode was varied considerably, a pronounced maximum always occurred. This indicated that the same phenomenon would be likely to occur in most electrical apparatus employing an electronegative gas as insulation.

Impulse data showed that the time required for corona stabilization was much less than one cycle of 60-cycle voltage, but more than a few microseconds.

Although breakdown values for sulfur hexafluoride 6 times that of nitrogen have been reported, they occur in the region of a maximum where corona precedes sparkover. To take advantage of this higher breakdown voltage, all solid insulation must be capable of withstanding violent corona.

At the pressure of the maximum, Fig. 8, about 2 atmospheres, the a-c corona onset voltage for sulfur hexafluoride was about 50-per-cent greater than for nitrogen. At 4 atmospheres, the corona-onset voltage for sulfur hexafluoride was about $2^1/_2$ times that of nitrogen. From a practical viewpoint, corona-onset voltage is probably more important to the designer than breakdown voltage.

Discussion

T. R. Foord (University of Glasgow, Scotland): No mention is made in the paper concerning the accuracy of the authors' measurements and whether the curves plotted were accurately reproducible. I consider information regarding reproducibility to be particularly important, as it may affect the authors' main conclusion concerning the correlation between the electrode spacing and the maximum in the sparkover-voltage versus gas-pressure curve. In doing similar work, I found that the negative-slope portion of the maxima for some gases was exceedingly difficult, indeed impossible, to reproduce in apparently identical experiments. As much as 80 per cent variation was obtained in extreme cases with Freon *12*. For air, however, when the negative slope is low and extended over a considerable pressure range,[1] good reproducibility (within 5 per cent) was obtained.

The conclusion of the authors that the maximum shifts to a lower pressure for an increased electrode spacing is substantiated by previously published work[1–4] on the positive point-to-plane sparkover in air. It is perhaps interesting to record that a similar effect occurs for a fixed point-to-plane configuration by diluting sulfur hexafluoride with nitrogen. The cause in this case, however, is probably due to a change in the relative predominance of dissociation mechanisms discussed in two recent papers.[5,6] Only by such fundamental investigations, combined with carefully selected and performed sparkover experiments, will a complete understanding of these unusual effects be possible.

G. Camilli, R. E. Plump, and T. W. Liao (General Electric Company, Pittsfield, Mass.): This paper describes some dielectric peculiarities of SF_6 in a nonuniform field. We can confirm the general observations reported in this paper with some new data of our own. For example, with a 1/4-inch square rod to 3-inch plane, 60-cycle breakdown results were as shown in Fig. 1 of the discussion. In the 1/2-inch gap, breakdown at 45 pounds per square inch gauge pressure was 33 per cent higher than at atmospheric pressure, but in the 1-inch gap the breakdown at 45 pounds per square inch gauge pressure is 13 per cent lower.

In comparison, the results of a 3-inch-diameter round-edge plane-to-plane configuration are shown in Fig. 2 of the discussion and illustrate the classical effect of pressure on the dielectric strength of a gas, and incidentally, are in good agreement with the "capacitor-plate" curve of the paper at atmospheric pressure.

We are also in reasonable agreement with Fig. 7 of the paper which shows maxima in the 1/2-inch rod-to-plane gap. We used a 1/4-inch rod and smaller plane, and found maxima at even lower pressures, that is, at about 100 centimeters of mercury absolute. Our sharper field appears to have brought on the region of anomaly sooner, and has the same effect as the authors' increasing gap distance.

The authors should be commended for their ingenious testing of impressed alternating voltage on the impulse wave, thereby obtaining an idea of the time requirement for corona stabilization. The assumption that the positive half-cycle is most effective in initiating breakdown appears to be well-founded and contributes further to our understanding of electronegative gases.

The fact that strong polarity effects occur in SF_6 should not be surprising. As suggested in other publications,[1,2] there is a variety of energy absorptions which a given gas is capable of, and at breakdown the total effect is a summation of the action and reaction of more than one force. Positive direct current in a nonuniform field diminishes the electronegative nature of SF_6 by sweeping out free electrons, and allows space charge due to positive ions to become much more controlling of the end result.

C. N. Works and T. W. Dakin: The additional data submitted in the discussion by Camilli, Plump, and Liao is very interesting, as it provides an independent confirmation of the breakdown character of this gas. The results obtained with their 1/4-inch rod-to-plane gap supports the statement made in the paper that the performance of the gap is determined more by the divergence of the field than the gap spacing. As they point out, a sharper point causes the maximum to occur at a lower pressure. This is also confirmed by the curves in references 2 and 3 of the paper.

The question raised by Dr. Foord in re-

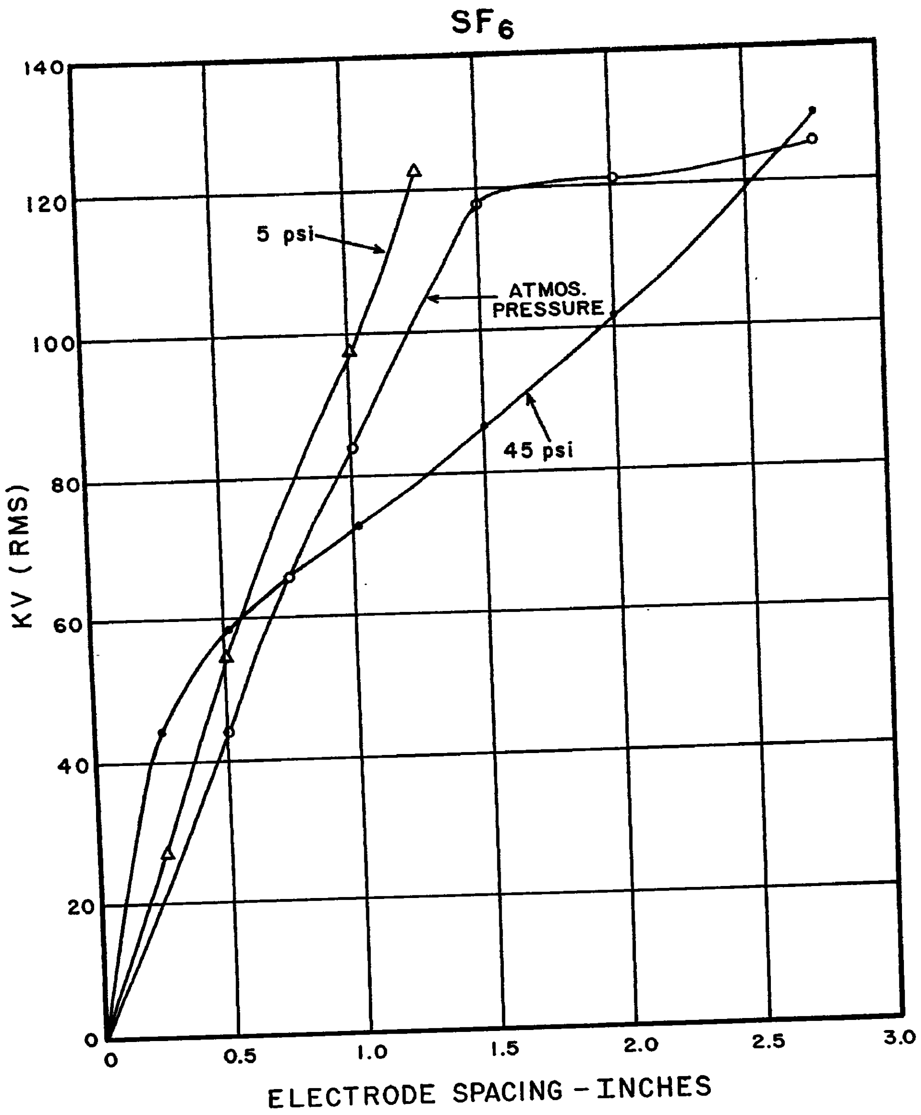

Fig. 1. 60-cycle breakdown voltage versus spacing, 1/4-inch square rod to plane

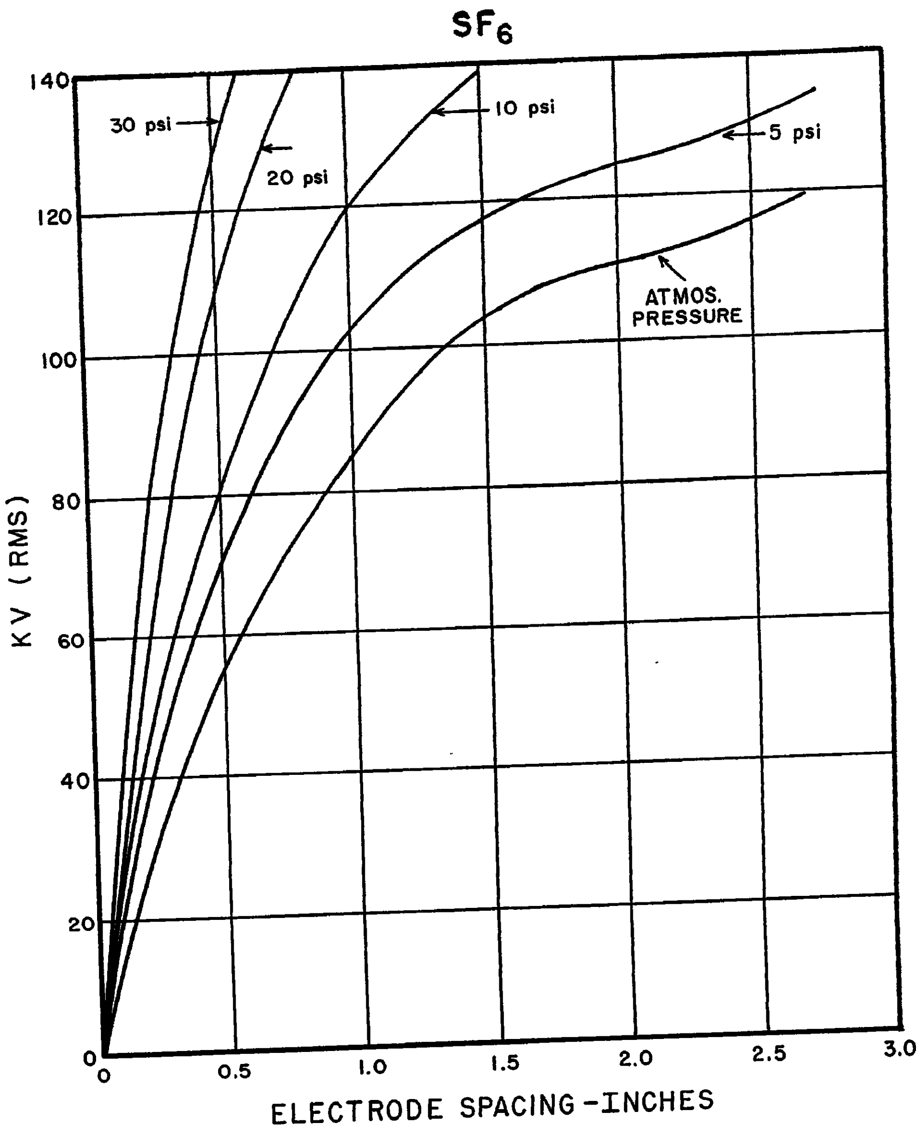

Fig. 2. 60-cycle breakdown voltage versus spacing, 3-inch-diameter round-edged plane-to-plane

gard to the accuracy of the measurements and the reproducibility of the curves is important. The tests were made with well-calibrated testing equipment in all cases, so that the observed breakdown voltages were accurate to about 2 per cent. The scatter of the points from a smooth curve was, with a few exceptions, less than 5 per cent. For the 1/2-inch square rod-to-plane electrodes, the tests which provided the data for some of the curves were repeated and the curves were reproduced to within 10 per cent. All the curves obtained for this electrode configuration were not published, as they are similar to the curves of the paper.

We have done some work with Freon and find that results are much more easily reproducible with SF_6 than with the Freons. Where there is a steep negative slope, as for the 1/2-inch gap in Fig. 3 and the 1-inch gap of Fig. 7 of the paper, there was experimental difficulty. As shown on the curves, either high values or low values of breakdown were obtained and it was not possible to obtain intermediate values. This difficulty only occurred for positive direct current. These steep slopes occur only for certain spacings for the various electrode arrangements. A possible explanation of this steep slope is given in reference 3 of the paper. These steep slopes probably indicate an unstable condition, but it is definite in these cases that there is an abrupt change in breakdown voltage at a critical pressure.

It is probable that decomposition-product molecules and ions participate in the corona-discharge process where the corona persists. This would likely cause fluctuations in the results, which might be greater in the case of more complex molecules. In the case of more complex molecules, the product molecules formed by recombination of fragments produced by the electron-initiated dissociation are appreciably different from the parent molecule. Unless the concentration of these decomposition products has reached an equilibrium value, where their rate of formation and diffusion away are balanced, the breakdown voltage observed following corona might fluctuate depending on the transient concentration of these products.

In all cases the values of the maxima were accurately established, and are believed to be reproducible with reasonable accuracy. In support of this statement, it is pointed out that data in this paper check closely data in an earlier paper by Camilli and Chapman,[1] and that the new data by Camilli, Plumb, and Liao are in good agreement with the data presented in this paper.

We agree with Dr. Foord that fundamental studies of the dissociation mechanisms of SF_6 should be combined with sparkover experiments to enable us to gain a better understanding of the breakdown mechanisms that may occur in this gas.

Voltage Regulation of 12-Phase Double-Way Rectifiers

Summary

Mathematical expressions for calculating the voltage regulation of double-way rectifiers connected for 12-phase operation have been derived and tabulated for ready reference. Calculated curves are presented for estimating voltage regulation, angle of delay, and overlap angle for any load out to short circuit. Regulation curves taken in the laboratory are included to substantiate the general trend of the calculated curves.

This paper is an extension of the 6-phase case;[1] the same notation is used, and similar treatment of the subject is employed in order to facilitate comparison.

CONVENTIONAL METHODS of calculating rectifier voltage regulation are valid only if the angle of overlap is less than 360 degrees divided by the number of phases. At larger angles of overlap an inherent delay angle, introduced by a-c reactance common to two or more simple rectifiers, reduces the direct voltage and thereby increases the voltage regulation. This phenomenon has been described in two papers,[1,2] recently presented to the Institute, in which curves and equations for determining voltage regulation of 6-phase rectifiers were given. Two earlier articles[3,4] recognized the phenomenon in 6-phase circuits.

Twelve-phase rectification obtained by connecting two double-way rectifiers in series on the d-c side is often employed in special applications requiring high direct voltages. The customary practice is to supply the rectifiers from two 3-phase transformer banks in parallel on the a-c side, one bank connected wye-delta, the other delta-delta. Operation of such rectifiers is affected to a greater extent by common a-c reactance than is operation of 6-phase rectifiers. This paper considers this 12-phase operation.

Nomenclature

α = first angle of forced commutation delay
α_m = maximum value of α
β = second angle of delay
$\gamma = u - 60°$ = interval of simultaneous commutations within one bridge
$\delta = u - 30°$ = interval of simultaneous commutations between two bridges
$\omega = 2\pi f$ = angular frequency
$E_{a,b,c}$ = source line-to-neutral instantaneous voltages
$E_{a1,b1,c1}$ = line-to-neutral voltages on primary of bridge I transformer
$E_{a2,b2,c2}$ = line-to-neutral voltages on primary of bridge II transformer
$E_{1,3,5}$ = line-to-neutral voltages on secondary of bridge I transformer
$E_{2,4,6}$ = line-to-neutral voltages on secondary of bridge II transformer
E_{a1}' = instantaneous value of E_{a1} during commutation in the other bridge
e_d = instantaneous direct voltage
E_d = average direct voltage under load
E_{do} = average direct voltage at no load
E_s = transformer secondary line-to-neutral rms voltage at no load
f = frequency of system
$i_{1,2,3,4,5}$ = instantaneous value of commutation currents on primary side of transformers
$i_{1c,2c,3c,4c,5c}$ = instantaneous value of commutation currents through rectifier tubes
I_c = commutated direct current
I_d = load current
I_dX_c/E_s = reactance factor based on load current
$k = X_s/X_c$ = ratio of common to total commutating reactance
L_L = inductance not common to both bridges
L_s = inductance common to both bridges
$L = L_s + L_L$ = commutating inductance
$p = d/dt$
t = time in seconds
u = commutating (overlap) angle
X_L = reactance not common to both bridges
X_s = reactance common to both bridges
$X_c = X_s + X_L$ = commutating reactance

Paper 53-242, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Summer General Meeting, Atlantic City, N. J., June 15–19, 1953. Manuscript submitted March 17, 1953; made available for printing April 16, 1953.

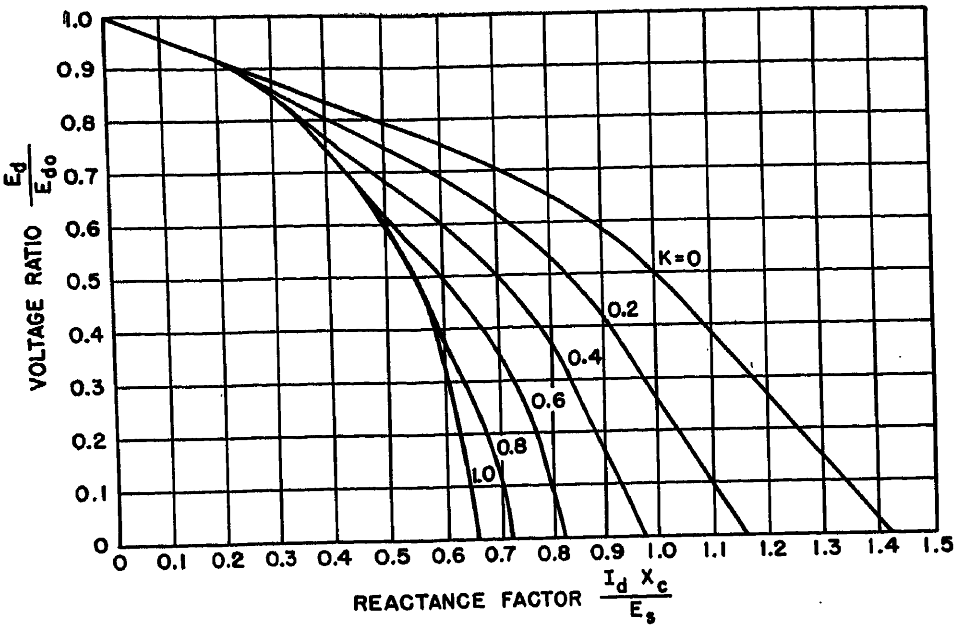

Fig. 1. Voltage regulation curves for 12-phase double-way rectifier

Table I. Limiting Values of Angles in the Several Modes of Operation

Mode	u	α	β
1	0→30°	0	0
2	30°	0→α_m	0
3	30°→60°	α_m	0
4	60°	α_m	0→30°
5	60°→(120°−2α_m)	α_m	30°

The chief difference between the 12-phase and 6-phase cases is the larger number of modes of operation in the 12-phase rectifier as load is increased from zero to short-circuit value. There are five modes of operation instead of three (instead of four, where leakage reactance between secondary windings is not negligible[5]). In the first mode of operation, as load current is increased from no load, the commutating or overlap angle u increases from zero to 30 degrees. During the second mode of operation, the commutating angle is fixed at 30 degrees, but the start of commutation is delayed by an inherent delay angle α which varies from zero to some maximum value α_m as the rectifier supplies increasing load current. Operation in the second mode is quite similar to 6-phase operation where leakage reactance between secondary windings is not negligible.[5] As is shown in the Appendix

$$\tan \alpha_m = \frac{k\sqrt{3}}{4-3k}$$

where k is the ratio of reactance common to both 6-phase rectifiers to total commutating reactance. The angle of inherent delay does not change during the third mode, while the commutating angle increases from 30 to 60 degrees. During the fourth mode of operation, the commutating angle is fixed at 60 degrees, and the start of commutation is delayed by a second angle of delay β, which increases from zero to 30 degrees. In the fifth mode, the total angle of delay ($\alpha_m+\beta$) is fixed, while the commutating angle increases from 60 to $(120-2\alpha_m)$ degrees at short circuit. The five modes of operation are summarized in Table I.

The ratio of direct voltage to no-load direct voltage (E_d/E_{d0}) is plotted against reactance factors in Fig. 1. These curves show that voltage regulation increases as the ratio of common to total reactance becomes larger.

Calculated values of commutating angle u are plotted against reactance factors in Fig. 2. To see the five modes of operation, consider $k=0.4$. The commutating angle increases from zero to 30 degrees at $I_dX_c/E_s=0.164$ during the first mode. The angle is then fixed at 30 degrees until the end of the second mode at $I_dX_c/E_s=0.307$. There is an increase in the angle from 30 to 60 degrees during the third mode, which ends at $I_dX_c/E_s=0.632$. Then the angle is fixed until the end of the fourth mode at $I_dX_c/E_s=0.875$. In the fifth mode, the angle increases to 92 degrees at $I_dX_c/E_s=0.975$, the short-circuit value.

Calculated values of angle of delay are plotted against reactance factors in Fig. 3. Both the first and second angle of inherent delay are given; for example, for $k=0.4$, the first angle α increases from zero to 14 degrees in the interval of I_dX_c/E_s from 0.164 to 0.307 and the second angle β increases from zero to 30 degrees, making a change from 14 to 44 degrees in the total angle of delay, in the interval of I_dX_c/E_s from 0.632 to 0.875.

Equations used in plotting the curves are derived in the Appendix.

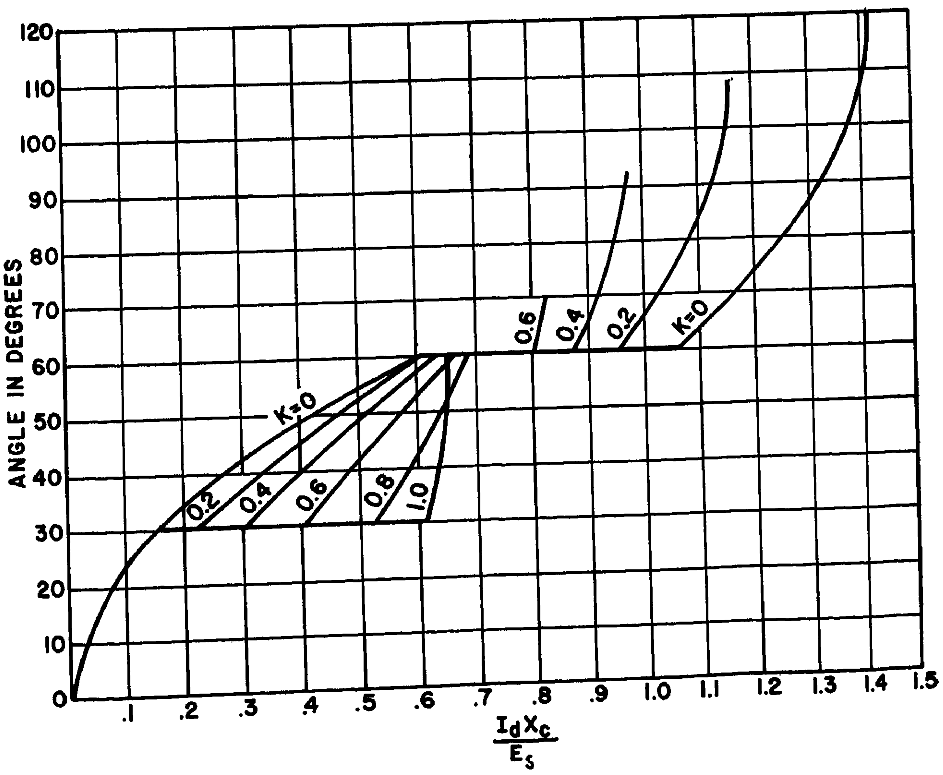

Fig. 2. Commutation angle as a function of reactance factor

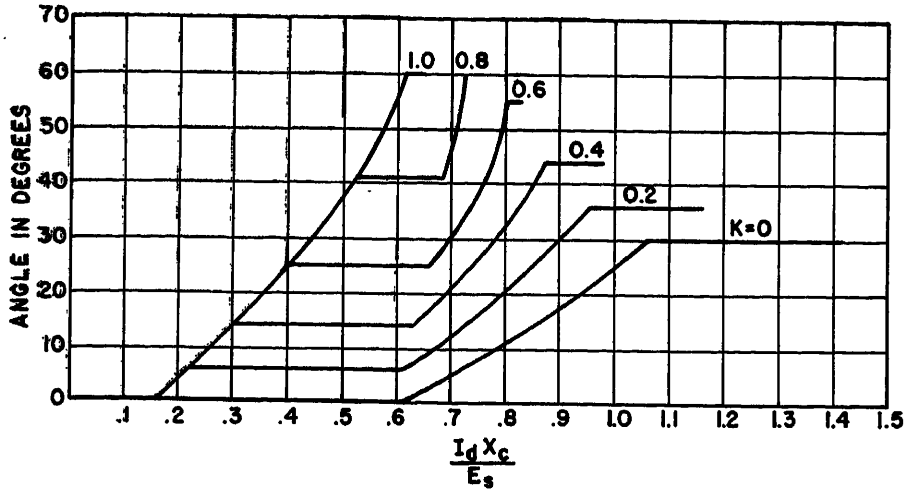

Fig. 3. Angles of delay as a function of reactance factor

Summary of Equations

Mode 1

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}}{2}(1-\cos u)$$

$$\frac{E_d}{E_{do}}=\frac{1}{2}(1+\cos u)$$

Mode 2

$$\frac{I_dX_c}{E_s}=\sqrt{6}\sin 15^\circ \sin(\alpha+15^\circ)$$

$$\frac{E_d}{E_{do}}=\cos 15^\circ \cos(\alpha+15^\circ)$$

Mode 3

$$\frac{I_dX_c}{E_s}=\left[\frac{3+\sqrt{3}}{2}\left(\frac{2-k\sqrt{3}}{2+k\sqrt{3}}\right)\sin\left(\frac{u}{2}-15^\circ\right)+\frac{3-\sqrt{3}}{2}\cos\left(\frac{u}{2}-15^\circ\right)\right]\sin\left(\alpha_m+\frac{u}{2}\right)$$

$$\frac{E_d}{E_{do}}=\frac{1-\sqrt{3}}{2\sqrt{2}}\left[\frac{2+k\sqrt{3}}{2-k\sqrt{3}}\sin\left(\frac{u}{2}-15^\circ\right)-(2+\sqrt{3})\cos\left(\frac{u}{2}-15^\circ\right)\right]\cos\left(\alpha_m+\frac{u}{2}\right)$$

Mode 4

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}}{2+k\sqrt{3}}\sin(\alpha_m+\beta+30^\circ)$$

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}(1-k)}{2-k\sqrt{3}}\cos(\alpha_m+\beta+30^\circ)$$

Mode 5

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{2}}{(1+k)(2+k\sqrt{3})}\times\left[\sin\left(\frac{u}{2}-30^\circ\right)+\sqrt{3}(1+k)\times\cos\left(\frac{u}{2}-30^\circ\right)\right]\sin\left(\frac{u}{2}+\alpha_m+30^\circ\right)$$

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}(1-k)}{2-k\sqrt{3}}\left[\cos\left(\frac{u}{2}-30^\circ\right)-\sqrt{3}(1+k)\sin\left(\frac{u}{2}-30\right)\right]\cos\left(\frac{u}{2}+\alpha_m+30^\circ\right)$$

Laboratory Tests

The trend of the calculated regulation curves was substantiated by tests on a model rectifier on the analogue computer, or Anacom. The technique of handling such problems on the Anacom was described in the paper on 6-phase rectifier regulation.[1] As in that case, the rectifier elements were represented by selected selenium cells having low voltage drop in the forward direction and very high impedance in the reverse direction. The circuit was supplied from a 19-volt 3-phase source of low impedance, providing an essentially infinite bus.

Data taken on the Anacom circuit are shown in Fig. 4. These data have been corrected for voltage drop across the rectifying elements and for losses in the circuit elements. The solid lines are the calculated curves taken from Fig. 1. Although the trend of the calculated curves were substantiated by Anacom data, there is some discrepancy between the laboratory data and the theoretical curves at the higher ratios of common to total reactance.

One handicap, peculiar to the 12-phase study, lay in the construction of the Anacom transformers. These transformers are provided with a variable turns ratio in 10-per-cent steps. Therefor, the delta-delta transformer bank could be set up with a 100-per-cent turns ratio, but the turns ratio of the wye-delta bank had to be set up with a 60-per-cent turns ratio instead of the desired 57.7 per cent. Some inaccuracies were introduced into the laboratory curves by the method employed to account for losses in the computer circuit elements. Data taken from the Anacom were first corrected for the tube drop corresponding to the load current. Then corrections were made for resistance drop by dividing the watts loss in the a-c circuit by the current in the d-c circuit, the conventional procedure of correcting for a-c circuit losses in rectifiers. The accuracy of this method depends upon how closely the current wave forms approach theoretical shapes. These two factors, lack of the exact transformer turns ratio required, and variation of the current wave from the exact theoretical shape, account for the differences between calculated curves and laboratory data.

Appendix. Twelve-Phase Operation With Two Double-Way Rectifiers in Series

A circuit consisting of two 6-phase full-wave bridges with d-c outputs connected in series is shown in Fig. 5. Transformer turns ratios are selected to give unity ratio of transformation between line-to-line voltages. As shown on the phasor diagram of Fig. 6, line-to-neutral voltages behind source reactance are

$$E_a=\sqrt{2}E_s\cos\left(\omega t+\frac{\pi}{2}\right)$$

$$E_b=\sqrt{2}E_s\cos\left(\omega t-\frac{\pi}{6}\right)\qquad(1)$$

$$E_c=\sqrt{2}E_s\cos\left(\omega t-\frac{5\pi}{6}\right)$$

where E_s is the rms value of transformer-secondary no-load line-to-neutral voltage.

At no load, the voltages applied to the anodes of one 3-phase rectifier group and to the cathodes of the other 3-phase rectifier group of each bridge are:

Wye-Delta (bridge I)

$$E_1=\sqrt{2}E_s\cos\left(\omega t-\frac{\pi}{3}\right)$$

$$E_3=\sqrt{2}E_s\cos(\omega t-\pi)$$

$$E_5=\sqrt{2}E_s\cos\left(\omega t+\frac{\pi}{3}\right)$$

Delta-Delta (bridge II) (2)

$$E_2=\sqrt{2}E_s\cos\left(\omega t-\frac{5\pi}{6}\right)$$

$$E_4=\sqrt{2}E_s\cos\left(\omega t+\frac{\pi}{2}\right)$$

$$E_6=\sqrt{2}E_s\cos\left(\omega t-\frac{\pi}{6}\right)$$

These voltages determine the normal time of commutation of the first 3-phase rectifier group of each bridge, and the negatives of these voltages determine the normal time of commutation of the second 3-phase rectifier group of each bridge. The 30-degree phase shift between the two bridges results in equivalent 12-phase operation.

Referring to Fig. 5, the reactance $X_L=2\pi fL_L$ includes the transformer reactance and all reactance between transformer primary terminals and the common point of

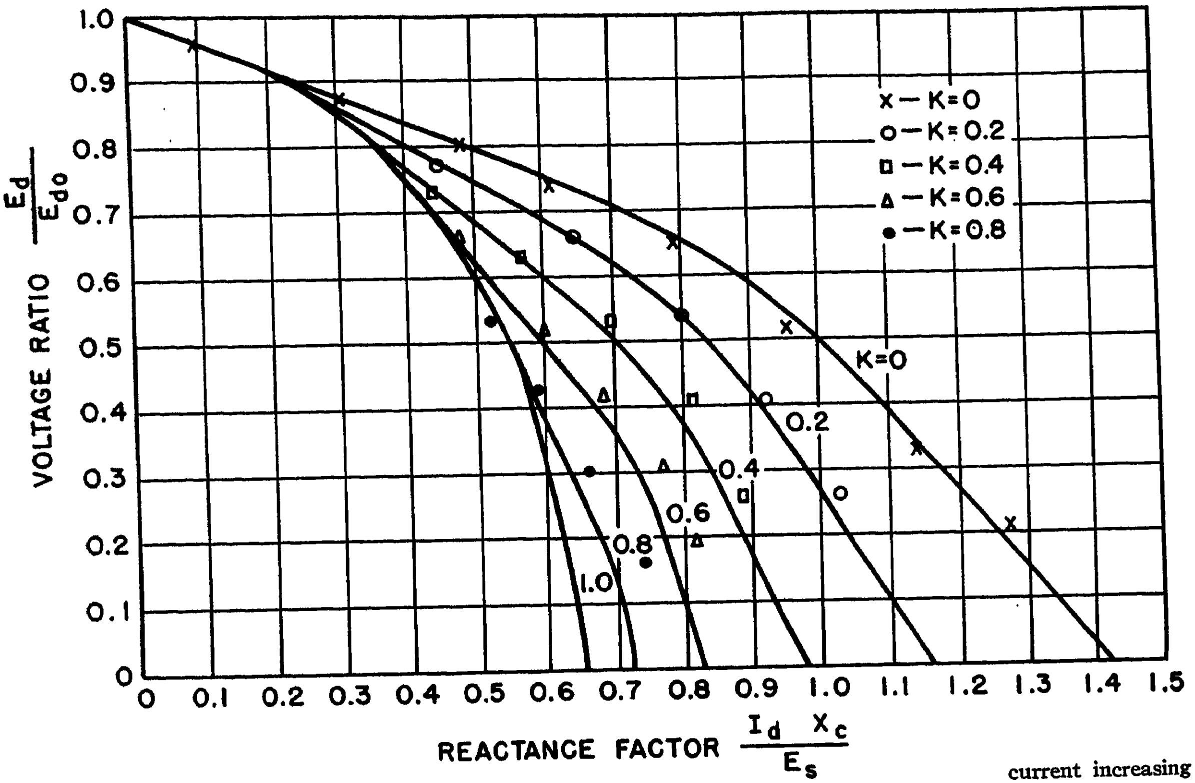

Fig. 4. Voltage regulation curves for 12-phase double-way rectifier showing laboratory data

the supply circuit. The reactance X_s includes all reactance between this common point and the source.

First Mode of Operation

During the first mode of operation, commutations occur at different times in the two bridges, that is, a commutation in bridge I is completed before the start of a commutation in bridge II.

Referring to Fig. 5, the tubes are numbered in the order in which they start to conduct and the current i_1 represents an instantaneous current increasing in T_1 and decreasing in T_9 during the commutation from T_9 to T_1. The following are obtained

$$E_{ab}=-\frac{3}{2}Lpi_1+E_{a1b1} \tag{3}$$

$$E_{bc}=E_{b1c1}$$

Since a T_9 to T_1 commutation imposes a temporary short circuit on terminals 5 to 1 on the secondary of the bridge I transformer, $E_{a1}=0$; and $E_{a1b1}=E_{c1a1}=-E_{b1c1}/2$. Therefore, from equations 3

$$pi_1=-\frac{2E_{ab}+E_{bc}}{3L}=-\frac{E_a}{L} \tag{4}$$

The current i_2 represents an instantaneous current increasing in T_2 and decreasing in T_{10} during the commutation from T_{10} to T_2. During this commutation, the following equation can be written

$$E_{ca}=2Lpi_2+E_{c2a2} \tag{5}$$

Since a T_{10} to T_2 commutation imposes a temporary short circuit on terminals 4 to 2 on the secondary of the bridge II transformer, $E_{c2a2}=0$, and

$$pi_2=\frac{E_{ca}}{2L} \tag{6}$$

During the first mode of operation, the average direct voltage can be obtained by taking the average of the instantaneous

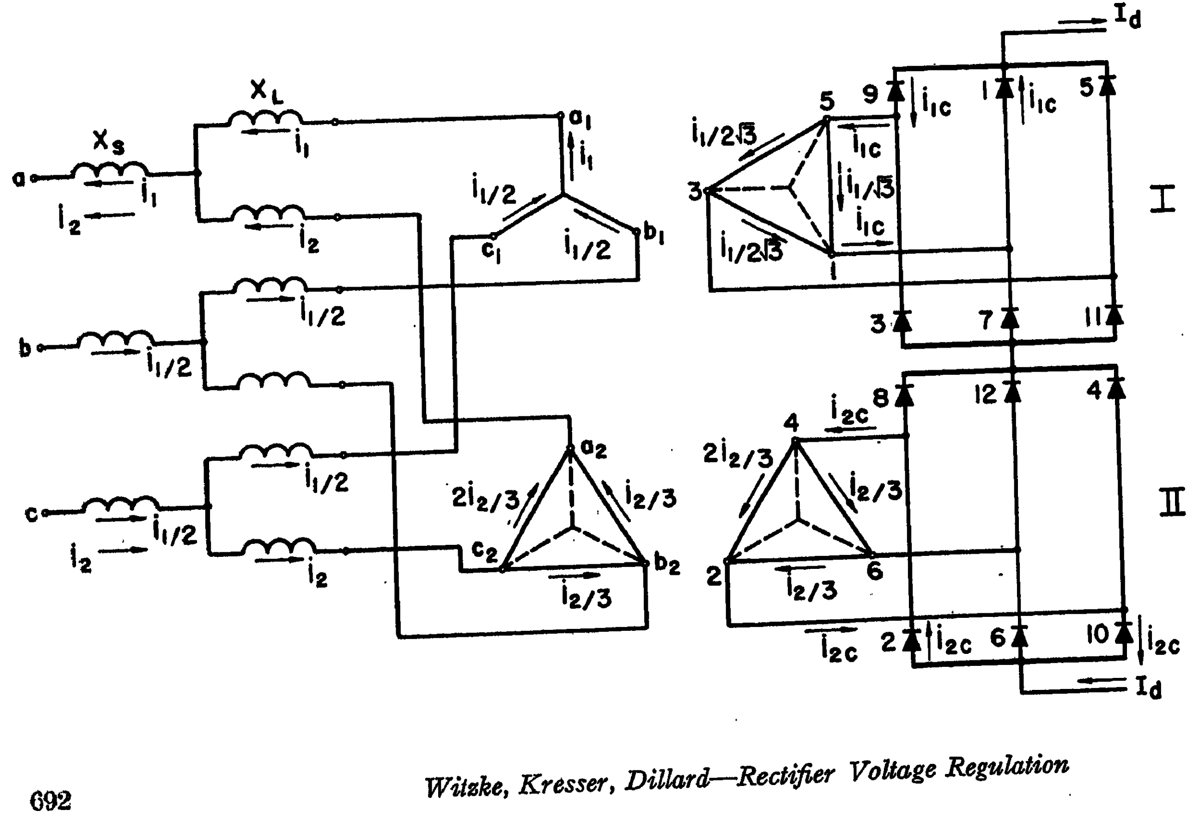

Fig. 5. Circuit diagram showing currents for commutations from T_9 to T_1 and T_{10} to T_2

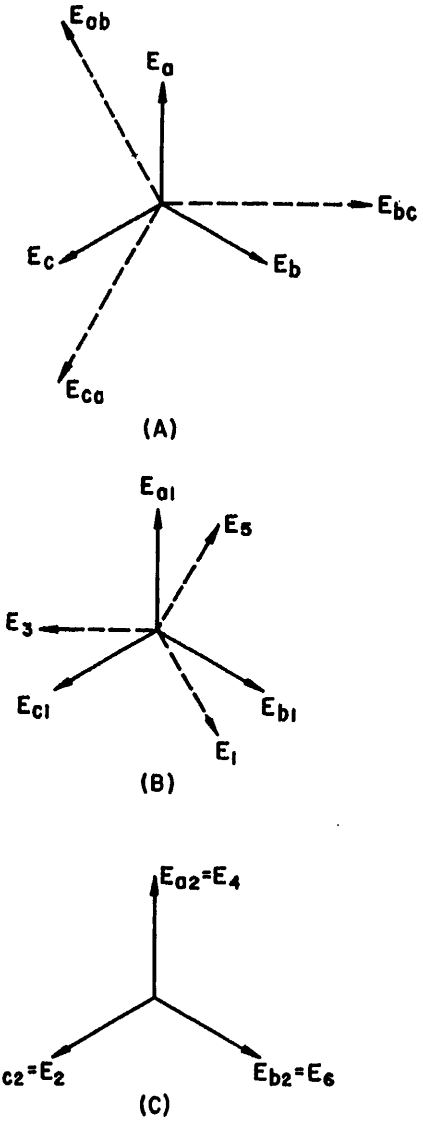

Fig. 6. Phasor diagrams

A. Line-to-neutral voltage behind source reactance
B. No-load voltages on wye-delta bank
C. No-load voltages on delta-delta bank

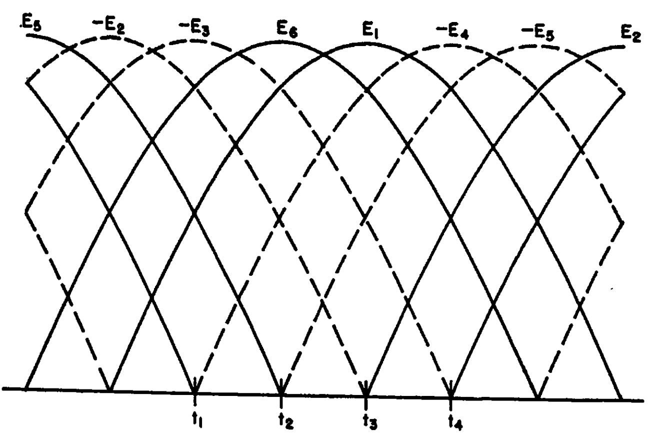

Fig. 7. Voltage wave shapes showing normal commutation times

values over a 60-degree period, since there is a commutation every 60 degrees in each bridge. The average direct voltages of the two bridges are equal, the instantaneous values being displaced by 30 degrees. Therefore, the average direct voltage for two bridges in series is twice the average voltage of a single bridge,[1] or

$$E_d=\frac{6\sqrt{6}}{\pi}E_s\left(\frac{1+\cos u}{2}\right) \qquad (7)$$

Dividing equation 7 by the no-load direct voltage, $E_{d0}=6\frac{\sqrt{6}}{\pi}E_s$

$$\frac{E_d}{E_{d0}}=\frac{1+\cos u}{2} \qquad (8)^*$$

The commutating angle is the same as for a single bridge,[1] or

$$\cos u=1-\frac{2I_dX_c}{\sqrt{6}E_s}.$$

from which

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}}{2}(1-\cos u) \qquad (9)^*$$

The limitation on u is 30 degrees, rather than 60 degrees as for a single bridge. That is, when the reactance factor is greater than the value for which $u=30$ degrees, forced delay is introduced, and the rectifier enters the second mode of operation.

Second Mode of Operation

During the second mode of operation the angle of overlap u remains fixed at 30 degrees and the start of commutations in each bridge is delayed by an angle α, which depends on the ratio of reactances X_L and X_s. As in the first mode of operation, however, a commutation in bridge I is completed before the start of the subsequent commutation in bridge II.

Normal start of commutation from T_9 to T_1 on bridge I, designated by t_1 on Fig. 7, is when $E_5=E_1$, that is, when $E_{a1}=E_{b1}/\sqrt{3}=0$. If at that time the commutation from T_8 to T_{12} is still going on in bridge II, equations similar to 5 and 6 hold for the T_8 to T_{12} commutation. During this commutation

$$pi_2=-\frac{E_{ab}}{2L}$$

Note that $i_1=0$ until the T_9 to T_1 commutation starts. Therefore, following Fig. 5, $E_{a1}'=E_a+L_spi_2$ or

$$E_{a1}'=E_a-\frac{L_s}{2L}E_{ab}=\frac{(2X_c-X_s)E_a+X_sE_b}{2X_c} \qquad (10)$$

The normal start of the T_9 to T_1 commutation has been selected at $\omega t=0$. Taking E_a and E_b from equation 1 at this instant, $E_{a1}'>0$. Therefore, for reactance factors greater than those for which $u=30$ degrees, forced delay in the start of the T_9 to T_1 commutation is introduced. By the same reasoning, the start of the T_8 to T_{12} commutation was delayed while T_7 to T_{11} were still commutating. This is similar to the single bridge circuit,[1] except that forced delay is introduced at $u=30$ degrees instead of $u=60$ degrees. Another difference is that the maximum delay angle is independent of the reactance factor, and is a function of the ratio of reactances only, as will be shown.

At some angle α_m, which is the angle of maximum forced delay, E_{a1}' will become zero. Letting $\omega t=\alpha_m$ in equation 1, substituting these values in equation 10, and equating to zero

$$E_{a1}'=\frac{(2X_c-X_s)}{2X_c}\sqrt{2}E_s\cos\left(\alpha_m+\frac{\pi}{2}\right)+\frac{X_s}{2X_c}\sqrt{2}E_s\cos\left(\alpha_m+\frac{\pi}{6}\right)=0$$

Carrying out the trigonometry

$$\tan\alpha_m=\frac{X_s\sqrt{3}}{4X_c-3X_s}=\frac{k\sqrt{3}}{4-3k} \qquad (11)^*$$

Since the largest value of k is unity ($X_s=X_c$ where $X_L=0$), the largest maximum delay angle is 60 degrees, as compared with 30 degrees for a single bridge circuit.[1] Also, from similarity with the single bridge, the commutating angle remains fixed at 30 degrees (rather than 60 degrees) for reactance factors greater than $(\sqrt{6}/2)\times(1-\cos 30°)$.

The average direct voltage is obtained from the instantaneous values over a 60-degree period. For bridge I, starting from the instant that the T_9 to T_1 commutation starts, in the interval $\omega t=\alpha$ to $\omega t=\alpha+30°$, T_{11}, T_9, and T_1 are conducting.

Therefore

$$e_{d1}=-E_3+E_1=\sqrt{3}E_{b1}$$

Since there is no commutation taking place in bridge II during this interval, $E_{b1}=-E_{c1}$, and from equations 3

$$E_{bc}=E_{b1c1}=2E_{b1}$$

Therefore

$$e_{d1}=\frac{\sqrt{3}}{2}E_{bc}=\frac{3\sqrt{2}}{2}E_s\cos\omega t$$

In the interval $\omega t=\alpha+30°$ to $\omega t=\alpha+60°$, the T_9 to T_1 commutation being completed, T_{11} and T_1 are conducting in bridge I. There is a commutation going on in bridge II, the T_{10} to T_2 commutation starting 30 degrees after the start of the T_9 to T_1 commutation. From Fig. 5

$$E_{ab}=-L_spi_2+E_{a1b1}$$

$$E_{ac}=-2L_spi_2+E_{a1c1}$$

which yield, upon simplifying

$$2E_{ab}-E_{ac}=2E_{a1b1}-E_{a1c1}$$

---

* Equations marked * are tabulated in the Summary section.

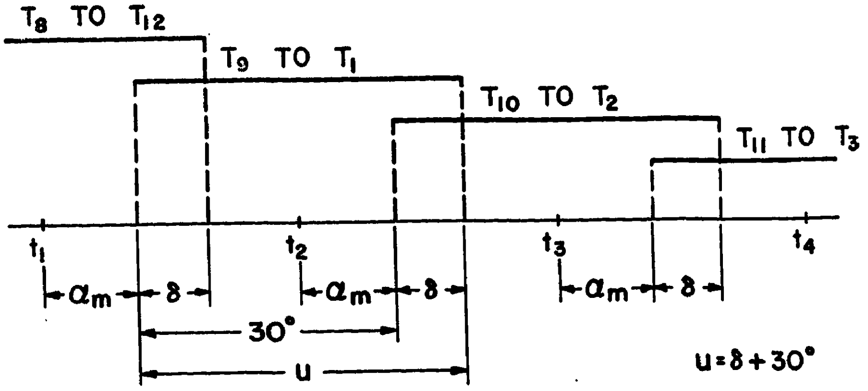

Fig. 8. Graph showing interval of commutations in the period from t_1 to t_4 during the third mode of operation

or $E_b = E_{b1}$. Therefore

$$e_{d2} = \sqrt{3}E_{b1} = \sqrt{6}E_s \cos\left(\omega t - \frac{\pi}{6}\right)$$

The total average direct voltage will be twice the average of the above two instantaneous voltages over a 60-degree period

$$E_d = \frac{6}{\pi}\left[\int_{\alpha}^{\alpha+\frac{\pi}{6}} \frac{3\sqrt{2}}{2}E_s \cos \omega t d\omega t + \int_{\alpha+\frac{\pi}{6}}^{\alpha+\frac{\pi}{3}} \sqrt{6}E_s \cos\left(\omega t - \frac{\pi}{6}\right) d\omega t\right]$$

Evaluating the integrals between the indicated limits, expanding, and collecting terms

$$E_d = \frac{6\sqrt{6}}{\pi}E_s \cos 15° \cos(\alpha + 15°)$$

But

$$E_{do} = \frac{6\sqrt{6}}{\pi}E_s$$

giving

$$\frac{E_d}{E_{do}} = \cos 15° \cos(\alpha + 15°) \qquad (12)^*$$

The commutating current, from Fig. 5, is $i_{1c} = (\sqrt{3}/2)i_1$ and $i_{1c} = I_d$ when $\omega t = \alpha + 30°$. Therefore, from equation 4

$$I_d = \int_{\alpha}^{\alpha+\frac{\pi}{6}} \frac{\sqrt{6}E_s}{2X_c} \sin \omega t d\omega t \qquad (13)$$

Integrating and simplifying

$$\frac{I_d X_c}{E_s} = \sqrt{6} \sin 15° \sin(\alpha + 15°) \qquad (14)^*$$

Limits on the second mode of operation are $\alpha = 0$ to $\alpha = \alpha_m$ where α_m is obtained from equation 11. Thus

$$\frac{\sqrt{6}}{2}(1 - \cos 30°) \leq \frac{I_d X_c}{E_s} \leq \frac{3-\sqrt{3}}{2} \sin(\alpha_m + 15°) \qquad (15)$$

Third Mode of Operation

For reactance factors greater than those for which $\alpha = \alpha_m$ in equation 14, commutation will start at α_m since at that point the two instantaneous voltages E_6 and E_1 become equal. Hence, there will be portions during the commutation period where both bridges will commutate simultaneously. During the third mode of operation the commutation (overlap) angle will increase with the increase in the reactance factor. This mode of operation continues until $u = 60°$.

Because of the symmetry of operation the simultaneous commutation interval δ is the same at the end as at the start of the commutating period, as shown in Fig. 8. Since a new commutation starts every 30°, the total commutating period $u = 30° + \delta$. However, in each bridge commutations start 60 degrees apart, making the interval of symmetry 60 degrees. Thus $u \leq 60°$ and $\delta \leq 30°$ during the third mode of operation.

The 60-degree angle of symmetry is composed of four distinct intervals as shown in Fig. 8. During the first interval, $\omega t = \alpha_m$ to $\omega t = \alpha_m + \delta$, simultaneous commutations exist from T_9 to T_1 (in bridge I) and T_8 to T_{12} (in bridge II). In the second interval, $\omega t = \alpha_m + \delta$ to $\omega t = \alpha_m + 30°$, the only commutation is T_9 to T_1. During the third interval, $\omega t = \alpha_m + 30°$ to $\omega t = \alpha_m + 30° + \delta$, simultaneous commutations exist from T_9 to T_1 (in bridge I) and T_{10} to T_2 (in bridge II). In the fourth interval, $\omega t = \alpha_m + 30° + \delta$ to $\omega t = \alpha_m + 60°$, the only commutation is T_{10} to T_2.

Referring to Fig. 5, the current i_2 is shown for the T_{10} to T_2 commutation. For the T_8 to T_{12} commutation, a similar current i_4 (not shown) flows in terminal b and out terminal a of Fig. 5. Bearing this fact in mind, the following equations apply for the 60-degree period, beginning at the start of the T_9 to T_1 commutation:

First interval, $\omega t = \alpha_m$ to $\omega t = \alpha_m + \delta$

Commutations exist from T_9 to T_1 and T_8 to T_{12}. Therefore

$$\begin{aligned} E_{ab} &= -\frac{3}{2}Lpi_1 - 2L_s pi_4 + E_{a1b1} \\ &= -\frac{3}{2}L_s pi_1 - 2Lpi_4 + E_{a2b2} \\ E_{bc} &= L_s pi_4 + E_{b1c1} = Lpi_4 + E_{b2c2} \\ E_{ca} &= \frac{3}{2}Lpi_1 + L_s pi_4 + E_{c1a1} \\ &= \frac{3}{2}L_s pi_1 + Lpi_4 + E_{c2a2} \end{aligned} \qquad (16)$$

$E_{a1} = 0$ and $E_{a2b2} = 0$

As shown in Fig. 5, $i_{1c} = (\sqrt{3}/2)i_1$ and $i_{4c} = i_4$. Therefore, after solving equations 16

$$\begin{aligned} pi_{1c} &= \frac{\sqrt{3}}{2}pi_1 \\ &= -\frac{1}{\sqrt{3}}\left[\frac{(2L-3L_s)E_{ab} - 2LE_{ca}}{(4L^2-3L_s^2)}\right] \\ pi_{4c} &= pi_4 = -\left[\frac{(2L-L_s)E_{ab} + L_s E_{ca}}{(4L^2-3L_s^2)}\right] \end{aligned} \qquad (17)$$

Second interval, $\omega t = \alpha_m + \delta$ to $\omega t = \alpha_m + 30°$

The only commutation is T_9 to T_1, and the current has already been derived in equation 4. Thus

$$\begin{aligned} pi_{1c} &= \frac{\sqrt{3}}{2}pi_1 = -\frac{\sqrt{3}}{2}\left[\frac{E_a}{L}\right] \\ &= -\frac{\sqrt{3}}{2}\left[\frac{E_{ab} - E_{ca}}{3L}\right] \end{aligned} \qquad (18)$$

$pi_{2c} = pi_2 = 0$

Third interval, $\omega t = \alpha_m + 30°$ to $\omega t = \alpha_m + \delta + 30°$

Commutations exist from T_9 to T_1 and T_{10} to T_2. Therefore

$$\begin{aligned} E_{ab} &= -\frac{3}{2}Lpi_1 - L_s pi_2 + E_{a1b1} \\ &= -\frac{3}{2}L_s pi_1 - Lpi_2 + E_{a2b2} \\ E_{bc} &= -L_s pi_2 + E_{b1c1} = -Lpi_2 + E_{b2c2} \\ E_{ca} &= \frac{3}{2}Lpi_1 + 2L_s pi_2 + E_{c1a1} \\ &= \frac{3}{2}L_s pi_1 + 2Lpi_2 + E_{c2a2} \end{aligned} \qquad (19)$$

$E_{a1} = 0$ and $E_{c2a2} = 0$

After solving equations 19

$$\begin{aligned} pi_{1c} &= \frac{\sqrt{3}}{2}pi_1 \\ &= -\frac{1}{\sqrt{3}}\left[\frac{2LE_{ab} - (2L-3L_s)E_{ca}}{(4L^2-3L_s^2)}\right] \\ pi_{2c} &= pi_2 = \frac{L_s E_{ab} + (2L-L_s)E_{ca}}{(4L^2-3L_s^2)} \end{aligned} \qquad (20)$$

Fourth interval, $\omega t = \alpha_m + \delta + 30°$ to $\omega t = \alpha_m + 60°$

In this interval the only commutation is T_{10} to T_2 and the current has already been derived in equation 6

$$\begin{aligned} pi_{1c} &= \frac{\sqrt{3}}{2}pi_1 = 0 \\ pi_{2c} &= pi_2 = \frac{E_{ca}}{2L} \end{aligned} \qquad (21)$$

During the first interval the current i_{1c} increases from zero at $\omega t = \alpha_m$ to some value I_{d1} at $\omega t = \alpha_m + \delta$, and is determined by equations 17. In the second interval, the current increases from the value I_{d1} at $\omega t = \alpha_m + \delta$ to some value I_{d2} at $\omega t = \alpha_m + 30°$,

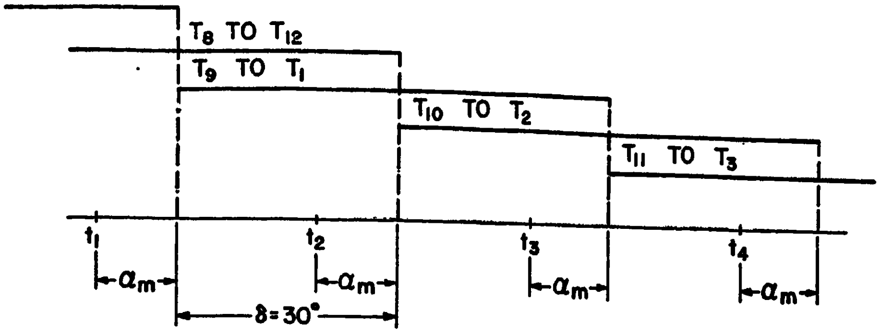

Fig. 9. Graph showing interval of commutations in the period from t_1 to t_4 at start of the fourth mode of operation

and is determined by equations 18. During the third interval, the current increases from the value I_{d2} at $\omega t=\alpha_m+30°$ to its final value I_d at $\omega t=\alpha_m+\delta+30°$, and is determined by equations 20. In the fourth interval, the current i_{1c} is zero.

Performing the indicated integrations with $E_{ab}=\sqrt{3}\sqrt{2}E_s$ cos $(\omega t+2\pi/3)$ and $E_{ca}=\sqrt{3}\sqrt{2}E_s \cos(\omega t-2\pi/3)$, inserting the boundary conditions, collecting terms, and reducing

$$I_d=\left[\frac{2(3+\sqrt{3})}{2X_c+\sqrt{3}X_s}\sin\frac{\delta}{2}+\frac{\sqrt{6}}{X_c}\sin\left(15°-\frac{\delta}{2}\right)\right]E_s\sin\left(\alpha_m+\frac{\delta}{2}+15°\right) \tag{22}$$

which can be written after rearranging, and substituting $k=X_s/X_c$ and $\delta=u-30°$.

$$\frac{I_dX_c}{E_s}=\left[\frac{3+\sqrt{3}}{2}\left(\frac{2-k\sqrt{3}}{2+k\sqrt{3}}\right)\sin\left(\frac{u}{2}-15°\right)+\frac{3-\sqrt{3}}{2}\cos\left(\frac{u}{2}-15°\right)\right]\sin\left(\alpha_m+\frac{u}{2}\right) \tag{23}^*$$

As before, the average direct voltage is obtained from the component instantaneous voltages averaged over a 60-degree period. Taking bridge I, and referring to Fig. 6(B)

$$e_d=-E_3+E_1=\sqrt{3}E_{b1} \tag{24}$$

where E_{b1} is determined for the particular interval considered.

In the first interval, from equations 16, where $E_{a1}=0$

$$e_{d1}=-\sqrt{3}\times\left[\frac{(2X_c^2-X_cX_s-X_s^2)E_{ab}+2(X_c^2-X_s^2)E_{ca}}{4X_c^2-3X_s^2}\right] \tag{25}$$

In the second interval, the only commutation is T_9 to T_1. Therefore, from equations 3

$$e_{d2}=\sqrt{3}E_{b1}=\sqrt{3}\left(-E_{ab}-\frac{3}{2}Lpi_1\right)$$

Substituting equation 18 and reducing

$$e_{d2}=\frac{\sqrt{3}}{2}E_{bc} \tag{26}$$

In the third interval from equations 19

$$e_{d3}=\sqrt{3}E_{b1}=\sqrt{3}\left(-E_{ab}-\frac{3}{2}Lpi_1-L_spi_2\right)$$

Substituting equations 20

$$e_{d3}=-\sqrt{3}\left[\frac{2(X_c^2-X_s^2)E_{ab}+(2X_c^2-X_cX_s-X_s^2)E_{ca}}{4X_c^2-3X_s^2}\right] \tag{27}$$

For the fourth interval, the only commutation is T_{10} to T_2, and in bridge I, T_{11} and T_1 are conducting. From Fig. 5

$$E_{ab}=-L_spi_2+E_{a1b1}$$

$$E_{ca}=2L_spi_2+E_{c1a1}$$

or

$$2E_{ab}+E_{ca}=2E_{a1b1}+E_{c1a1}=-3E_{b1}$$

from which

$$e_{d4}=\sqrt{3}E_{b1}=-\left[\frac{2E_{ab}+E_{ca}}{\sqrt{3}}\right] \tag{28}$$

Integrating each voltage of equations 25, 26, 27, and 28 between the limits of its interval as given above and dividing by $\pi/3$ to obtain the average voltage, reducing, and further dividing by $E_{do}=(3\sqrt{6}/\pi)E_s$ (for a single bridge), there is obtained

$$\frac{E_d}{E_{do}}=\left\{\sqrt{2}\left[\frac{(3+\sqrt{3})(2X_c^2-\sqrt{3}X_s^2)-(3-\sqrt{3})X_cX_s}{4X_c^2-3X_s^2}\right]\sin\frac{\delta}{2}+(2+\sqrt{3})\sin\left(15°-\frac{\delta}{2}\right)\right\}\times\cos\left(\alpha_m+\frac{\delta}{2}+15°\right) \tag{29}$$

which can be written by substituting $u=\delta+30°$, as shown on Fig. 8

$$\frac{E_d}{E_{do}}=\frac{1-\sqrt{3}}{2\sqrt{2}}\left[\frac{2+k\sqrt{3}}{2-k\sqrt{3}}\sin\left(\frac{u}{2}-15°\right)-(2+\sqrt{3})\cos\left(\frac{u}{2}-15°\right)\right]\times\cos\left(\alpha_m+\frac{u}{2}\right) \tag{30}^*$$

Fourth Mode of Operation

The period of simultaneous commutations between the two bridge circuits cannot exceed 60 degrees, since at $\delta=30$ degrees the commutating angle is 60 degrees, as shown in Fig. 9. When the commutating angle of a single bridge circuit reaches 60 degrees, further increase in the reactance factor will introduce forced delay within the bridge circuit.[1] Similarly, in the case of 12-phase operation, an increase in the reactance factor beyond the value for which $\delta=30$ degrees will introduce an additional forced delay of angle β within each bridge. Thus, as shown in Fig. 10, there will be a total delay of $\alpha_m+\beta$ in the start of commutation, followed by a commutation angle of 60 degrees. In this mode of operation, the maximum value of β is 30 degrees. The limiting value of $\alpha_m+\beta$ ($\beta\leqq30°$) is 60 degrees, at which point the direct voltage is zero.

There are two commutating intervals involved in this mode of operation: in the first interval, $\omega t=\alpha_m+\beta$ to $\omega t=\alpha_m+\beta+30°$, commutations from T_9 to T_1 and T_8 to T_{12} occur simultaneously; in the second interval, $\omega t=\alpha_m+\beta+30°$ to $\omega t=\alpha_m+\beta+60°$, commutations from T_9 to T_1 and T_{10} to T_2 occur simultaneously.

Currents in the first interval are determined by equations 16 and 17, in the second interval by equations 19 and 20. Performing the integrations the same way as in deriving equation 23

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}X_c}{2X_c+\sqrt{3}X_s}\sin(\alpha_m+\beta+30°)$$

which can be written

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{6}}{2+k\sqrt{3}}\sin(\alpha_m+\beta+30°) \tag{31}^*$$

The instantaneous voltages in the two intervals are given by equations 25 and 27, respectively. Following the same procedure used in deriving equation 30

$$\frac{E_d}{E_{do}}=\sqrt{3}\times\left[\frac{(2X_c^2-\sqrt{3}X_s^2)-(2-\sqrt{3})X_cX_s}{4X_c^2-3X_s^2}\right]\times\cos(\alpha_m+\beta+30°) \tag{32}$$

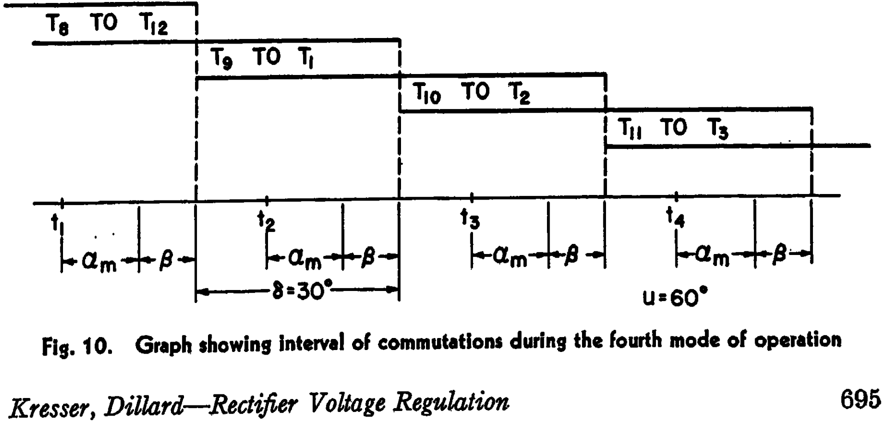

Fig. 10. Graph showing interval of commutations during the fourth mode of operation

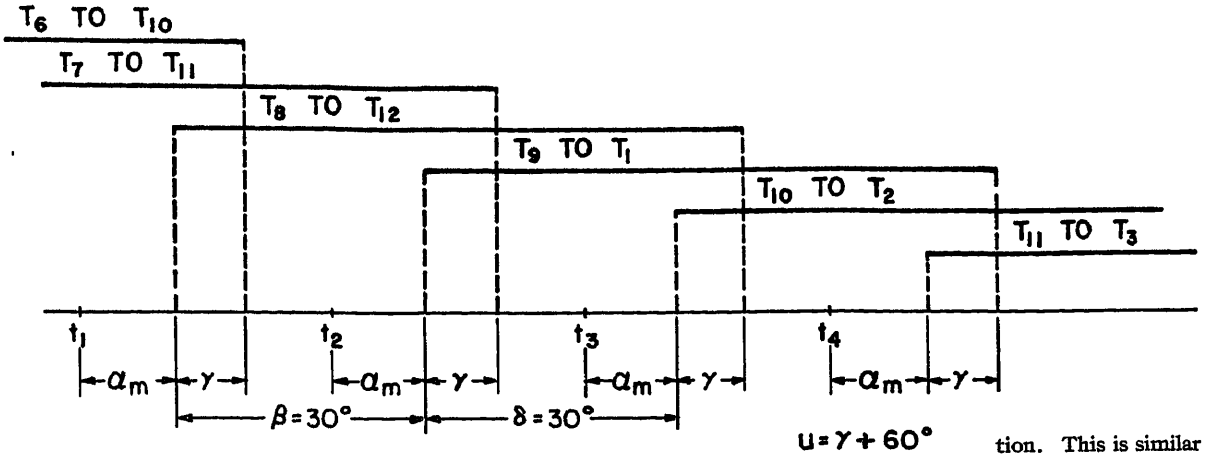

Fig. 11. Graph showing interval of commutations during the fifth mode of operation

which can be written

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}(1-k)}{2-k\sqrt{3}}\cos(\alpha_m+\beta+30°) \qquad (33)^*$$

Fifth Mode of Operation

Equations 31 and 33 apply for values of reactance factors and ratio of source to commutating reactance for which $\alpha_m+\beta \leqq 60°$ and $\beta \leqq 30°$. Thus, for $\alpha_m \leqq 30°$, β increases over the full range of 0 to 30 degrees, and the fourth mode of operation terminates at $\beta=30$ degrees. When $\alpha_m=30$ degrees, the voltage ratio is zero when $\beta=30°$. This represents the dividing point, as for $\alpha_m>30°$, the voltage ratio becomes zero before $\beta=30°$.

For ratios of source reactance to commutating reactance less than 2/3, there is a fifth mode of operation. This mode is analogous to the third mode of operation of a 6-phase double-way[1] (single bridge), in that there are intervals when three phases commutate simultaneously, resulting in a temporary 3-phase short-circuit.

During the period of commutation from T_9 to T_1, there are five distinct intervals, as shown in Fig. 11. In the first interval $\omega t=\alpha_m+\beta$ to $\omega t=\alpha_m+\beta+\gamma$, commutations exist from T_7 to T_{11} and T_9 to T_1 (in bridge I) and from T_8 to T_{12} (in bridge II). In the second interval, $\omega t=\alpha_m+\beta+\gamma$ to $\omega t=\alpha_m+\beta+30°$, commutations exist from T_9 to T_1 (in bridge I) and T_8 to T_{12} (in bridge II). During the third interval, $\omega t=\alpha_m+\beta+30°$ to $\omega t=\alpha_m+\beta+30°+\gamma$, there are commutations from T_9 to T_1 (in bridge I) and T_8 to T_{12} and T_{10} to T_2 (in bridge II). In the fourth interval, $\omega t=\alpha_m+\beta+30°+\gamma$ to $\omega t=\alpha_m+\beta+60°$, there are two commutations, T_9 to T_1 (in bridge I) and T_{10} to T_2 (in bridge II). During the fifth interval, $\omega t=\alpha_m+\beta+60°$ to $\omega t=\alpha_m+\beta+60°+\gamma$, there are three commutations, T_9 to T_1 and T_{11} to T_3 (in bridge I) and T_{10} to T_2 (in bridge II). In the fifth mode, the angle $\beta=30°$.

In Fig. 12, the current i_1 is the instantaneous current corresponding to i_{1c}, the commutating current for a T_9 to T_1 commutation. This is similar to current i_1 of Fig. 5. Also shown in the figure are the commutating currents i_3 and i_{3c}, corresponding to a T_7 to T_{11} commutation, and i_4 and i_{4c}, corresponding to a T_8 to T_{12} commutation. Not shown in the figure are similar currents for other commutations involved: i_2 which flows in terminal c and out terminal a during a T_{10} to T_2 commutation; and i_5 which flows in terminal c and out terminals a and b during a T_{11} to T_3 commutation. These currents will be used in the derivations which follow:

First interval: $\omega t=\alpha_m+\beta$ to $\omega t=\alpha_m+\beta+\gamma$.

Commutations are T_7 to T_{11} and T_9 to T_1 (bridge I) and from T_8 to T_{12} (bridge II). Therefore

$$\begin{aligned}E_{ab}&=-\frac{3}{2}Lpi_1-\frac{3}{2}Lpi_3-2L_spi_4+E_{a1b1}\\&=-\frac{3}{2}L_spi_1-\frac{3}{2}L_spi_3-2Lpi_4+E_{a2b2}\\E_{bc}&=\frac{3}{2}Lpi_3+L_spi_4+E_{b1c1}\end{aligned} \qquad (34)$$

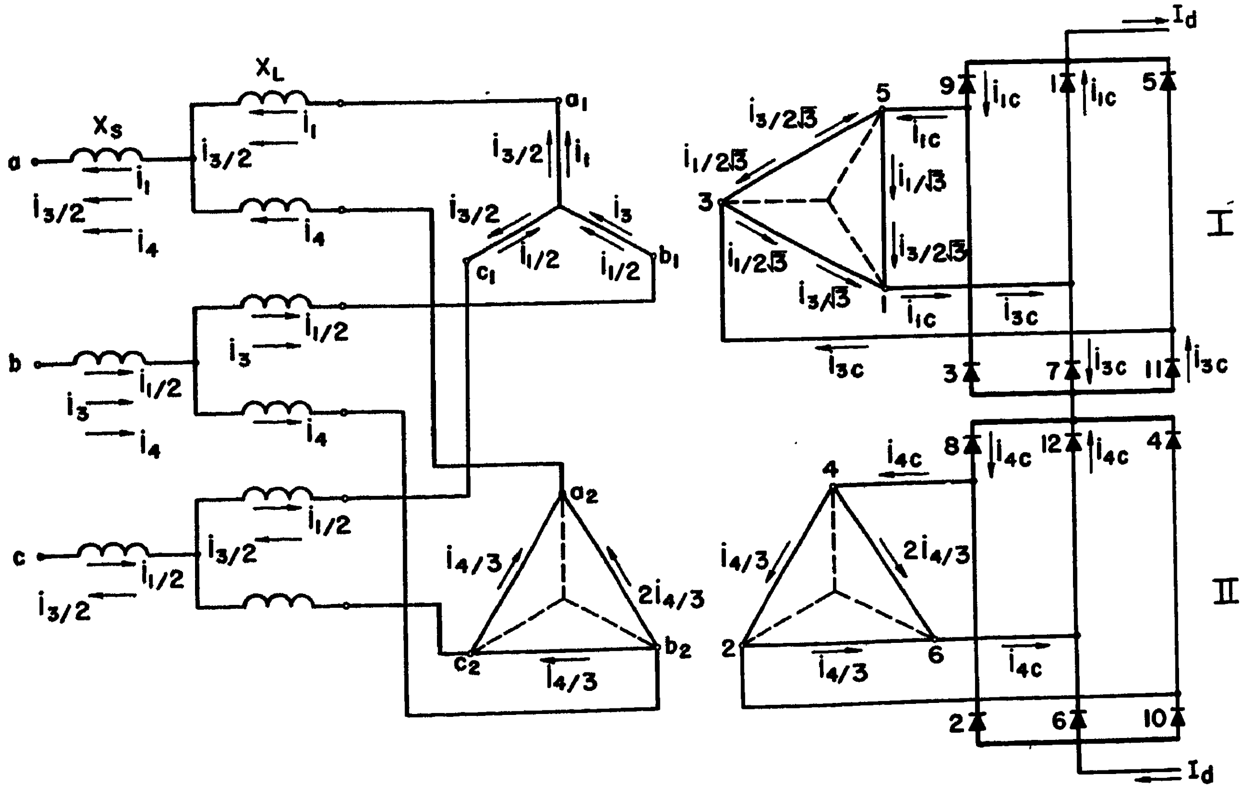

Fig. 12. Circuit diagram showing currents during the first interval of the fifth mode of operation

$$E_{a1b1}=E_{a2b2}=E_{b1c1}=0$$

As shown in Fig. 12, $i_{1c}=(\sqrt{3}/2)i_1$, $i_{3c}=(\sqrt{3}/2)i_3$, $i_{4c}=i_4$. Therefore, after solving equations 34

$$pi_{1c}=\frac{\sqrt{3}}{2}\,pi_1=-\frac{1}{\sqrt{3}}\times\left[\frac{(2L+L_s)E_{ab}+2(L+L_s)E_{bc}}{2L(L+L_s)}\right] \quad (35)$$

SECOND INTERVAL: $\omega t=\alpha_m+\beta+\gamma$ to $\omega t=\alpha_m+\beta+30°$.

The only commutations are T_9 to T_1 (bridge I) and T_8 to T_{12} (bridge II). Therefore, from equations 17

$$pi_{1c}=\frac{\sqrt{3}}{2}\,pi_1=-\frac{1}{\sqrt{3}}\times\left[\frac{(2L-3L_s)E_{ab}-2LE_{ca}}{(4L^2-3L_s^2)}\right] \quad (36)$$

THIRD INTERVAL: $\omega t=\alpha_m+\beta+30°$ to $\omega t=\alpha_m+\beta+30°+\gamma$.

There are commutations from T_9 to T_1 (bridge I) and T_8 to T_{12} and T_{10} to T_2 (bridge II). Therefore

$$E_{bc}=-L_s pi_2+L_s pi_4+E_{b1c1}$$
$$=-Lpi_2+Lpi_4+E_{b2c2}$$

$$E_{ca}=\frac{3}{2}Lpi_1+2L_s pi_2+L_s pi_4+E_{c1a1} \quad (37)$$

$$E_{a1}=0,\ E_{a1b1}=E_{c1a1}=-\frac{E_{b1c1}}{2},\ E_{b2c2}=0$$

After solving equations 37

$$pi_{1c}=\frac{\sqrt{3}}{2}\,pi_1=\frac{1}{\sqrt{3}}\left[\frac{E_{bc}+2E_{ca}}{2(L+L_s)}\right] \quad (38)$$

FOURTH INTERVAL: $\omega t=\alpha_m+\beta+30°+\gamma$ to $\omega t=\alpha_m+\beta+60°$.

There are commutations from T_9 to T_1 (bridge I) and T_{10} to T_2 (bridge II). Therefore, from equations 20

$$pi_{1c}=\frac{\sqrt{3}}{2}\,pi_1=-\frac{1}{\sqrt{3}}\times\left[\frac{2LE_{ab}-(2L-3L_s)E_{ca}}{4L^2-3L_s^2}\right] \quad (39)$$

FIFTH INTERVAL: $\omega t=\alpha_m+\beta+60°$ to $\omega t=\alpha_m+\beta+60°+\gamma$.

There are three commutations, T_9 to T_1 and T_{11} to T_3 (bridge I) and T_{10} to T_2 (bridge II). Therefore

$$E_{ab}=-\frac{3}{2}Lpi_1-L_s pi_2+E_{a1b1}$$

$$E_{bc}=-L_s pi_2-\frac{3}{2}Lpi_5+E_{b1c1}$$

$$E_{ca}=\frac{3}{2}Lpi_1+2L_s pi_2+\frac{3}{2}Lpi_5+E_{c1a1} \quad (40)$$
$$=\frac{3}{2}L_s pi_1+2Lpi_2+\frac{3}{2}L_s pi_5+E_{c2a2}$$

$$E_{a1b1}=E_{b1c1}=E_{c1a1}=E_{c2a2}=0$$

After solving equations 40

$$pi_{1c}=\frac{\sqrt{3}}{2}\,pi_1=\frac{1}{\sqrt{3}}\times\left[\frac{(2L+L_s)E_{ca}+2(L+L_s)E_{bc}}{2L(L+L_s)}\right] \quad (41)$$

Following the same procedure used in obtaining equation 23 during the third mode of operation and substituting $\beta=30°$, $\gamma=u-60°$, $k=X_s/X_c$

$$\frac{I_dX_c}{E_s}=\frac{\sqrt{2}}{(1+k)(2+k\sqrt{3})}\left[\sin\left(\frac{u}{2}-30°\right)+\sqrt{3}(1+k)\cos\left(\frac{u}{2}-30°\right)\right]\times\sin\left(\frac{u}{2}+\alpha_m+30°\right) \quad (42)^*$$

The average direct voltage is obtained, following the same procedure used in obtaining equation 30, by averaging the instantaneous voltages over a 60-degree period of symmetry. It is necessary to consider only the first four current intervals since they extend over a 60-degree period, and a second symmetrical voltage pattern starts at the beginning of the fifth interval. Taking bridge I, and referring to Fig. 6(B)

$$e_d=-E_3+E_1=\sqrt{3}E_{b1} \quad (43)$$

where E_{b1} is determined for the particular interval considered.

In the first interval, from equations 34, during the T_7 to T_{11} commutation

$$e_{d1}=\sqrt{3}E_{b1}=0 \quad (44)$$

In the second interval, the only commutations are T_9 to T_1 and T_8 to T_{12}; therefore, equation 16 applies. Thus

$$e_{d2}=-\sqrt{3}\left[\frac{(2X_c^2-X_cX_s-X_s^2)E_{ab}+2(X_c^2-X_s^2)E_{ca}}{4X_c^2-3X_s^2}\right] \quad (45)$$

This is the same as equation 25.

In the third interval, commutations exist from T_9 to T_1, T_8 to T_{12}, and T_{10} to T_2. Therefore, from equations 37

$$e_{d3}=\sqrt{3}E_{b1}=\frac{\sqrt{3}}{2}\,[E_{bc}+L_s pi_2-L_s pi_4]$$

which can be solved with equations 37 to yield

$$e_{d3}=\sqrt{3}\left[\frac{(L-L_s)E_{bc}}{2L}\right] \quad (46)$$

In the fourth interval, the only commutations are T_9 to T_1 and T_{10} to T_2. This interval is the same as the one that gave equation 27 in the third mode of operation. Therefore, from equation 27

$$e_{d4}=-\sqrt{3}\left[\frac{2(X_c^2-X_s^2)E_{ab}+(2X_c^2-X_cX_s-X_s^2)E_{ca}}{4X_c^2-3X_s^2}\right] \quad (47)$$

Integrating the voltages of equations 44, 45, 46, and 47 between the limits of each interval, dividing by $\pi/3$ to obtain the average voltage (as was done to get equation 29), and further dividing by $E_{do}=(3\sqrt{6}/\pi)E_s$, there is obtained after substituting $\beta=30°$, $\gamma=u-60°$, and $k=X_s/X_c$

$$\frac{E_d}{E_{do}}=\frac{\sqrt{3}(1-k)}{2-k\sqrt{3}}\left[\cos\left(\frac{u}{2}-30°\right)-\sqrt{3}(1+k)\sin\left(\frac{u}{2}-30°\right)\right]\times\cos\left(\frac{u}{2}+\alpha_m+30°\right) \quad (48)^*$$

Discussion

I. K. Dortort (I-T-E Circuit Breaker Company, Philadelphia, Pa.): It is indicated in the paper that at $K=0$ (no common reactance) the 12-phase circuit shown in Fig. 5 behaves in the same manner as the 6-phase double-way circuit. This is confirmed by the limiting curves of Figs. 1, 2, and 3. For $K=0$ and highly inductive loads the curves are exactly the same as obtained from two earlier articles (refs. 1 and 2 of the paper). With no common a-c reactance the two 6-phase systems must be entirely independent, and can have no effect on each other.

When two displaced 6-phase systems are connected in parallel, the inductance of the d-c system is common to both and will maintain the total current at constant value without preventing the flow of sixth-harmonic current between the two. The derivations of this paper will apply to two displaced 6-phase double-way rectifiers in parallel, if each is separately equipped with sufficient d-c inductance, or an interphase transformer is placed between them to hold the sixth-harmonic circulating current to a very small value.

R. L. Witzke, J. V. Kresser, and J. K. Dillard: We appreciate the observations made by Mr. Dortort in his discussion, particularly with reference to the operation of two displaced 6-phase systems connected in parallel. It is significant that the derivations given in the paper apply to the parallel connection where there is sufficient inductance in the load circuit to limit the sixth-harmonic circulating current to a very low value. This means that the curves are more general than indicated in the paper, which was limited to consideration of two displaced 6-phase systems connected in series.

Heat Transfer from Electron Tubes at High Altitudes and High Ambient Temperatures

MRS. B. O. BUCKLAND
MEMBER AIEE

THIS paper contains the results of a series of temperature tests conducted on a *6AQ5* beam power tetrode at full rating at simulated altitudes and ambient temperatures. The effects of altitude, shielding, tube position, and ambient temperature on temperature rise of the hottest spot of the glass envelope are shown. A few measurements were made of the effect of surrounding a single tube by a cluster of other tubes of the same type and rating. The tube was not delivering any output.

The temperature at which a tube or unit may operate must be limited if adequate life is to be attained. High plane speeds and altitudes increase operating temperatures by imposing a higher ambient temperature and by reducing the convective heat transfer. Also, tubes must often be shielded to protect them from vibration and shock, further reducing the heat transfer and increasing the severity of operating conditions. Evaluation of these altitude, ambient temperature, and shielding effects is necessary for the design of air-borne equipment.

Effect of Altitude, Excluding Higher Ambient Temperature

Test results at room temperature and altitudes up to 123,000 feet for several types of shielding and mounting plates, in both vertical and horizontal positions, are summarized in Fig. 1. Ambient temperature was measured by a thermocouple inside the bell jar.

SHIELDING

Fig. 1 shows that:

1. Blackened shields result in much lower hot-spot temperature of the glass envelope than shiny shields.

2. Use of a slotted shield, instead of a full shield, further reduces temperature of the tube envelope.

3. The unshielded tube runs the coolest, although not much below the slotted shield. See also Fig. 2.

TUBE POSITION AND MOUNTING

1. Mounting the tube horizontally results in a hot spot at the top of the tube. This hot spot is higher than the corresponding hot spot with vertical mounting.

2. Tube temperatures appear to be somewhat lower if the tube is mounted on a blackened metal plate, but the effect of the mounting plate on temperature is small compared to the effect of shielding; see Fig. 1.

Effect of Altitude, Including High Ambient Temperature

An increased ambient temperature reduces the envelope temperature rise but always increases the actual temperature. This effect is indicated in Figs. 3, 4, and 5. The average of three thermocouples embedded in the oven walls was used as the external ambient temperature.

Effect of Enclosure

Close proximity of the tube to the enclosure walls results in an appreciably higher temperature rise of the tube envelope. This is shown in Fig. 4, where test points for the lowest ambient temperature (room temperature) were obtained without any oven around the tube, whereas all tests at higher ambient temperatures were made with the small oven enclosing the tube. Fig. 8 shows that in the latter case, the distance from the envelope of a centrally located tube to the oven wall is about 1.7 inches. In Fig. 4 the curves through the higher ambient test points are extrapolated to room temperature to permit comparison with test points taken without the oven.

In actual practice, tubes are likely to be installed even closer to the walls of the enclosure. Thus, the results here reported from tests in the oven are as significant as, or even more significant than, the tests without the oven. For closer proximity of the tube to an enclosing wall the temperature rises for the various conditions here considered may be higher than the present curves would indicate.

Proximity of Other Tubes

Limited data on the operation of tubes in a cluster indicate an appreciable tem-

perature rise over that found in a single tube operation; see Figs. 6 and 7. Therefore, in using the quantitative data in this report, care should be taken to allow for any proximity effects that may exist due to the presence of other heat sources.

Test Procedure

Measurement of envelope hot-spot temperatures was made for the *6AQ5* at full rating under a variety of conditions. Means had to be provided for measuring temperature accurately, holding vacuum, holding input power constant and measuring it, and attaining high ambient temperatures. Since the tube output was not under investigation, the anode and screen were tied together, with a separate circuit for the heater. The tube rating is 16.85 watts, made up of 14.00 watts for anode and screen together, and 2.85 heater watts. All data were corrected to this rating before being plotted.

All tests were carried out in a 12-inch-diameter bell jar held on a steel plate by vacuum sealing grease. The steel plate was perforated in several places to accommodate various connections: vacuum pump and manometer connections, tube power supply, thermocouple connections, and oven heater connections. All plugs for electrical connections were vacuum tight, being the standard feed-through terminals for hermetic sealing.

For higher ambient temperatures, an electrically heated oven was used inside the bell jar. Fig. 8 shows the tube cluster arrangement inside the oven. For single-tube tests, the central position was used.

MEASUREMENT AND CONTROL

Temperature Measurement

Due to the high temperatures expected, chromel-copnic thermocouples were used. Their outputs were read with a Leeds and Northrup potentiometer. The wires for measuring the glass envelope temperature were 5 mils in diameter; all others were 15 mils. The 5-mil size was used because preliminary tests showed that conduction along the wires caused the 15-mil couples to read some 35 to 40 degrees centigrade (C) less than the 5-mil size for a rise of the order of 150 C. The cold junction was immersed in an ice and water bath.

Experimentation with various techniques showed that the best way of fastening the couple to the glass consisted of bending the wires adjacent to the bead into an arc. Then the thermocouple was tied to the envelope with glass thread at two positions about 1/2 inch apart. The springiness of the bent wire is sufficient to hold the bead firmly against the glass. Wire of this fine thickness does not appreciably disturb the free-convection boundary layer.

Room ambient temperatures were measured by a thermocouple inside the bell jar, located some distance away from the tube under test. Higher ambient temperatures were measured by three thermocouples inside the oven. The oven thermocouples were fastened to the oven walls by peening them into the material on the inside. For the single-tube vertical tests, the thermocouple was placed opposite the anode center. For the single-tube horizontal tests, the thermocouple was placed at the top of the tube, above the anode center.

Vacuum Control and Measurement

The vacuum system of Fig. 9 was used in all cases. The vacuum was set by the valve in the line between pump and bell jar, with the pump operating just enough to take care of the system leakage after the desired vacuum was reached. Pressure was measured with a Bennert manometer. The maximum vacuum that the system would hold with the valve wide open was 0.1 centimeter of mercury.

Input Power Control and Measurement

The tube power supply was controlled by a voltage regulator. Current and voltage to the plate and screen were measured with *DP-2* meters while heater current and voltage were measured with a *P-3* ammeter and a Simpson *V.O.M.*

High Ambient Temperature Control

The electric furnace, Fig. 8, was used to simulate high ambient temperatures. This furnace, which contained the tube or tubes, was placed in the bell jar. The several heating elements were wound for the same watts per square inch power density, and the wall temperatures measured. Adjustments to secure uniform temperature were made by placing variable resistors in the circuits and adjusting these until the three thermocouples read very nearly the same. The oven wall thermocouple temperature averages were used as the external ambient temperature.

PRELIMINARY TESTS

The position of the hot spot was explored by fastening couples at intervals

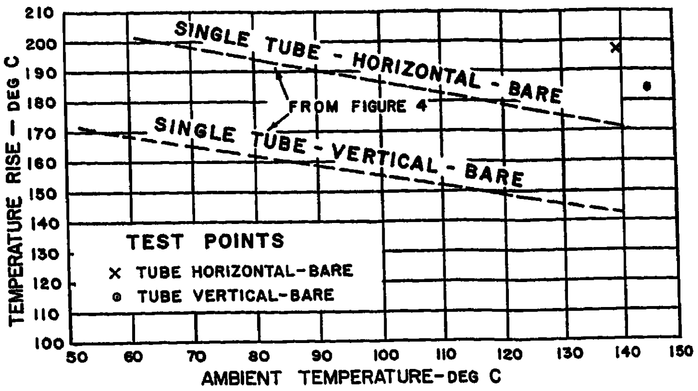

Fig. 6. Effect of the proximity of other heat sources at sea level, for varying ambient temperatures. Tube in center of cluster of seven tubes

along the length of the tube. The location was found to be at approximately the center of the anode, as shown in Fig. 10.

Heating curves were run to determine the time to reach substantial equilibrium. The results were:

Bare tube, no oven, 8 minutes
Shielded tube, no oven, 15 minutes
Oven tests, 2 hours

CORRECTION TO RATED POWER DISSIPATION

Throughout the experimental procedure the total input power was to be held at the rated value of 16.85 watts. However, small deviations occurred in most of the tests. A correction was applied so that all results would represent behavior at rated input.

Where the deviation from rated power was small, less than 4 per cent, the corrected temperature rise was taken as proportional to the power input, without introducing an appreciable error.

For the few cases of power deviation greater than 4 per cent, account had to be taken of the variation in heat-transfer coefficients with temperature. Since in all these cases the power input was low, the corrections were less than would be given by a linear power-ratio multiplication. Test points as plotted on all curves have been corrected to 16.85 watts input.

Analysis of Data and Results

The temperature data are plotted against altitude rather than air pressure in centimeters, although pressure is the parameter regulated in the laboratory. The altitudes were converted from data[1] of Navord Report *1488*, plotted on Fig. 11.

In all cases, an increase in altitude increases the temperature rise and actual temperature of the tube envelope. This is primarily due to the reduction in heat transfer by free convection as altitude is increased; see Fig. 10.

ROOM-AMBIENT SINGLE-TUBE DATA

The variation in temperature rise with shielding, altitude, and tube position is qualitatively in accord with theory. Heat transfer by free convection should vary directly as the square root of the air density and by radiation directly as the emissivity. Departures from this simple theory are accounted for by the introduction of an air resistance between bulb and shield, and by the high conductivity of the shield material, which distributes the concentrated input power at the glass envelope over a wider area of the shield. The slotted black shield causes temperature rises that are substantially lower than for any other shield because most of the envelope surface remains uncovered. The full shiny shield causes a greater temperature rise than the full black shield because radiation from the shiny shield is much less.

Inspection of Figs. 1 and 2 shows that addition of a shield to the bare tube has more effect on the temperature rise at low altitudes than at high altitudes.

Heat is transmitted from the tube to the shield in two parallel paths; by radiation and by conduction through a narrow air space. From the shield it flows to the surroundings by convection and radiation, again in parallel. At sea level heat flow by convection is much greater than it is at high altitudes. Therefore the total resistance to flow at high altitudes is higher than it is at sea level, with a consequent reduction in the percentage of the resistance of the total circuit due to the shield. Thus the percentage increase in temperature due to the shield becomes less as the altitude increases.

The data show that hot spot temperatures are higher if the tube is mounted horizontally rather than vertically and that the difference decreases as altitude

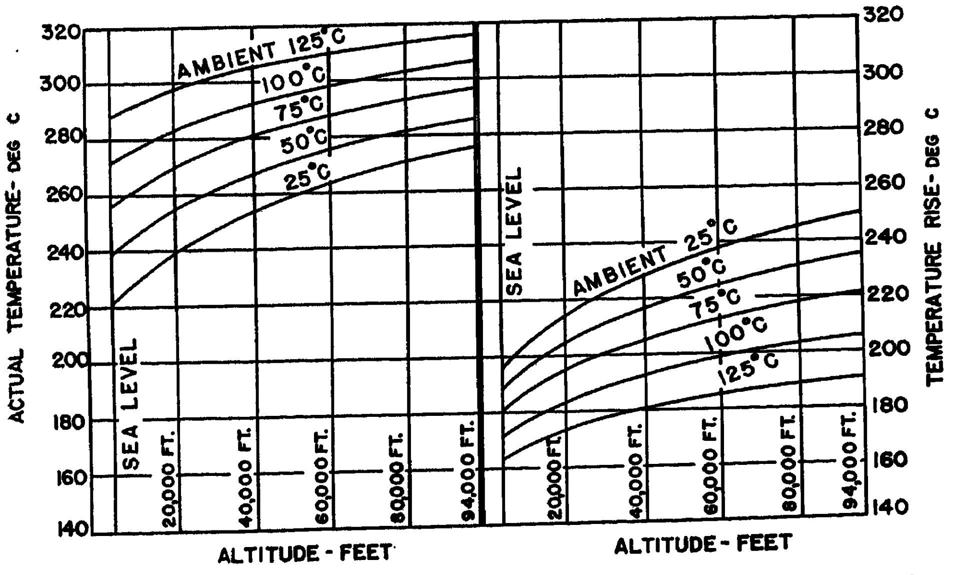

Fig. 5. Illustrative curves showing the effect of ambient temperature on both temperature rise and actual temperature, at altitude, tube vertical, slotted shield

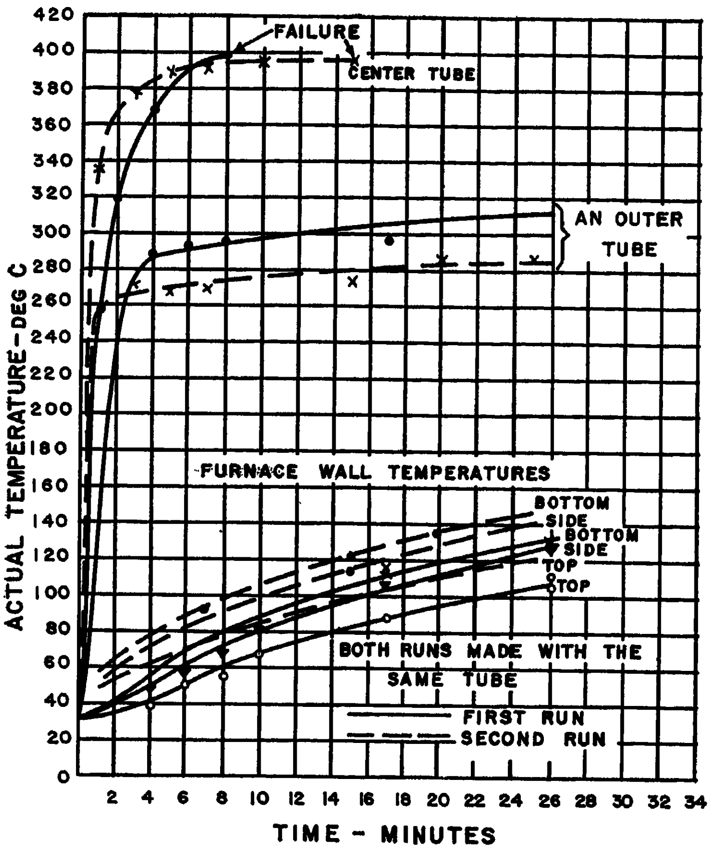

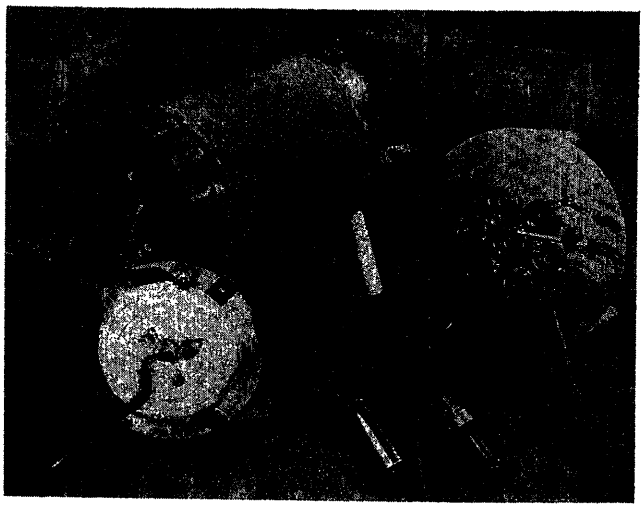

Fig. 7 (left). Test at altitude of tubes in cluster. Center tube operated to failure. Tubes vertical, bare. Air pressure 0.2 centimeter mercury. Altitude approximately 123,000 feet

Fig. 8 (above). Electrically heated oven used to simulate high ambient temperature thermocouples peened into inside walls. One at top, one at side wall, one at bottom

increases. For the case of uniform circumferential heat generation, a tube mounted vertically has a hot spot of constant temperature around the circumference of the tube. In the horizontal position a hot spot, shown by the data to be of higher temperature, exists at the top surface. Since the difference in hot spot temperatures is due to a difference in free convection, it decreases with increasing altitude.

HIGHER-AMBIENT SINGLE-TUBE DATA

The curves of Figs. 3 and 4 show the trend of decreasing temperature rise with increasing ambient temperature. This is expected theoretically since both radiation and free convection heat transfer increase with increasing ambient temperature.

Because two hours were required to reach equilibrium for each point, only two tests at higher ambients were run over the complete range of altitudes. Attempts at using shorter intervals resulted in curves whose slopes were the same as those of Fig. 3 but whose temperature rises did not follow the expected trend with increasing ambient temperature. The points of Fig. 4 were taken at 2-hour intervals, but at sea level and at one high vacuum point only. The data for any ambient temperature may be interpolated to include all altitudes by using the slopes of the curves on Fig. 3.

While temperature rise decreases with increasing ambient temperature, actual temperature increases. The difference between sea level and high altitude rises, Fig. 4, decreases as ambient temperature is raised. Moreover, the effects of tube position and of shielding tend to become less as the ambient increases. All these results are due to increasing heat transfer by radiation with increasing ambients, and to decreasing heat transfer by convection with increasing altitude.

All the test points made at room ambient, both for sea level and at 1.0 centimeter air pressure, from Fig. 1, are included in Fig. 4 as room temperature data. These points lie well below the straight lines of test results for higher ambient extrapolated down to room ambient.

This anomaly illustrates an extremely important concept, namely, the effect on the temperature of close proximity of the tube to the enclosure wall. All the room ambient runs were made in a large bell jar, while the higher ambient runs were made in the small oven photographed in Fig. 8 with the tube in the central position. At sea level, with the tube enclosed in the oven, and with no oven power, the tube heated the walls to 50 C. Therefore, no room ambient point could be taken with the tube enclosed in the oven. It it had been possible to cool the walls to room ambient, or 30 C, the temperature rise would have followed the straight line. This means that enclosing the tube causes an additional rise at sea level of 16 C for the bare tube above the original 160 C rise and 11 C for the slotted shield. If it had been possible to heat the bell jar walls to the desired ambients, the rise of the tube would parallel the present straight lines, would lie considerably below them, and would include the room ambient points. This rise would represent the effect of a single tube in a larger space at the specified ambient. In cases where a single tube is thus located, its temperature rise will be substantially less than the curves of Fig. 4, but in most cases the tube will be enclosed, and the curves as drawn are more realistic.

With the information from Figs. 3 and 4, two families of illustrative curves are plotted for the vertical tube with slotted shield (Fig. 5). The family on the left

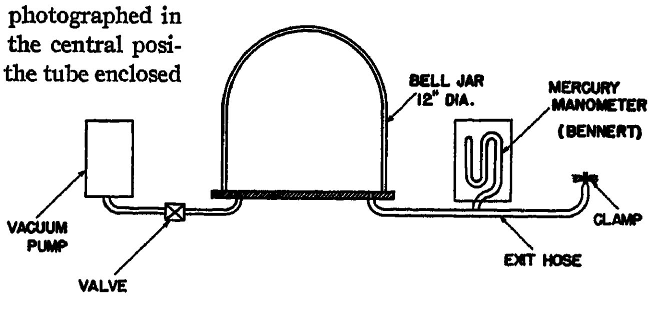

Fig. 9. Schematic diagram of the vacuum system used to simulate high altitude pressure

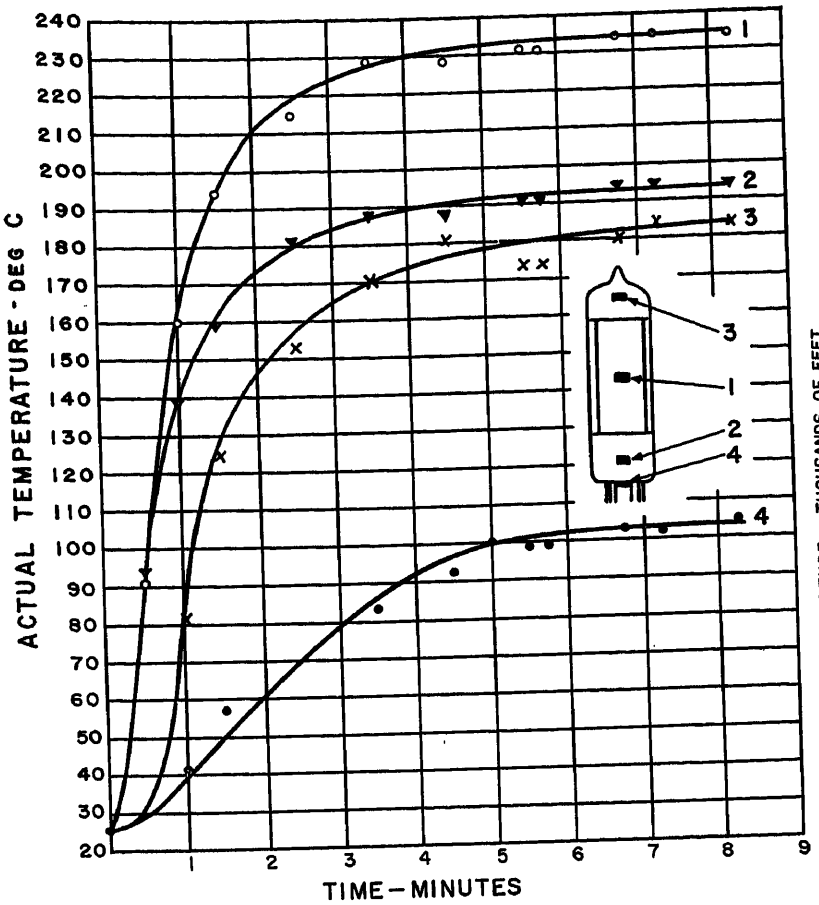

Fig. 10. Temperature data locating the tube envelope hot spot

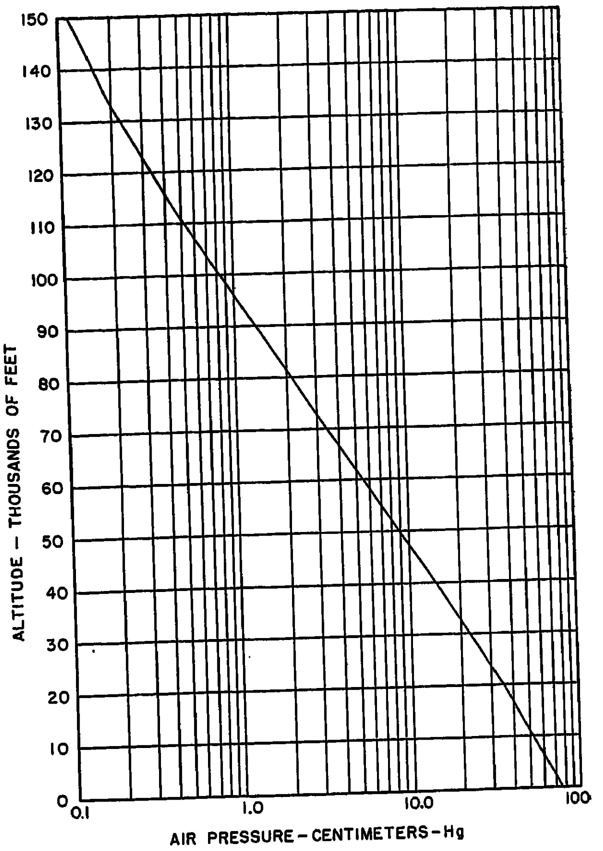

Fig. 11. Relation between altitude and pressure^2

show temperature rise, and it will be noted that the rise is highest for the lowest ambient. The family on the right show actual temperature, and here the total temperature is highest for the highest ambient. Both families show that the temperature rises as the altitude increases.

Tubes in Cluster

Operation of the tube under test in the center of a circle of six similar tubes shows a substantially greater temperature rise in cluster than in single-tube operation. This was to be expected since the presence of the surrounding tubes increases the temperature of the air and of the enclosing surface. At sea level the seven tubes heated the walls to about 140 C with no power on the furnace. Consequently only two points could be taken, one with the tube vertical and the other with it horizontal.

These two sea level points are sufficient to illustrate the proximity effect. Fig. 6 shows the test points, with bare single tube data, shown dashed, from Fig. 4 added for comparison.

At high altitude, steady state operation could not be reached. Expecting the tube to fail, thermocouple readings were taken from the start. Actual temperatures as functions of time are plotted in Fig. 7. From the observed difference between center tube and outer tube, it appears that proximity effects are even greater at altitude than at sea level.

It is interesting to note that both runs in Fig. 7 were made with the same tube. After the first run, when failure occurred, the apparatus was allowed to cool, and a second run was taken, as the tube appeared to recover. Again failure occurred. In both cases, the tube failed at approximately 400 C. It no longer functioned after the second run.

Included in Fig. 7 is a temperature curve for one of the tubes in the surrounding circle. Its rise is comparable with that of a single tube at a corresponding ambient. The thermocouple was fastened on the outer side, nearest the oven wall, and thus presumably did not measure the hottest spot. Apparently the hot spot will exist on the side adjacent to the center tube. Because of the poor conductivity of the glass, a fairly large circumferential gradient is likely to exist between the point of measurement and the actual hot spot.

The limited information on tubes in

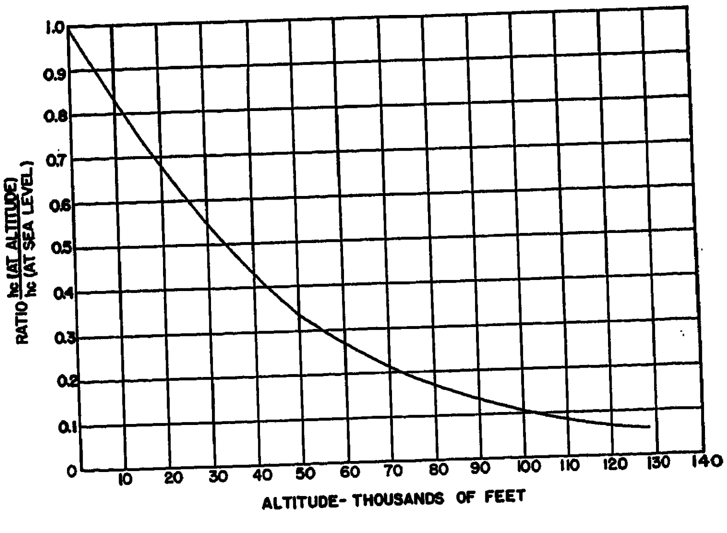

Fig. 12. Effect of altitude on free convection coefficient for constant temperature

clusters is valid for the particular tube spacing and enclosure of these tests. It clearly illustrates the increase in operating temperature which results from using an enclosed bank of tubes. However, to generalize from these data in the case of other configurations, with other heat sources such as transformers or resistors, might lead to serious error.

Appendix. Generalization of Data

To predict bulb hot spot for a tube during the process of design offers severe difficulties. There are two main paths for heat dissipation, one by conduction through the base, the other by free convection and radiation from the surface. The division between these paths depends on tube geometry and materials, which determine the thermal resistances. Evaluation of these resistances for use in a complete thermal circuit requires knowledge of thermal conductivity and dimensions of all heat conducting paths, as well as surface heat-transfer coefficients. The circuit will be complicated, but its solution may afford a reasonable estimate if the temperature distribution must be known before the tube is built.

Even the fairly complete information of the present tests offers difficulty when an analytical study of the bulb temperature is attempted. Using the rated input of 16.85 watts and glass bulb area of 4.75 square inches, the power density for the bare tube is 3.55 watts per square inch. Referring to the well-known heat-transfer relations,[2] the bulb temperature is calculated to be much higher than the test figure. Therefore, a substantial portion of the heat must be dissipated elsewhere. Assuming that both the measured temperature rise at sea level and the published heat-transfer coefficients are correct, the power density for heat flow from the surface is 2.45 watts per square inch. This means that approximately 30 per cent of the heat is dissipated by conduction.

This figure of 2.45 watts per square inch at sea level can now be used to calculate the temperature rise at altitude. The free-convection coefficient at sea level is 0.008 watt per square inch per degree centigrade, and the radiation coefficient is 0.0072. At 60,000 feet, h_c is reduced to 27 per cent of its value at sea level (from Fig. 11, which gives the effect of changing pressure without changing temperature) or 0.0022. A further correction for the effect of temperature, without changing power input, amounting to 0.95, is given in reference 2. The final coefficient is then 0.0021. Since the radiation coefficient is a function of temperature, several tries are necessary to determine the new temperature. As the first approximation, assume the rise is 225 C over a 25 C ambient. Then $h_r = 0.0098$. Hence

$$t_w - t_a = 2.45/(0.0021 + 0.0098) = 206 \text{ C}$$

For the second approximation, assume the rise is 210 C. Then, $h_r = 0.0092$, and $t_w - t_a = 217$ C. The actual value may then be taken as the average between 217 C and 206 C, or 212 C. Comparison with Fig. 1 shows that the test temperature rise at 60,000 feet is 222 C, exceeding the calculated temperature by 10 C.

A similar calculation at 120,000 feet gives 232 C instead of the test of 240 C. The same procedure can be carried out for higher ambient temperatures, where the principal influence is on the radiation coefficient. This procedure should then be reasonably satisfactory for determining the effect of altitude and ambient temperature on any other bare tube, when the temperature at sea level is known.

When it comes to predicting the effect of shielding on the glass envelope temperature, the method is more cumbersome. The previously outlined procedure will give the temperature of the shield provided the emissivity is known, but not the temperature of the glass bulb enclosed within it. The bulb is separated from the shield by a dead air space, so that heat is transmitted by conduction through the air as well as by radiation to the shield. To evaluate these resistances in the thermal circuit between bulb and shield requires air gap dimensions and air conductivity, as well as shield emissivity. For the shiny shield, the principal path of heat flow is by conduction through the air, resulting in a substantially lower bulb temperature than will be the case without this conduction. At high altitudes, fortunately, the conductivity of the air remains constant, being practically independent of pressure in this pressure range. Thus, while free convection outside the shield falls off rapidly with increasing altitude, conduction between bulb and shield does not; in fact, the conductivity of air increases with temperature. A rough calculation was made of bulb temperatures, with 1/16-inch air gap, thermal conductivity 0.0009 watts per inch per degree centigrade, for shield emissivities of 0.9, for the black shield, and 0.4 for the shiny shield. The result for the black shield at sea level was 272 C and for the shiny shield 358 C. Comparing these results with the tests of Fig. 1 shows that the method gives conservative results, as both calculations exceed the tests by some 30 C.

Discussion

E. R. G. Eckert (University of Minnesota, Institute of Technology, Minneapolis, Minn.): The author has covered the field which she set out to investigate very thoroughly and in the Appendix is given a theoretical treatment which the complex nature of the setup permits.

Conditions with higher ambient air temperature are investigated by placing an oven around the arrangement of electron tubes. The question arose in my mind in this connection whether the situation shown in Fig. 4 that an extrapolation of the higher temperature curves down to room temperature does not agree with direct measurements at room temperature is due only to the proximity effect which the author mentions or partially also due to the situation that the oven wall temperatures may be higher than the temperature of the air between the electron tubes and the oven walls.

In the Appendix, the author mentions that a heat transfer between the electron tube and its shield would occur by conduction through the air. I wonder whether the air space between tube and shield is closed off sufficiently to prevent a convection flow caused by the fact that the air in this space is probably warmer than the air outside the shield (chimney effect).

Mrs. B. O. Buckland: Prof. Eckert's remarks about the effect of enclosing the tube in a small oven are very much to the point. It is not possible that the oven wall temperatures were higher than the temperature of the air in the oven, as the oven was completely enclosed with heating elements on top and bottom as well as on the sides. During the test, a thermocouple was placed in the air between the tube and the wall, and in all cases it measured some temperature intermediate between tube and walls. Because its temperature was a function of its position in the boundary layer, its use as a reference temperature was discarded.

The air space between the envelope and shield of a *6AQ5* is approximately 1/16 inch. At the base there is no room for air flow, so for this particular case the chimney effect is absent. However, for larger tubes with wider spaces between shield and envelope, the chimney effect would undoubtedly be present.

The Effect of Minor Constituents in High Dielectric Constant Titanate Capacitors

W. W. COFFEEN
NONMEMBER AIEE

Synopsis: The potentials and limitations of high dielectric constant capacitors are briefly outlined. Additives used to modify the dielectric properties of $BaTiO_3$ are listed and classified into two groups: 1. the "shifters," whose additions primarily cause a shift in the temperature of the Curie peak, and 2. the "depressors," whose additions result primarily in a depression of the Curie peak. The effect of $BaSnO_3$ and $PbSnO_3$ additions are used to illustrate the behavior of the shifter group, and the variations in the performance of the other members of this group are discussed. Similarly, the effect of additions of $MgSnO_3$, $Bi_2(SnO_3)_3$, $MgTiO_3$, and $CaTiO_3$ are shown as typical of the behavior of members of the second group. Generalizations are offered regarding the effect of composition on nonlinearity and aging, and these are illustrated.

BARIUM titanate ceramic capacitors were revealed in the postwar period as the newest gem of the capacitor industry. As in most gems, however, when the eyes were no longer dazzled by the glitter, in this case, of its unusually high dielectric constant, some flaws began to appear. During the years since the war, ceramic capacitor manufacturers have been busily engaged in learning to improve and augment the sterling qualities of barium titanate by the use of additives while their partners in circuitry, the electrical engineers, have sought to find new and different applications to take advantage of the unique properties of these high dielectric constant ceramic materials.

The data of this paper are presented in an effort to acquaint the electrical engineer with the tools of the trade of the ceramic engineer in formulating barium titanate capacitors. It is hoped that a clearer understanding of both the potentials and limitations of barium titanate capacitors will result, giving rise to a more rapid and more satisfactory utilization of these materials in electric circuits.

Present Limitations of Titanate High Dielectric Constant Capacitors

The range of application of high dielectric constant capacitors in the electronic industry is indicated in Fig. 1, representing data taken from P. S. Schmidt.[1] High dielectric constant capacitors are restricted commercially to a rather narrow but very important range of capacitance from about 100 to 20,000 micromicrofarads. Crystalline ceramic dielectrics as a whole are limited in their use in capacitors by two important physical considerations. First, no satisfactory commercial process has yet been devised for inexpensive production of multiple-layer capacitors. Second, for cheapest production processes, thicknesses are limited to about 20 mils. Thicknesses down to about 5 mils may be produced by somewhat more costly methods[2,3] but weaknesses due to the increased voltage gradients tend to restrict the use of the high dielectric constant bodies in the thinner films.

The ranges of dielectric constant required for various sizes of capacitors using plates 0.005 inch and 0.020 inch thick with commercially acceptable areas are shown in Fig. 2. As Fig. 2 implies, bodies may be compounded having dielectric constants as high as 10,000. However, the higher the dielectric constant, the more restricted is the operating range. For example, *K*-10,000 bodies will have minimum dielectric constants of 10,000 over a temperature range of about 10 to 15 degrees centigrade; *K*-6,000 bodies may have dielectric constants of 6,000 or above over a range of about 30 to 40 degrees centigrade; *K*-3,000 bodies may retain this value as a minimum over a range of 60 to 70 degrees centigrade, while *K*-1,000 bodies may be obtained which will be operable over a range of 140 degrees centigrade from −55 to 85 degrees centigrade. When additional requirements on the variation of the dielectric constant above the minimum value must be met, the operating ranges may be reduced still further. The result is that for capacitors of 20-mil thickness, 20,000 micromicrofarads is about the upper limit of capacitance which can be obtained for capacitors capable of any general application. Thinner capacitors might be used, of course, to obtain capacitance values well above 20,000 micromicrofarads but, unfortunately, as will be noted later, the bodies with higher dielectric constants are much more sensitive to variation from bias voltages, and this effect is magnified to such an extent by the increased voltage gradient in the thin films that only very special use can be made of the bodies of highest dielectric constant in the thin films.

From this discussion, it is obvious that two general methods of approach to the improvement of high dielectric constant capacitor bodies are open: 1. to develop bodies of at least an intermediate level of dielectric constant, but with improved performance under the higher voltage gradients, or 2. to develop bodies of higher dielectric constant which exhibit less variation in dielectric constant with temperature. Both approaches are being utilized commercially today.

W. W. Coffeen is with the Metal and Thermit Corporation, Rahway, N. J.

The author wishes to express his appreciation to G. L. Dillman, W. J. Suto, and Fred Does, Jr., who prepared and measured the stannate-titanate specimens; to Dr. L. R. Bickford, Alfred University, Dr. R. R. Shively, Jr., Zenith Radio Corporation, and J. L. Jenkins, Radiation, Inc., for permission to utilize data from personal communications; and to J. W. Deaderick, American Lava Corporation, for his critical review.

Table I. Classification of Additives

Shifters	Depressors
$BaSnO_3$	$MgSnO_3$
$SrSnO_3$	$NiSnO_3$
$CaSnO_3$	$Bi_2(SnO_3)_3$
$PbSnO_3$	$MgZrO_3$*
$CuSnO_3$	Fluorides of Ba, Ca, Sr, Mg, etc.
$ZnSnO_3$	$CaTiO_3$
$CdSnO_3$	$MgTiO_3$
$BaZrO_3$	
$CaZrO_3$	
$SrZrO_3$	
$SrTiO_3$	
$PbTiO_3$	

* $MgZrO_3$ is generally recognized to be a solid solution of MgO and ZrO_2 in a 1-to-1 mole ratio, rather than a compound.

Before discussing the use of additives to $BaTiO_3$, it is well to review the characteristics of $BaTiO_3$ itself. Fig. 3 shows the variation of dielectric constant and dissipation factor as a function of temperature according to von Hippel.[4] Examination of these data shows that $BaTiO_3$ has a dielectric constant of about 1,400 and dissipation factor of about 0.0150 at room temperature. These characteristics are reasonably constant in the range of 25 to 85 degrees centigrade and $BaTiO_3$ would be satisfactory in this respect for some applications. However, for use at temperatures above 85 or below 25 degrees centigrade, the variations in dielectric constant become very large; at the lower temperatures, high dissipation factors are encountered. However, the short service life of capacitor bodies containing only $BaTiO_3$ is perhaps their most serious disadvantage. While dielectric strengths of 100 volts per mil or more have been reported for $BaTiO_3$ disks at room temperature, failure frequently occurs in a few hours at a temperature of 85 degrees centigrade with voltage gradients as low as 50 volts per mil.

Insulation resistance, initially of the order of 10^{13} megohms, decreases very rapidly under such life test conditions. Fortunately, service life is improved substantially by almost any of the additives used to produce changes in dielectric constant and dissipation factor, so that the latter criteria become dominant in the initial stage of development of an improved body. One other characteristic of $BaTiO_3$, which is also common to many of the high dielectric constant titanate bodies, is the variation in their properties as a function of voltage gradient. In general, the dielectric constant is increased slightly as the initial voltage is applied, and then decreased rapidly as the voltage gradient is increased. The initial increase is normally more pronounced with alternating than with direct

Role of Additives in Controlling Dielectric Properties

Among the first studies of the effect of additives to barium titanate were those of Wainer and his associates, which resulted in a number of patents[5-7] disclosing the use of the titanates, stannates and zirconates of the alkaline-earths. Some of these additives have been discussed very briefly by Graf.[8] The stannates have been studied in more detail by the author.[9,10] The advantages obtained by the use of lead stannate have been disclosed in a recent patent.[11] The use of fluorides has been the subject of two British patents.[12,13] Simple oxides such as MgO, BaO, TiO_2, MnO_2, Fe_2O_3, ZrO_2, SnO_2, and others have been used in very small quantities, primarily to produce minor changes or to improve firing behavior.

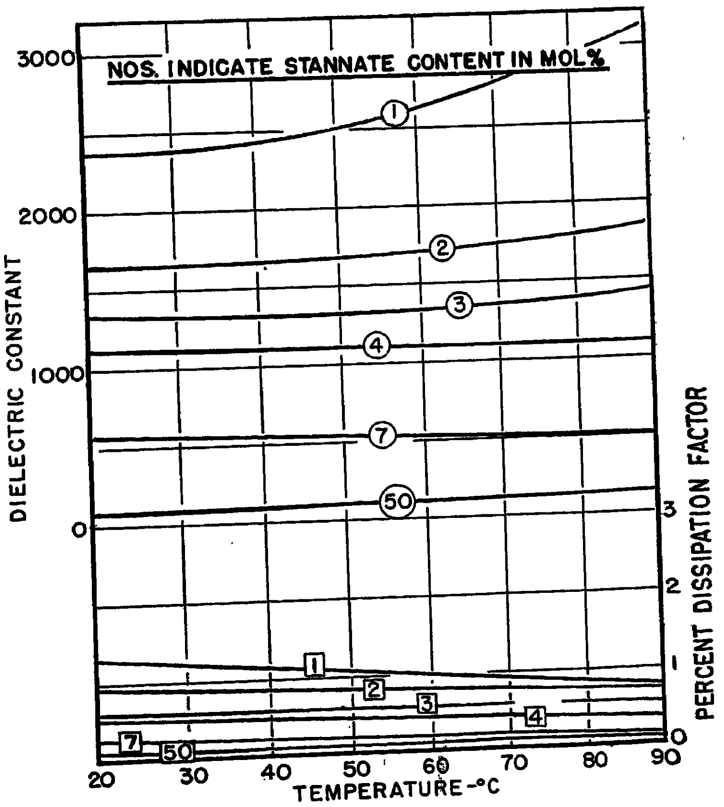

Fig. 7. $Bi_2(SnO_3)_3$-$BaTiO_3$ system, dielectric data at 1 kc, 0.1 volt per mil

The additives can be classified into two general types. One type which we can call the shifters has the effect of shifting the temperature of the Curie peak of barium titanate, normally downward. The second type can be called depressors and, in general, this type tends to depress the Curie peak, although small additions of some of the members of this class increase the dielectric constant at temperatures below the original Curie temperature, while depressing the value of ϵ' at temperatures in the vicinity of 120 degrees centigrade. There are variations within each group, as we shall see, but they are divided roughly as shown in Table I.

The behavior of a shifter type of additive is illustrated by the behavior of $BaSnO_3$, shown in Fig. 4. These curves are based on unpublished data presented by Bickford and Kane at the 15th Symposium on Ceramic Dielectrics held in April 1952 at Rutgers University. Reference to the figure shows the continuous drop in Curie temperature as the amount of $BaSnO_3$ in the body is increased. The downward shift is accompanied by a broadening of the peak and a change in the peak dielectric constant, this value increasing with small additions of $BaSnO_3$, then decreasing again.

The other shifters, with the exception of $PbTiO_3$, behave in a similar manner, but differ in degree. $SrTiO_3$ shifts the peak most slowly per mole added and has the sharpest peaks. Stannates in general shift the peak most rapidly per mole added. Zirconates are intermediate in rate of shift. Peak values of dielectric constant are highest for barium, calcium, and strontium stannate additions, and these additives are virtually interchangeable on a molar basis.[10] $PbSnO_3$ bodies exhibit the flattest curves of any of the shifters. Fig. 5 shows the results of composition changes in the system: $BaTiO_3$–$PbSnO_3$. $PbTiO_3$ is unique in that addition of this material produces an increase in the Curie temperature with accompanying decrease in dielectric constant values in the lower temperatures. Bodies containing $CuSnO_3$ are characterized by comparatively high dissipation factors and $CdSnO_3$ bodies are difficult to fire, so neither of these has any commercial interest.

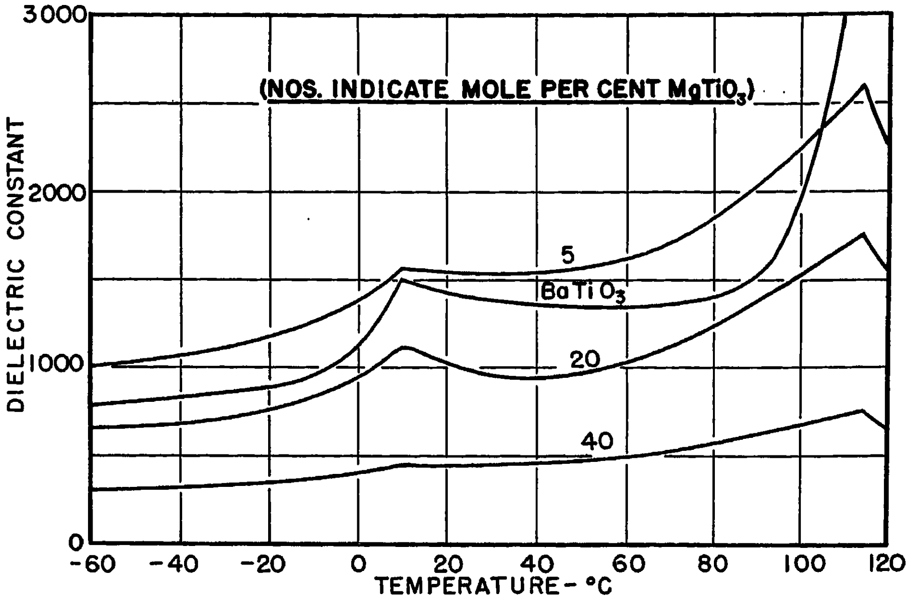

Fig. 8. Dielectric constant versus temperature for bodies of $BaTiO_3$+$MgTiO_3$. All data at 1 kc

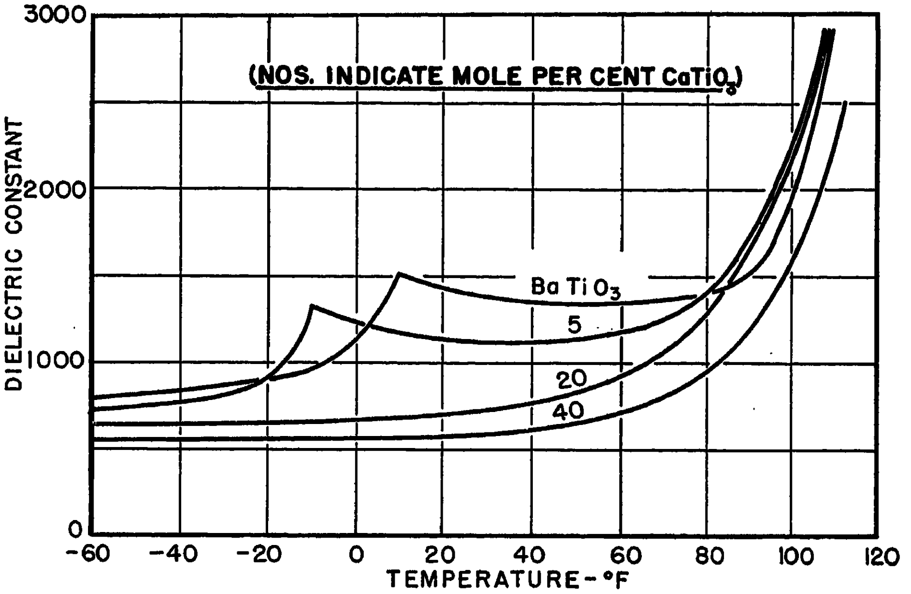

Fig. 9. Dielectric constant versus temperature for bodies of $BaTiO_3$+$CaTiO_3$. All data at 1 kc

The behavior of the depressor type of additive is illustrated in Fig. 6, showing the changes made by varying composition in the $BaTiO_3$–$MgSnO_3$ system. The levels of dielectric constant are considerably lower (<2,500) here than those obtained by the use of shifters (up to 10,000), but much improved stability is evident. Also, dissipation factors are lower in general than those associated with the higher dielectric constant bodies. $NiSnO_3$ and $MgZrO_3$ act similarly to $MgSnO_3$. $NiSnO_3$ has the advantage over the magnesium compounds in that it is not susceptible to the grain-growth difficulties in firing which are often encountered with the use of the latter.

$Bi_2(SnO_3)_3$ is unique in its behavior in this class and the result of additions of this material to $BaTiO_3$ are shown in Fig. 7. Very flat curves, exhibiting less than 1 per cent change in dielectric constant over the operating range of 20 to 85 degrees centigrade, can be obtained with bodies of this type.

$MgTiO_3$ and $CaTiO_3$ additions behave somewhat differently from other members of this class and their characteristics are indicated in Figs. 8 and 9. $MgTiO_3$ additions tend to depress the curve characteristics of $BaTiO_3$ but with no change in peak position. $CaTiO_3$ additions depress the curve in a similar manner with no change in the position of the Curie peak but produce a downward shift in the temperature of the lower transition point.

Obviously, the use of the shifters and depressors in combination to produce bodies of intermediate dielectric constant

and intermediate temperature stability is suggested. Fig. 10 gives data on three bodies involving both types of additives as examples of what can be accomplished by this technique.

It was mentioned previously that while the relations of dielectric constant and dissipation factor to temperature are prime criteria in high dielectric constant capacitor body development, other factors must also be considered. In many applications the nonlinearity of the dielectric is important. Although few data are available at present, there appears to be a rough correlation between level of dielectric constant and degree of nonlinearity as shown in Fig. 11. In the group of bodies shown, the $PbSnO_3$ body has the highest dielectric constant, the $MgSnO_3$ body next, followed in turn by the $Bi_2(SnO_3)_3$ body, the alkaline-earth stannate body, and finally $Bi_2(SnO_3)_3$ and $CaSnO_3$ themselves.

Aging rates likewise seem to increase in general with an increase in level of dielectric constant as shown in Fig. 12.

Although the potential properties of a high dielectric constant capacitor are determined by a proper choice of additives, it should be recognized that these properties are often not realized in production without the aid of very careful adjustment and control of processing. The various steps in manufacture such as mixing, forming, firing, silvering, attachment of leads, and final coating all require study to insure that the finished capacitor will have the properties indicated by laboratory tests. Performance of dielectric bodies in production trials is often equal in importance to the dielectric properties themselves in dictating a satisfactory choice of additives.

Conclusions

1. The minor constituents of high dielectric constant titanate capacitor bodies play a major role in determining the dielectric properties of the bodies.

2. All of the dielectric properties are susceptible to alteration, but not independently.

3. Additives to $BaTiO_3$ bodies may be divided into shifters, which produce primarily bodies having very large dielectric constants, and depressors, which produce primarily bodies with lower dielectric constants.

4. In general, bodies possessing higher dielectric constants are likely to have higher dissipation factors, and to show greater variation with temperature change, greater nonlinearity and higher aging rate, than will bodies of lower dielectric constant.

5. Combinations of shifter- and depressor-type additives may be used to formulate bodies having optimum properties.

Some Aspects of Joint Use of Wood Pole Lines with Increasing Line Voltage

W. E. BLOECKER
MEMBER AIEE

W. R. BULLARD
FELLOW AIEE

THE joint use of wood poles by supply and communication companies has been an established way of doing business for well over 50 years. Because of changing technologies in both the power and telephone fields the successful co-ordination of facilities on the same pole line requires continuous review. It is the purpose of this paper to discuss the problems which were introduced by the trends to higher supply voltages.

Before going into that part of the subject, it will be well to review some of the background. The joint use of wood poles or, as it is more commonly referred to, joint use, is the use of the same pole line to support the wires or cables of both the power companies and the communication companies. A special term, joint crossing pole, is applied to the case where the wires of the two utilities are attached to the same pole at a point where their routes intersect. As the discussion progresses, it will be recognized that many of the considerations of joint use apply equally well to what are called conflicting rights of way which are situations where the physical arrangements of power and communication wires are such as to make contacts possible in the event of line troubles or during construction activities.

It is clear that the joint occupancy of poles, or situations involving numerous crossings of power and communication circuits, require added engineering consideration to assure the safety of the public, of utility workmen and of property, comparable to that afforded by separate nonconflicting plants. What then are the reasons for entering into joint use construction?

There are several important advantages which a single-pole line offers over separate lines under many circumstances for example:

1. In situations where, because of topography or other limitations, suitable separate nonconflicting rights of way either are not obtainable, or are difficult or expensive to obtain.

2. Accurate control of separations and other construction features affecting safety at crossings and other locations where proximity is unavoidable.

3. Elimination of objections to double lines by municipalities or other civic groups which ultimately might take the form of ordinances or other restrictive regulations.

4. Possibilities of economies in construction.

5. Conservation of pole timber now in short supply.

For reasons such as these, the joint use of pole lines to carry supply and communication circuits, started before 1900, has developed to the point where there are in the United States some 11,000,000 poles doing this double duty, not counting the cross poles. Of these jointly used poles, there are about 8,500,000 in urban areas, and about 2,500,000 in rural areas. Since 1945 the total number of jointly used poles has been increasing at the rate of about 500,000 each year.

In the beginning, practically all of the situations for which joint use appeared justified involved power voltages of less than 5 kv, and the protection arrangements of the telephone plant were designed accordingly. As a result, 5 kv came to be considered the maximum sup-

Paper 53-317, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B. C., Canada, September 1–4, 1953. Manuscript submitted February 4, 1953; made available for printing July 1, 1953.

W. E. Bloecker is with the American Telephone and Telegraph Company, New York, N. Y.; W. R. Bullard is with Ebasco Services, Inc., New York, N. Y.

ply voltage with which joint construction could safely be established. The greater part of urban joint construction today involves voltages less than 5 kv. However, with increasing loads, the power companies found it necessary to employ higher voltages. The continuation and extension of joint construction with these higher voltages involved a reappraisal of the reaction on noise induction and protection. That these considerations have been effectively worked out may be seen from the fact that most of the rural joint use today involves distribution voltages of 12 kv, and extending as high as 25 kv, while urban joint use with 13.2 kv is fairly common in some areas. There are a growing number of situations of joint use with 33 kv, some scattered cases of joint use with 44 kv (5 miles in one case), with 69 kv (2 miles in one case), and there is one situation where arrangements were worked out for something over 400 feet of telephone cable to be joint with 110 kv.

This is not to say that all caution has been cast aside but rather that, where proper co-ordinated protection has been applied, both to the power and to the communication systems, joint use may well represent the best engineering solution without reference to any arbitrary voltage limitation.

Noise Considerations

As far as inductive co-ordination is concerned, it might appear that the higher couplings resulting from the relatively close spacing of power and communication conductors add to the difficulties. However, the fixed relationship between the two types of plant results in a more uniform exposure which facilitates control of the coupling. In general, noise problems are no more difficult to solve than where the power and communication lines are at roadway separation.

In considering the effect of increasing voltage on power system influence, that is, its potentiality for impairing transmission on neighboring communication facilities, it may be said that under some conditions it will increase, and under others it will decrease.

The circumstances under which power circuit influence is likely to go up when voltages increase are:

1. When there are relatively large harmonics of the higher orders impressed on the distribution system usually at the source of power supply.
2. Where the loads are relatively light, at least during certain periods of the day.

The circumstances under which noise influence is likely to go down are:

1. Where the wave shape of the power supply system is fairly good and the harmonic currents are of the lower orders: 3, 5, 7, and 9.
2. Where the transformer kilovolt-amperes per mile of line is fairly high, the reason being that transformer magnetizing currents are likely to control current wave shape on lower voltage lines, and these currents decrease as the voltage increases.

In any event, the correction of an inductive situation involving a high-voltage distribution circuit is generally less difficult than one involving a low-voltage circuit for two reasons:

1. Harmonic currents tend to be smaller on the higher impedance circuits.
2. Where harmonic currents are large enough to cause trouble, it is much easier to reduce their effect because shunt devices for high impedance circuits are easier to design and cheaper to build than similar devices for low-impedance circuits.

Protection Considerations

The approach to successful, safe operation of power and telephone circuits on the same poles or involving numerous crossings rests on the following basic considerations:

1. Adequate structural arrangements to minimize the possibility of contacts occurring, and to provide safe working conditions.
2. Co-ordinated electrical protection arrangements for power and telephone facilities to minimize hazards to persons, and to limit plant damage in the event of accidental contact.

The broad basis for structural arrangements rests on the generally accepted standards of good engineering as set forth in the National Electrical Safety Code published by the National Bureau of Standards and approved by the American Standards Association. It is the result of contributions by engineers of the wire-using companies, and reflects their experience and best judgment at any given state of electrical development. This code, however, is no immutable law. In fact, it is now in its fifth edition, as industry has learned from experience what changes are desirable or necessary, and has recognized the latest technical developments. Organizational work is now under way looking to a new edition, which will include consideration of those aspects relating to voltage classifications and clearances, strengths of structures, and items which have called for extensive interpretation since the fifth edition was published.

The code allows considerable latitude in interpretation, and to arrive at sound construction practices the Joint Committee on Plant Co-ordination, sponsored by the Edison Electric Institute and the Bell Telephone System, has issued specification *M-12*[8] which, in general, outlines methods for attaching the two plants to the poles, and gives the requirements for pole strengths, guying, wire sags and tensions, and clearances, both above the ground and between the two plants. Specifications which provide for adequate working and climbing space for the workmen of both utilities are also included. As an example of keeping up with a changing art, proposals for further savings in pole timber by judicious reduction of clearance requirements have been made, and it is the thought that, as experience is gained with these proposals, they could ultimately be incorporated into *M-12* with such changes as seem desirable. Because of its nature, *M-12* has been incorporated in many joint use contracts, frequently by reference, in order to permit changes resulting from technical developments to be incorporated in *M-12* and consequently in the construction practices, without reopening the contract itself.

Adequate electrical protection involves, basically:

1. Prompt and positive de-energization of the power conductors in the event of contact with communication plant.
2. Establishment and maintenance of good low-resistance grounds on the communication plant.

Prompt de-energization is important to limit the duration of hazardous voltages on the communication plant so as to minimize the possibility of personal injury, and to limit the extent of plant damage. The low-resistance ground is important to assist in obtaining prompt de-energization, and also to minimize the magnitude of voltage rise on the communication plant before de-energization. Thus, it will be seen that the electrical protection involves the practices of both the power and communication systems, and the co-operative engineering and application of proper protection devices to the two systems is what is meant by the term co-ordinated protection.

Co-ordinated Electrical Protection

Co-ordinated electrical protection involves consideration of a number of factors, some of which relate to the power system, and others to the communication plant, so that each particular situation needs to be reviewed as an individual case reflecting the particular conditions. These factors are discussed in the following.

VOLTAGE OF POWER SYSTEM

From the standpoint of prompt and positive de-energization it can be stated as a general principle that the higher the supply voltage, the better the situation. A couple of homely arithmetical examples will illustrate this point:

1. Assume a 4-kv circuit (2.4 kv to neutral) with 250-kva load per phase. The power load current would be slightly over 100 amperes, which would probably mean that fuses or circuit breakers set to operate at about 200 amperes would be provided. In the event of accidental contact with telephone plant such that the total impedance of the fault circuit is around 10 ohms, the fault current would be about 240 amperes, giving a small margin of current to operate fuses or circuit breakers.
2. With an increase to 12.5 kv (7.2 kv to neutral) with a load of 750 kva per phase, the full-load current again would be of the order of 100 amperes. However, an accidental contact would result in a fault current of 550 amperes (making allowance for the somewhat higher reactance of the supply transformer) thereby providing a substantial margin to insure prompt de-energization.

TYPE OF POWER SYSTEM

The type of power system distribution has an important bearing on the assurance that de-energization will be prompt and positive under fault conditions. The multigrounded neutral system is the most favorable from this standpoint, since the frequent grounding of the neutral conductor, together with the neutral conductor itself, affords a low impedance path for fault currents in the event of faults to neutral, or to other metallic structures or circuits associated with the neutral. The multigrounded neutral also provides by suitable bonding, a ready means of obtaining a good ground for telephone cables and protectors.

In case of a unigrounded system, whether the neutral conductor is carried along with the phase wires or not, a fault to ground completes a circuit back to the substation through the earth. The impedance of this fault current path may be relatively high, depending to a great extent on the ground contact resistance.

In the case of isolated delta systems in the event of a fault to ground of a single-phase conductor, the capacitance to ground of the unfaulted phase conductors provide the only path for fault currents. Therefore, in a single-phase fault to ground, the fault current is the leakage and charging current of the unfaulted conductors. Generally, the smaller the system and the lower the voltage, the smaller will be the resulting fault current. The questions to be answered in this case are whether or not such fault current is sufficient to operate the power system protection equipment, and if not, whether the voltage on the communication plant is held low enough through low impedance grounds to be safe.

The occurrence of a single fault on an isolated delta system increases the voltage to ground of the nonfaulted phase wires, and the breakdown of another conductor often follows. In the event of a double fault, the situation is similar to that of the unigrounded system. In some delta systems grounding banks are used at the supply substation. From the standpoint of co-ordinated protection, this arrangement modifies the isolated delta system to a form more or less like that of the unigrounded system, depending upon the characteristics of the grounding means.

TYPE OF TELEPHONE PLANT

Two types of telephone plant, namely, cable and open-wire, may be involved in joint use with power systems.

In the case of cable, the impedance of any fault to ground is kept low by frequent bonding of the sheath to the neutral conductor of a multigrounded neutral system where such a system is present. In other cases, a ground may be obtained by the connection of the cable sheath to the sheath of buried or underground cables. Bonding to other extensive underground structures, such as water pipe systems, is also often effective in lowering the impedance to ground. With either of these methods of grounding to extensive underground systems, the cable sheath corrosion aspects need to be given careful consideration.

For open-wire situations where voltages above 3 kv to ground are encountered, carbon gap devices designed to break down at about 3 kv are connected between each wire and ground at approximately 1/2-mile intervals. A feature of the design of these devices is their ability to handle large amounts of current. For example, in the case where the power system reclosers operate three times before de-energizing permanently, the device is able to carry three successive shots of 600 amperes of 1-second duration each, and up to 1,300 amperes for durations of 2/10 second. To be effective, the resistance of the ground connections must be low and here again the multigrounded neutral, where available, is most useful.

CHARACTERISTICS OF POWER PROTECTIVE SYSTEMS

Power protective devices may have several forms and may, particularly in the case of transmission circuits, involve rather complex arrangements. For distribution circuits, however, they usually consist of fuses or circuit breakers, the operation of which depends on current in individual power conductors. For practically all distribution circuits, the speed of operation depends on the ratio of the fault current to the expected full-load current; the higher this ratio, the faster the operation. Considering the requirements for co-ordinated protection, it will be clear that the objective is to have the fault current sufficiently high with respect to full-load current so that prompt de-energization is practicable, and to have the de-energization equipment such as to take advantage of this condition.

LENGTH AND LOCATION OF EXPOSURE

The length and location of the exposure with reference to the substation has an important bearing on the performance of co-ordinated protection. The most critical point at which a fault may occur is that where the fault current is at a minimum compared to the rating of the fuse or setting of the circuit-breaker relay which protects that part of the power circuit, and consequently where the de-energization will be the slowest expected.

There will be other possible points of contact where the fault currents may be substantially higher, but in these cases the speed of operation of fuses or circuit breakers will be higher, and the total energy dissipated at the fault may be no greater than it would be with the lower fault current at the critical point.

Generally, detailed consideration of the factors affecting co-ordinated protection is given only in the case of new and unusual situations. Usually this only involves assuring that the power circuit will de-energize promptly with a fault at the most critical location. Where the telephone plant is well grounded, it is not necessary to take its impedance into account in these calculations. But once the facts have been developed by a particular power company and telephone company, agreement can be reached on an area basis, and further studies of specific cases falling within the area of agreement are not required.

Field Experience

A measure of the satisfactoriness of joint-use arrangements in any voltage range is the experience of the utilities from the standpoint of electrical accidents to personnel, and plant damage. An analysis of electrical accidents indicates that there is no significant difference between what has in the past been called normal joint use and so-called higher voltage joint use. It is interesting that most of the accidents occur in connection with construction activities and are of such nature that their occurrence cannot be related to voltage. The type of accidents which do occur unfortunately result too frequently from lack of attention to ordinary safety precautions and to failure to observe carefully thought out working practices.

Insofar as telephone plant damage is concerned, experience indicates that there is little relationship between the extent of the damage and the voltage on the joint-use lines. This is a result, to a large extent, from the more favorable de-energization characteristics of the higher voltage systems.

Type-ON Carrier Telephone

R. D. FRACASSI
NONMEMBER AIEE

H. KAHL
NONMEMBER AIEE

IN THE normal process of laying out toll circuits, it is found that many of the circuits will be made up of a combination of open wire and cable facilities. The new short-haul carrier systems will be found on many of the facilities, type-*O* on open wire[1] and type-*N* on cable.[2] Consequently, in built-up circuits, it will frequently be necessary to interconnect *O* and *N* carrier facilities at the open wire cable junction. The junctions of open wire and cable will occur most frequently at population centers which serve as terminals for the two facilities. However, there will be numerous cases where the junction will occur at the frontier of the cable expansion program, and may represent a complete change of facility from open wire to cable in the center of a route.

At a junction it is, of course, always possible to connect any two systems together on a channel basis by connecting terminals back-to-back at voice frequency. Thus, one 12-channel *N* system terminal can be used to extend the channels of three 4-channel *O* system terminals. This arrangement involves complete circuits in each of the terminals and is obviously an extravagant use of equipment. Some equipment saving can be made by the omission of the compandor and signaling circuits. These circuits are standard equipment with both type-*O* and type-*N* terminals, and when omitted they must be replaced by supplementary units which are called through-channel circuits and which are now in production. However, the interconnection of channels on any voice frequency basis is not attractive economically.

The greatest saving in equipment is effected when the transition from type-*O* facility to type-*N* facility is made at carrier frequencies. Such a transition is necessarily restricted in form and does not mean the conversion of the single sideband type-*O* signals to the double sideband type-*N* signals. The practical approach involves the conversion of the type-*O* signals, in groups of four channels, to frequency allocations capable of being transmitted over the *N* line.

It is feasible to transmit *O*-type signals over *N* repeatered cable pairs if essentially the same range of carrier frequencies is used. That is, if the *O* frequencies are translated into the *N* frequency range they can be transmitted over *N* facilities in place of the regular *N* transmission. This transmission of *O*-type signals over cable circuits equipped with *N* repeaters has been designated the *ON* system, that is *O* transmission over *N* facilities. To accomplish this transmission requires that the *O* transmission from the open wire line be transferred to the *N* carrier frequency range, and also that it must be co-ordinated in level and direction of transmission with the regular *N* systems which may also exist in the same cable. The transmission of type-*O* signals over a type-*N* line also forms the basis for a 20-channel all-cable system.

The *ON* system, like the *O* and *N* systems, is intended for short-haul use. A circuit in an *ON* system should provide satisfactory service for distances up to at least 200 miles, including the open wire portion of the circuit when type *O* is involved.

Two important considerations in the development of this equipment were:

1. To provide maximum flexibility in the translation of any *O* line frequency to any position in the *ON* band without the need of special equipment.
2. To make use of as much of the presently developed *O* and *N* equipment as possible, not only to keep the development of new equipment to a minimum, but also to make the *ON* system available at the earliest possible date.

Frequency Allocation

Fig. 1 shows the frequency allocation of the *ON* system. Also shown for comparison are the standard *N* line frequencies. It is seen that the low-frequency *N* group extends from 44 to 140 kc; in comparison, the *ON* low-groups range is from 40 to 136 kc and comprises the five standard *O* system line frequencies, namely the *OB* system low and high groups, the *OC* system low and high groups, and the *OD* system low group. The reason for using this frequency allocation is that these groupings correspond to the passbands of the type *O* components used in the type *ON* equipment. Although the *ON* low-groups range extends down to 40 kc, which is 4 kc below the standard low-group *N* range, those additional frequencies are satisfactorily transmitted by standard *N* repeaters.

Although the standard *O* equipment provides the allocation only in the low-group band of the type-*N* carrier line, this group by means of an *ON* repeater may be translated to a frequency range corresponding to the high *N* carrier line frequencies. Fig. 1 also shows the frequency allocations of the high *N* and the high *ON* frequency groupings. Since the *ON* frequency range fell 4 kc below the *N* in the low-group range, it follows that it will extend 4 kc above in the high-group, but these additional frequencies can also be transmitted by *N* repeaters.

It is observed that the *ON* groups, consisting of five standard type-*O* line groups, add up to a total of 20 channels. One particular difference exists between the grouping used for *ON* and the *O* line frequencies in that the individual 4-channel groups are arranged side by side for one direction of transmission in the *ON* arrangement, in contrast to the *O* line arrangement in which the 4-channel groups are oppositely directed. Furthermore in the 96-kc range of an *ON* group there are four 4-kc gaps which provide separation between adjacent *O* groups. This permits these groups to be separated by means of standard *O* filters.

Although the allocation of the *ON* frequencies in the *N* band does not make complete use of the frequency space available, the advantages may be summarized as follows:

1. The *ON* low-groups frequencies correspond to type-*O* line frequencies; thus standard *O* filters and frequency grouping can be used.
2. The separation of groups permits individual groups of four channels to be added as desired using standard *O* equipment.
3. Essentially standard *O* terminals can be used at the end of the cable portion of the circuit.
4. The flexibility of being able to translate any *O* line frequency group to any position in the *ON* group is attained.

System Description

The *ON* system is fundamentally an arrangement whereby five 4-channel

The authors wish to acknowledge the contributions made by other members of the technical staff of the Bell Telephone Laboratories in the development of the *ON* system; also the collaboration of members of the Department of Operation and Engineering of the American Telephone and Telegraph Company in outlining field requirements and the problems to be met in the technique of application.

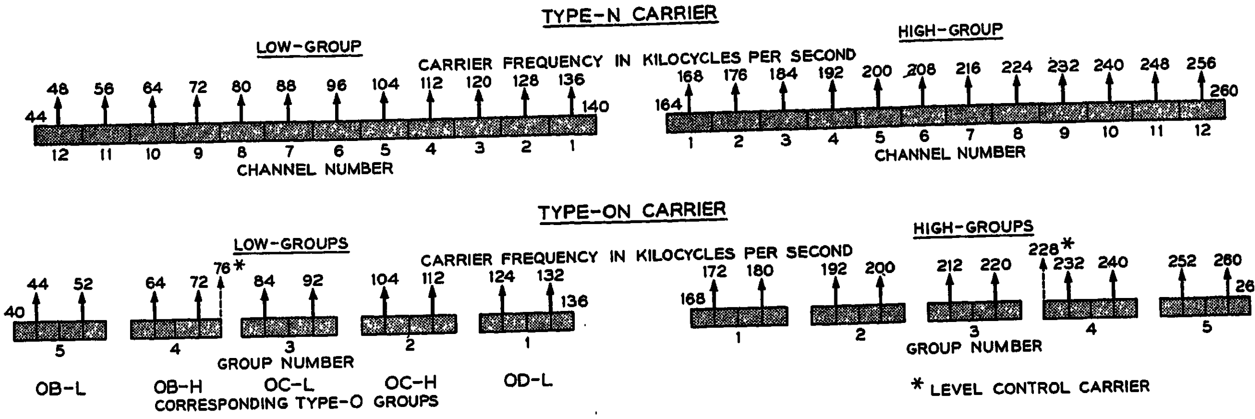

Fig. 1. Type-ON carrier frequency allocation

type-*O* groups or systems are transmitted over a type-*N* line. Fig. 2 illustrates the general equipment layout for a typical 20-channel open-wire cable *ON* arrangement. The equipment involved at the junction of the open wire and cable includes essentially standard type-*O* units and a modified type-*N* repeater. The *ON* junction converts the five assigned type-*O* systems to the low-group frequency band of the type-*N* system. The *ON* repeater provides amplification, slope adjustment of carrier amplitudes, and frequency conversion to the type-*N* high-group band as required to co-ordinate with the standard type-*N* transmission. The *ON* terminal at the other end of the cable provides for the termination of 20 channels and again consists almost wholly of standard type-*O* units.

The *ON* system may also be used in all-cable layouts. The equipment requirements for such an arrangement providing for the transmission of 20 channels over a single *N* line are shown in Fig. 3.

Modulation Plan

The type-*ON* carrier modulation plan shown in Fig. 4 is designed to place five different 4-channel groups, each corresponding to a type-*O* group or system in a frequency band capable of being transmitted over a type-*N* line. The plan is based on the use of the basic 4-channel band of 180 to 196 kc provided by the type-*O* equipment. Each basic 4-channel group is converted to an allocated *ON* low-groups position by use of a group modulator and associated frequency, according to Fig. 4. The full *ON* complement of five groups covers the frequency band from 40 to 136 kc.

When the system layout requires that transmission to the first repeater section must be in the low-groups band in order to co-ordinate with type-*N* systems, the band of frequencies from 40 to 136 kc is applied to the line by the *ON* repeater without further modulation. When high-groups are required, the *ON* repeater applies a further step of modulation with a carrier frequency of 304 kc so that the *ON* low-groups are converted to *ON* high-groups. Modulation in the repeaters along the type-*N* line converts these bands of frequencies back and forth between low-groups and high-groups in a manner similar to the type-*N* plan.

The *ON* modulation plan may be considered a 2-step process when applied at the junction of open wire and cable. Four-channel groups are received on the open wire line side of the junction at type-*O* line frequencies and then each is modulated to the basic 4-channel band of 180 to 196 kc. The second step modulates each group to its *ON* low-groups allocation. Since the basic 4-channel carrier frequency band of 180 to 196 kc is common to each of the *OA*, *OB*, *OC* and *OD* systems, it follows that the five groups of *ON* may be composed of any combination of 4-channel type-*O* systems. This flexibility is an essential requirement for a practical system since it avoids undesirable restrictions on its field of application.

A simpler single-step modulation plan was considered for the translation from the type-*O* line frequencies to the *ON* frequencies but rejected because of the limitations involved. This plan made use of frequency frogging repeaters similar to those used in *OB*, *OC*, and *OD* carrier. In a type-*OB* repeater, for example, an input frequency band of 40 to 56 kc is converted to an output band of 60 to 76 kc. The same procedure could be used to translate a type-*O* 4-channel group of line frequencies to an allocation in the *ON* low-groups band by appropriate selection of modulating frequency and filters.

One of the factors which influenced the rejection of the single-step modulation plan was concerned with the large number of redesigned filter units that would be required. The standard type-*O* auxiliary filters used in repeaters contain a section with a low-group passband and another with a high-group passband. For use in a single-step modulation plan for *ON* there would be a need for a large number of redesigned auxiliary filters to provide for the numerous combinations of type-*O* line frequencies and *ON* low-groups allocations.

A second factor bearing on the choice of the 2-step modulation plan over the single-step arrangement was concerned

with the provision for *OA* systems. The standard *OA* repeater is a nonfrequency-frogging circuit, and use of the single-step modulation plan would require the design of a new repeater circuit.

The *ON* modulation plan, as described in the preceding, applies to the transmitting direction and represents the modulation steps applied in going from the basic 4-channel band of the *ON* junction or terminal to the frequencies applied to the pair in the cable. In the receiving direction the process is reversed. Frequencies are received from the type-*N* line in the band opposite to that used on the transmitting side. When the frequencies arriving on the receiving cable pair are in the *ON* low-groups band the *ON* repeater supplies amplification without modulation. Selection and modulation in 4-channel groups is then carried out by the junction or terminal equipment in accordance with properly allocated filters and group oscillator frequencies.

When the received signals are in the *ON* high-groups band, the *ON* repeater supplies a step of modulation to convert these to the low-groups band for proper selection in 4-channel groups.

Junction

A block schematic of the junction equipment is shown in Fig. 5. The 20 channels to be transmitted over the *ON* system are shown to be composed of 16 channels from a complete type-*O* system and four channels from an *OB* system which is being transmitted over a pair of wires in the frequency spectrum just above a type-*C* system. A representative arrangement might equally well consist of 20 channels derived from five different *OB* systems.

The line filters involved in any arrangement of facilities are the same as

those used in type-*O* and identical mounting arrangements are used.

The circuits used in the junction for the selection of each 4-channel type-*O* group and the transformation of each group from the line frequencies to the basic band of 180 to 196 kc are identical with those used in type-*O* terminals. These consist of group receiving, group transmitting and group oscillator circuits. In Fig. 5 they are shown designated GRP 1 REC OW, GRP 1 TRSG OW, OSC 1 OW, etc. The numeral designation serves to identify the *ON* group assignment and the OW suffix distinguishes these circuit units from others which are more properly associated with the cable side of the junction.

A noise generator circuit is contained in the group transmitting units for use in standard type-*O* carrier to provide a nominal amount of masking noise at the channel terminals. This feature is not required in the junction application of these units and the noise circuit is disabled by removal of the single vacuum tube involved.

Each 180- to 196-kc 4-channel *ON* group is next passed through a group transmitting unit which converts the frequencies to the particular *ON* group allocation in the type-*N* low-group band. In the case of *ON* GRP 1 the oscillator OSC 1 CA supplies a modulation frequency of 316 kc to the group transmitting unit GRP 1 TRSG CA for conversion of the 180- to 196-kc band to 120 to 136 kc. The oscillator frequencies involved in other *ON* group conversions are indicated in Fig. 5, and are in accordance with the modulation plan of Fig. 4. The outputs of the group transmitting units are multipled through a combining network and connected to the *ON* repeater.

The group transmitting units designated GRP 1 TRSG CA, etc., are again standard type-*O* units. The carrier supply for the modulators in these units is obtained from type-*O* repeater oscillator units which have been modified to provide the frequencies required by their application in type-*ON*.

In the opposite direction of transmission the signals received by the junction equipment from the *ON* repeater are also in the *ON* low-groups frequency band. Five group receiving circuits, one for each *ON* group, are used with their inputs arranged in multiple. These circuits are designated GRP 1 REC CA, etc., and consist of standard type-*O* group receiving units. In the *ON* application of these units the plug-in directional filter is omitted and in its place a simple strapping plug is used. A schematic of the GRP 1 REC CA circuit is shown in Fig. 6. The auxiliary filters used in these applications are standard type-*O* designs. Each *ON* group requires a different code to select properly the 4-channel group involved. In each *ON* group, carrier supply for the modulator in the GRP

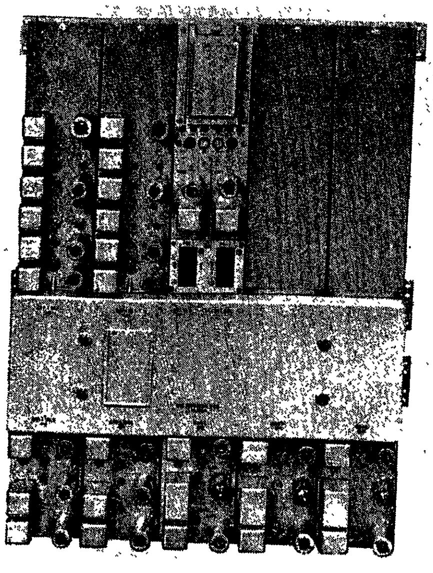

Fig. 8. ON junction group 1

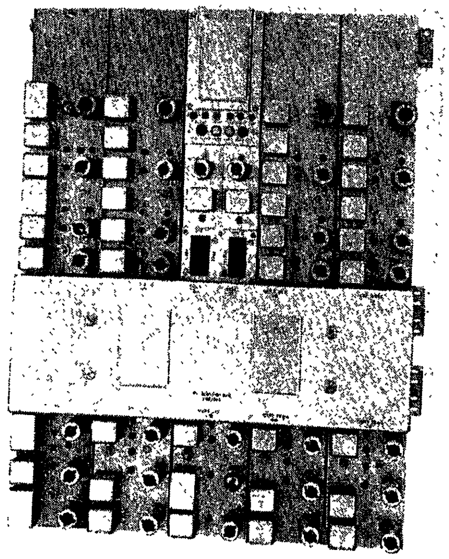

Fig. 9. ON junction groups 4 and 5

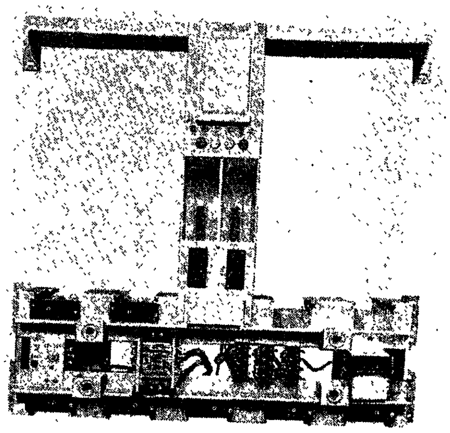

Fig. 10. Junction framework ON group 1

REC CA circuit is obtained from the same source that supplies the modulator in the GRP TRSG CA circuit.

The physical arrangement for a 20-channel *ON* junction is shown by the sketch in Fig. 7. The circuit units are mounted on three different junction mountings. The basic mounting is designated *ON* junction GRP 1, and it contains the combining networks and level control oscillator. It also provides overflow mounting space for the OW oscillators associated with *ON* groups 3 and 5. The equipment for *ON* groups 2 to 5 is divided in pairs of groups and located on two mountings.

Power supply circuits, fuses, alarm lamps, and the mounting accommodations for some of the oscillators are provided by the plug-in upper central units in each of the mountings. Fusing arrangements are such as to provide protection on a per-*ON*-group basis.

Figs. 8 and 9 show fully equipped laboratory models of junction mountings. Fig. 10 shows the GRP 1 mounting framework and associated power supply unit. The shelves used in the junction mountings are the same die castings used in the type-*O* terminal and repeater mountings.

ON Repeater

The primary function of the *ON* repeater is to convert the low-groups frequencies transmitted and received by the junction to the frequency bands required by the associated type-*N* line. It is made up of a standard type-*N* LH or HL section and a new LL section which includes an equalizing network. These sections or ubassemblies may be combined into four different arrangements to meet the needs of different applications. The optional arrangements are as shown in Table I.

The illustration in Fig. 11 shows a LH LL type-*ON* repeater schematic. The LH refers to the W-E side of the repeater which converts the low-groups frequencies at its input to high-groups at its output. The +7-decibel (db) slope network at the W-E input has a rising loss characteristic with frequency. It introduces a 7-db slope in the magnitude of the carriers received from the *ON* junction. At the repeater output the slope is such as to place the highest frequency carrier at the greatest amplitude as in type-*N* carrier. Regulation in the repeater stabilizes the output on a total power basis and the type-*ON* carriers are delivered to the line at essentially the same amplitudes as corresponding carriers in type-*N*. This co-ordination of carrier amplitudes minimizes the problems of crosstalk and maintenance.

The *ON* carriers in the E-W side of Fig. 11 are received from the *N* line at *ON* low-groups frequencies and are passed through the repeater without modulation. The −7-db slope network in the E-W repeater equalizes the carrier amplitudes which are received from the cable with a nominal 7-db amplitude slope as in type-*N*.

The schematic of Fig. 12 illustrates the *ON* repeater circuit for the case where the frequencies delivered to and received from the type-*N* line are in the low-groups and high-groups bands respectively.

The *ON* repeater consists of three subassemblies as indicated by the dashed lines of Figs. 11 and 12. The subassemblies are interconnected by plug and jack connectors and the assembled *ON* repeater is the same in appearance as the standard *N* unit. The repeater is mounted on repeater mounting brackets on shelves like those of type-*N*, and may be operated adjacent to type-*N* repeaters. The associated *ON* repeater mounting wiring on the side facing the cables is the same as for type-*N* repeaters. This provides for standard *N* arrangements of over-the-cable power supply circuits, span pads, and artificial lines as required. The repeater mounting wiring facing the *ON* junction includes the +7-db slope network.

The *ON* repeater is also used at the *ON* terminal to provide the same functions described for the junction.

ON Terminal

The equipment at an *ON* terminal includes an *ON* repeater, a level control oscillator, and combining network circuit and five slightly modified type-*O* terminals. Each 4-channel terminal terminates one *ON* group and the modified terminals are accordingly identified as *ON* Terminal GRP 1, *ON* Terminal GRP 2, etc. Fig. 13 is a block schematic of a terminal arrangement.

In type-*ON* carrier, as in type-*O*, the transmitted carrier is used at the receiving terminal for channel regulation and demodulation. Prior to its use for either of these functions, the received carrier is passed through a selective circuit to remove extraneous signals which would be a source of interference. The pick-off

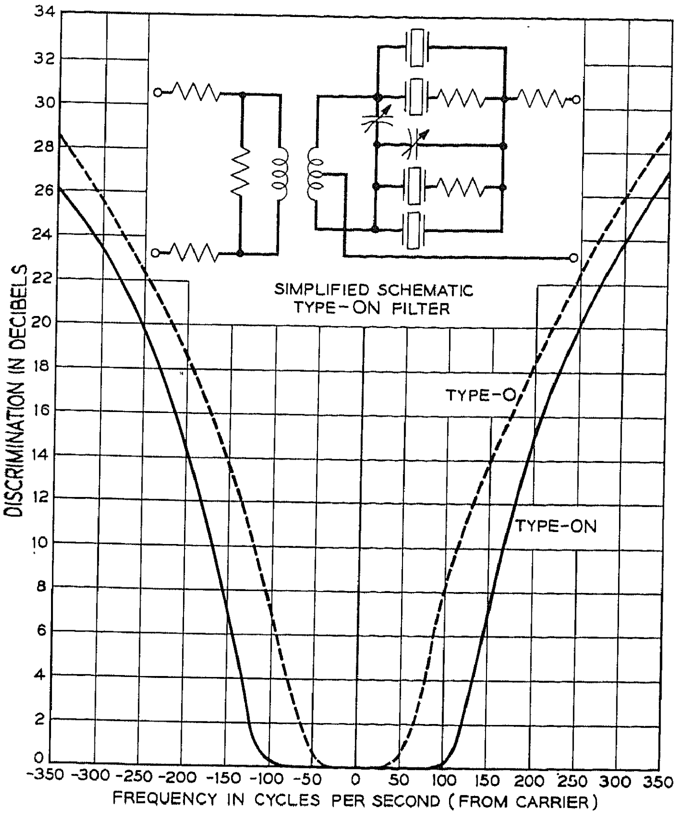

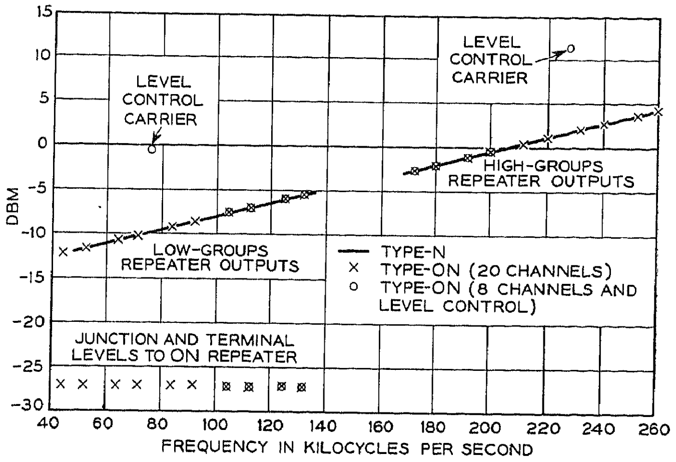

Fig. 14 (left). Type-ON carrier pick-off filter

Fig. 15 (above). Type-ON carrier levels

filter used for this purpose in type *O* has a passband of approximately ±50 cycles.

The required bandwidth of the pick-off filter is determined by the maximum error expected in the absolute frequency of the received carrier. Variations in frequency are contributed by the oscillators in the channel circuits, terminal group circuits, and frequency-frogging repeaters. In type-*O* the accumulated errors are not expected to exceed ±50 cycles for the longest systems.

In type-*ON* carrier the received carrier frequency error is expected to be greater than in type *O* because of the added variation introduced by the frequency-frogging repeaters of the type-*N* line. To care for this the pick-off filter has been redesigned to provide a passband of ±100 cycles. Twin channel units used in *ON* terminals or terminals of type-*O* systems involved in open wire-cable *ON* arrangements must be modified to provide the wider pick-off filter. The new filter is identical with the one it replaces from the standpoint of mounting arrangements and circuit connectons. Fig. 14 shows the loss characteristic of the new filter and its schematic circuit.

The directional filters have been omitted in the receiving group units and each 4-channel terminal is brought out on a 4-wire basis at carrier frequency as at the junction. The terminal group receiving circuits are similar to the one illustrated in Fig. 6 for the junction. In each *ON* group, the group oscillator frequency and the group receiving auxiliary filter are the same as those used at the junction. Masking noise is used at the terminals as in type *O*.

Partially Equipped *ON* Systems

When less than the full 20 channels are being transmitted over the *ON* system, the level control oscillators are used to provide an artificial load equivalent to the missing channel carriers. The purpose of the level control oscillators is to stabilize the amplitudes of the *ON* channel carriers in the *N* line at nominal values independent of the number of *ON* groups being transmitted. Without a level control carrier the effect of the *N* repeater regulator is to increase the magnitude of the remaining channel carriers as *ON* groups are dropped. The regulator circuit attempts to keep the total power at the repeater output constant.

The level control oscillator is used only when four or fewer *ON* groups are being transmitted over the *N* line. The recommended order of application of numbered *ON* groups is 1, 2, 3, 5, and 4. The level control oscillator output is reduced as system loading is increased, and it is removed altogether when group 4 is finally added.

Transmission Levels

The nominal amplitudes of the ten *ON* channel carriers in the type-*N* line are essentially the same as the corresponding type-*N* carriers. Fig. 15 shows the carrier amplitudes at low-groups and high-groups repeater outputs. The *ON* magnitudes fall on the sloped lines representing the positions of the type-*N* carriers. The chart also shows the carrier amplitudes delivered to and received from the *ON* repeater by the *ON* junction or terminal. The operating levels in the type-*O* units of the *ON* junction or terminal are the same as in standard type-*O* practice.

The carrier to side-band ratio of the *ON* channel circuits is unchanged from type-*O*. Both the message side-band level and the signaling tone amplitude are 6 db below the channel carrier.

Fig. 15 also illustrates the magnitude of level control carrier required to stabilize the channel carriers when only four carriers (eight channels) are being transmitted. As discussed in the preceding the level control carrier amplitude is lowered as channels are added, and removed completely when the full 10 *ON* carriers are applied.

Transmission Considerations

The over-all transmission performance of type-*ON* is expected to be comparable to type-*O*. The over-all frequency characteristic of an *ON* channel will be controlled largely by the type-*O* channel and group filters. When long type-*N* lines are involved, some degradation of the channel frequency characteristic will result from residual equalization effects in the line. These effects will be kept under control by the use of automatic deviation regulator circuits which have been developed recently for use on long type-*N* systems.

Phase distortion, an influence on the amplitude frequency characteristic of some channels in long type-*N* systems, is not a factor in type-*ON*. The single side-band *ON* type of transmission is not sub-

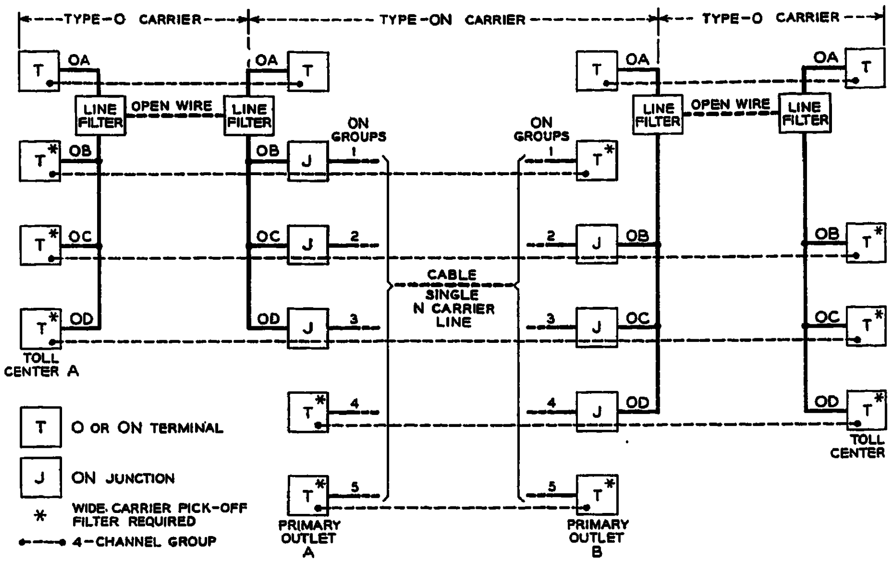

Fig. 16. Circuit layout illustrating flexibility provided by type-ON carrier

ject to amplitude effects such as those caused by the phase displacement of the two side bands used in type-*N*.

Channel net loss variations of *ON* channels are expected to be no greater than those in type-*O*. Two factors which are peculiar to *ON* operation affect transmission variations in opposite ways and should largely nullify each other. One factor, tending to improve channel net loss stability, involves the employment of extra regulating circuits in *ON* as compared to type *O*. For example, at the junction of open wire and cable, regulation is furnished by both the *ON* repeater and receiving group unit. Similarly, at the *ON* terminal the receiving circuit employes regulation in the *ON* repeater, group receiving circuit, and twin channel unit, as compared to only the group-receiving unit and twin channel unit in type-*O*.

The factor contributing towards a degradation of stability involves the individual channel regulators which are less effective with the single side-band transmission employed by *ON* than with the double side band used in type-*N*. Variations in the type-*N* line equalization are expected to produce noticeable effects in the channel net loss.

Owing to the difference in channel levels of type-*N* and type-*ON*, some inequality will exist in crosstalk between these systems. The double-side-band type-*N* system transmits each message side band at a level 15 db below the carrier. The single-side-band type-*ON* system operates with the side-band level 6 db below the carrier. With the carriers of type-*N* and type-*ON* being transmitted over the cable at like amplitudes this results in crosstalk from *ON* to *N* which is approximately 6 db greater than from another *N* system. Similarly the crosstalk from *N* to *ON* is approximately 9 db less than from another *ON* system. Only *ON* groups 2 and 4 have carriers which coincide with the type-*N* carriers and therefore offer the possibility of intelligible crosstalk. It is expected that the unfavorable type-*N* crosstalk situation will be tolerable for any paired or quadded cables to be used for *ON* systems.

A special crosstalk problem exists where *ON* is applied to a cable containing an *N* system on which program is being transmitted. The *N* program is located in the space usually occupied by message channels 5, 6 and 7, with the carrier frequency falling at what corresponds to the carrier of message channel 6. In this situation a 4-kc crosstalk tone is produced in the program circuit by one of the carriers of *ON* group 3 (92 kc in low-groups or 212 kc in high-groups.) In marginal cases involving paired cables with poor crosstalk loss between pairs it may be necessary to drop the level of *ON* group 3 by 3 to 6 db in order to reduce the interference effect to a tolerable limit.

Owing to the higher message side-band level of the *ON* channels it is expected that the cable noise effect will be 3 to 6 db less in these channels than in type-*N*. In an open wire-cable circuit the noise should be controlled by the open wire portion of the system, and performance should be comparable to type *O*.

APPLICATIONS

The *ON* system, in its broader aspects, was originally planned as a part of the over-all type-*O* carrier development to provide flexibility and economy in short-haul circuit layouts involving different types of basic facilities. For example, the operation of *O* systems through long entrance or intermediate cables where the use of *N* instead of *O* repeaters would result in substantial economies; the operation of *O* carrier through cables carrying *N* systems with the ability to transfer to open wire facilities, on a carrier frequency basis, at intermediate points or cable terminals; as circuit growth and economic considerations permit, the use of *O* carrier on an open wire route to be developed as a

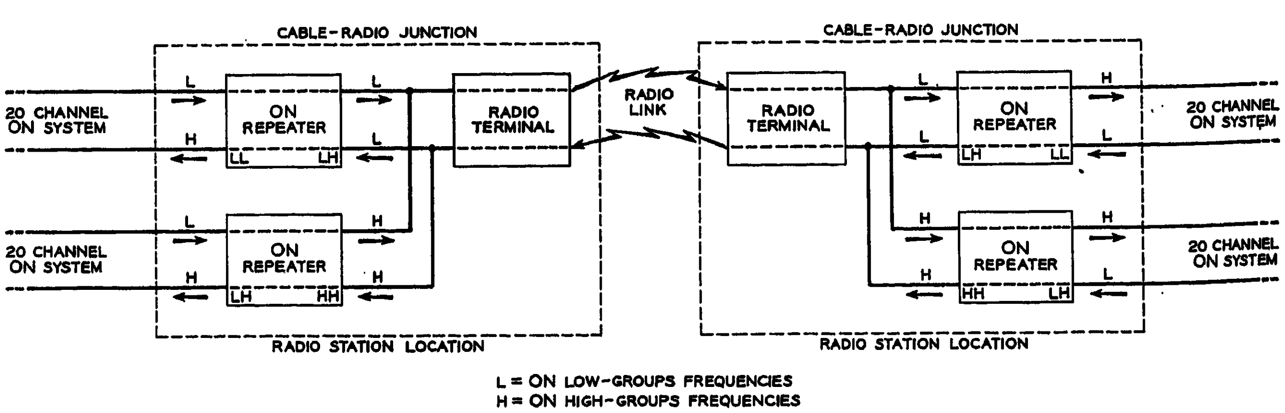

Fig. 17. Forty channels of ON carrier arranged for transmission over a radio link

carrier cable route, for all or a part of its length, by periodic cable extensions.

In addition to these applications, it now appears that the *ON* system will have a very considerable field of use as a 20-channel all-cable carrier system. A further important use anticipated for *ON* carrier is the future relief of *N* cables. This can be done by replacing *N* with *ON* terminals, thereby deriving eight additional channels per quad (or two pairs) without changes in the line facility and existing *N* repeaters. The *ON* system is also expected to find an important field of application in channelizing radio systems (up to 40 channels being obtainable) as outlined later in more detail.

A more detailed example of effective use of the *ON* equipment is illustrated in the simulated circuit layout on Fig. 16. The arrangement shows a section of cable between two primary outlets with open wire facilities extending from each of these outlets to toll centers. The facilities involved consist of a complete type-*O* system from the toll center *A* to the adjacent primary outlet, a type-*ON* system involving a single type-*N* line between the primary outlets, and a complete type-*O* system to the toll center *B*. The dashed lines in light print indicate 4-channel groups.

The arrangement shows one *ON* group used to furnish four channels of all-cable *ON* carrier between the two primary outlets. Two other groups of *ON* are used for 4-channel blocks of circuits involving open wire and cable. One 4-channel group extends from toll center *A* to primary outlet *B*, while the other provides channels from primary outlet *A* to toll center *B*. The remaining two *ON* groups are used in an open wire-cable–open wire arrangement providing eight channels between the two toll centers.

The flexibility provided by the arrangement of Fig. 16 is made possible by the *ON* feature which permits the application of *ON* terminals or junctions at the ends of a type-*N* line in any combination desired.

Type-*ON* also provides an effective method for channelizing circuits over a radio link. The arrangement in Fig. 17 shows the application of forty *ON* channels to radio terminals. The *ON* repeaters provide for transmission to and from the radio terminals in the *ON* low-groups frequency band of 40 to 136 kc, and the high-groups band of 168 to 264 kc. The repeater providing the low-groups input to the radio terminals is the same unit described in connection with the junction and terminal applications. The repeater providing high-groups frequencies is a similar type of unit in that one side does not employ modulation. The latter unit, incorporating a HH section, is not available at present. Slope networks associated with the repeaters provide amplitude correction so that all channels are applied to the radio terminals at equal levels.

No Discussion

The Influence of Magnetic Amplifier Circuitry Upon the Operating Hysteresis Loops

HAROLD W. LORD
FELLOW AIEE

THE scope of this paper will be limited to the steady-state characteristics of those high-performance magnetic amplifier circuits which are classed as single-phase self-saturated types. No attempt will be made to indicate when considerations presented herein are applicable to the 100-per-cent external feedback type. Only resistive loads will be considered.

While the several basic methods of analysis of self-saturated magnetic amplifiers available today are helpful in predicting an approximate control characteristic curve, they lack the precision required by many designers. Experimental data show that the same magnetic components will have somewhat different control characteristics when used in different circuits. This effect is present in circuits which are so similar that the presently available methods of analysis predict that their control characteristics would be identical.

Many of the methods of analysis include the concept that the self-saturated magnetic amplifier is a magnetomotive-force-controlled device. Other methods consider it as a voltage-controlled device during the period in which the flux level is being reset. Either or both of these concepts will be employed in this paper, depending upon the circuit under discussion.

In order to facilitate a mathematical analysis, the magnetization characteristics of the core usually are so simplified that the results of the analysis are meaningless when rectangular hysteresis loop materials are considered. No attempt will be made to provide quantitative information in this paper. The operation of the several circuits to be considered will be related qualitatively to the actual operating dynamic minor hysteresis loop. (The term "dynamic hysteresis loop" as used herein is defined as the relationship between magnetic induction **B** and apparent magnetizing force **H**. The apparent magnetizing force includes that required by the static hysteresis loop, taken over the same operating flux densities, plus all magnetizing forces required to overcome eddy current effects associated with the rate-of-change of flux required by the operating conditions.)

It is the author's hope that, by considering the relationships of operating core characteristics to circuit operating conditions, the reader will obtain:

1. A better understanding of the basic circuit operation.

Paper 53-311, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B. C., Canada, September 1–4, 1953. Manuscript submitted June 2, 1953; made available for printing July 22, 1953.

HAROLD W. LORD is with the General Electric Company, Schenectady, N. Y. The author wishes to acknowledge the help of Myron Egtvedt in obtaining the oscillograms and data used in the paper.

2. Some of the reasons for the effect of the circuit upon the control characteristic.
3. A better appreciation of the part played by the dynamic magnetization properties of the core in determining those characteristics.

Some Pertinent Magnetic Characteristics

The rapid expansion of interest in, and application of, magnetic amplifiers has been attributed in large part to the development of magnetic materials, such as Deltamax, having very rectangular d-c hysteresis loops. However, nearly all of the analytical methods published so far fail to relate the control characteristic to a truly rectangular loop. Those methods which do consider the hysteresis loop usually show that a self-saturated magnetic amplifier would have an infinite gain or trigger action between full output and minimum output if the hysteresis loop were assumed to have an extremely high, or infinite, maximum differential permeability. It is therefore customary to assume a nonrectangular parallelogram type of hysteresis loop in order to circumvent this difficulty. Deltamax not only has a very rectangular d-c hysteresis loop but exhibits rectangular dynamic hysteresis loops with extremely high maximum differential permeabilities (exceeding 10^6). Although rectangular loop materials, used in self-saturated magnetic amplifiers, do show some trigger action in the region of cutoff,[1] such trigger effects are not limited entirely to rectangular loop materials. Moreover, the slope of the major portion of the control characteristic does not correspond to that of the high differential permeability, being much less than that predicted by the analysis. It appears, therefore, that an important factor is being neglected in the analysis. I believe this neglected factor involves the proper consideration of the eddy-current effects which cause the operating dynamic hysteresis loops to be wider than the static loop.

In an earlier paper[2] it was shown that there was a reduction in the eddy-current effects at 60 cycles by a thickness reduction from 0.002 inch to 0.001 inch. This eddy-current reduction cannot be accounted for by skin effect. The metallurgists believe it is related to domain boundary movements, detailed considerations of which are beyond the scope of this paper. However, the fact that eddy-current effects are present in thin gauge material, at rates of change of flux (*d***B**/*dt*) which correspond to very low frequencies, can be demonstrated through the use of a hysteresigraph.[3]

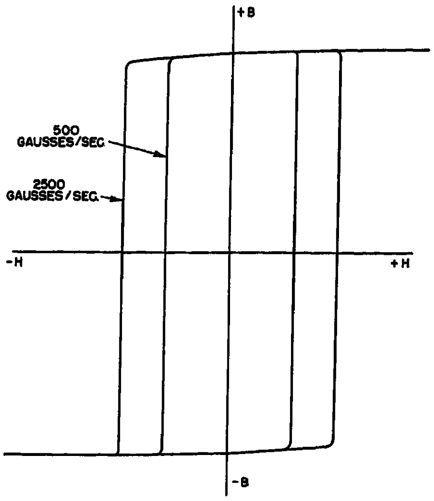

Fig. 1. Static loops of 65-Permalloy for two low rates of change of flux

The hysteresigraph automatically plots, on rectangular co-ordinates, the **B-H** curve of a test core. The curves of Fig. 1 were made on a machine which has sufficient long-time stability to allow several minutes for completing a curve and also has sufficient speed to permit one to be completed within a few seconds. The vertical portions of the two loops were made by setting the value of **H** to the indicated value and timing the change in induction **B** with a stopwatch. The test specimen was a spirally wound core of 0.005-inch 65-Permalloy. The narrowest loop was obtained at very low values of *d***B**/*dt* and corresponds to the so-called d-c or static hysteresis loop of this core. A small increase of **H** in excess of that required by the static loop does not provide an instant or rapid change in flux. Instead, the *d***B**/*dt* increases to such a value that the magnetomotive force in excess of that required by the static loop is balanced out by eddy currents associated with the domain boundary velocities required by the flux change. The loops show that for a greater excess of **H** the *d***B**/*dt* is higher. It should be noted that for all of these loops the apparent maximum differential permeability (*d***B**/*d***H**) is infinite, since the flux is changing with a constant apparent **H**.

This dependence of *d***B**/*dt* upon apparent **H** provides a means for explaining the observed performance of such rectangular hysteresis loop materials in those self-saturated magnetic amplifier circuits which have a high-impedance control circuit. (The term "high-impedance control circuit" as used herein will designate those control circuit conditions which do not allow the free flow of the even harmonic components of current in the control circuit. This is sometimes called "constrained magnetization."[4] The term "low-impedance control circuit" as used herein will designate those control circuit conditions which allow the free flow of the even harmonic components of current in the control circuit. This is sometimes called "natural magnetization."[4])

Ferrite magnetic materials have very high resistivities and therefore do not exhibit the previously described eddy-current effects at power and audio frequencies. If the metallurgists succeed in developing a ferrite having hysteresis loops whose maximum differential permeability is as high as that of Deltamax, then certain magnetic amplifiers employing such a material would be likely to have the triggering tendencies and performance characteristics as predicted by an analysis based upon its static loop.

Self-Saturating Single-Core Half-Wave Circuit

This circuit, shown in Fig. 2, is often analyzed as a basic element of the so-called doubler and full-wave circuits. The latter two circuits combine two similar cores which are assumed (sometimes erroneously) to operate into a common load resistance without affecting their individual control characteristics as obtained for the simple half-wave circuit. Since a single core provides no means for balancing out the fundamental components, the half-wave circuit must always have a relatively high impedance control circuit. This is, therefore, one circuit in which the current supplied by the control circuit is relatively constant at all instants throughout the cycle and so requires the eddy-current considerations in order to explain its operation when rectangular hysteresis loop core materials are employed.

Fig. 3(A) shows idealized static and dynamic major hysteresis loops and minor operating loops for a core material when used in this circuit; Figs. 3(B) and (C) show one cycle of operation of the circuit for minimum output and for firing angles of 120 degrees and 0 degrees (full output). The shaded areas emphasize the 120-degree firing angle conditions. The heavy curve in Fig. 3(B) indicates the induced voltage in the gate winding of the inductor, while the heavy curve in Fig. 3(C) indicates the current through the gate winding. In this case the rectifiers are assumed to be ideal in the inverse direction and the voltage drop across the load and rectifier due to the prefiring current is assumed to be almost negligible. Also, the applied voltage is made just sufficient to cause the peak-to-peak flux density swing at minimum output to be a fraction less

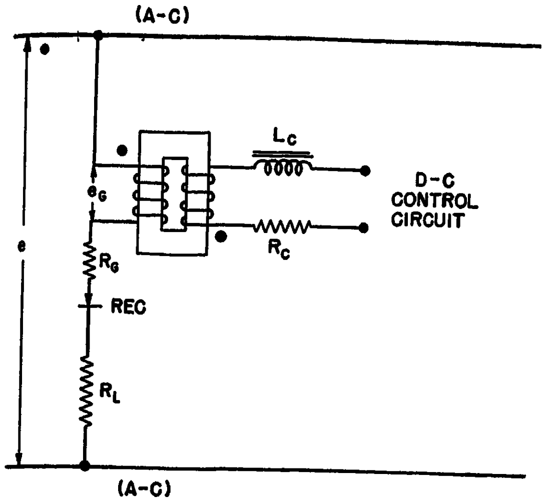

Fig. 2. Half-wave magnetic amplifier circuit

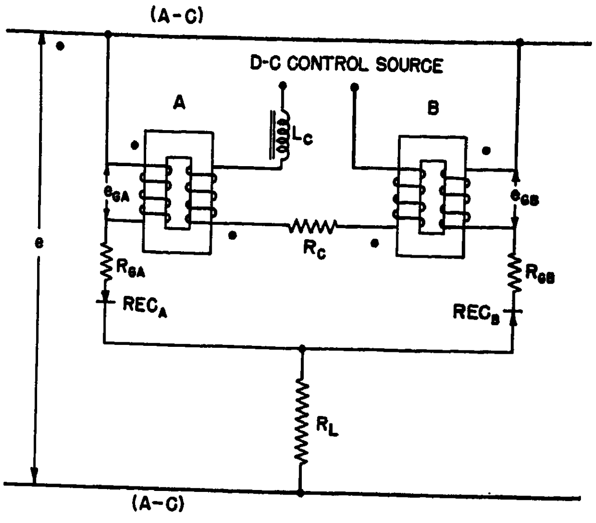

Fig. 4 (right). Doubler magnetic amplifier circuit with high-impedance control circuit

than two times the saturation density.

Consider first the condition of zero control current. After one cycle of operation following application of the alternating voltage, the core will remain in the region of $+B_s$ (swinging from $+B_r$ to 3) and the voltage across the coil will be substantially zero at all times, just as though it were a closed switch. The current through the gate winding will be half-cycles of sine waves as shown by the light solid curve of Fig. 3(C) and limited only by the total circuit and load resistance.

Now suppose the control current is adjusted to such a value as to provide a magnetomotive force corresponding to H' of Fig. 3(A). Then, during the negative half-cycle in which the rectifier is blocking, this value of H' will produce in the inductor core a negative volt-time area corresponding to the shaded portion in the negative half of Fig. 3(B). The flux density in the core will therefore be reset to B' during this period. When the next positive half-cycle occurs, the gate coil can absorb the positive volt-time area as shaded. This positive area is equal to the negative area provided during the preceding negative half-cycle, hence firing is delayed until 2′. The gate current during the prefiring period has a value corresponding to the total width of the minor hysteresis loop. This is true since the current in the gate winding not only must supply the current required by core excitation but, in addition, must balance out the magnetomotive force due to the control coil current. The control current continues to flow during the positive half-cycle and opposes the magnetomotive force required by the core during this period. After the core saturates, or fires, the current through the gate winding rises to 3′, being limited for the rest of the cycle only by the total circuit and load resistance.

If the control current is further increased to correspond to H'', the core will be completely reset to $-B_s$ during the negative half-cycle. Then, during the subsequent positive half-cycle, the core flux will just fall short of reaching saturation at $+B_s$ so the inductor will not fire. This is the condition of minimum output. For this condition the current through the gate coil during the positive half-cycles has a value corresponding to the total width of the dynamic hysteresis loop at

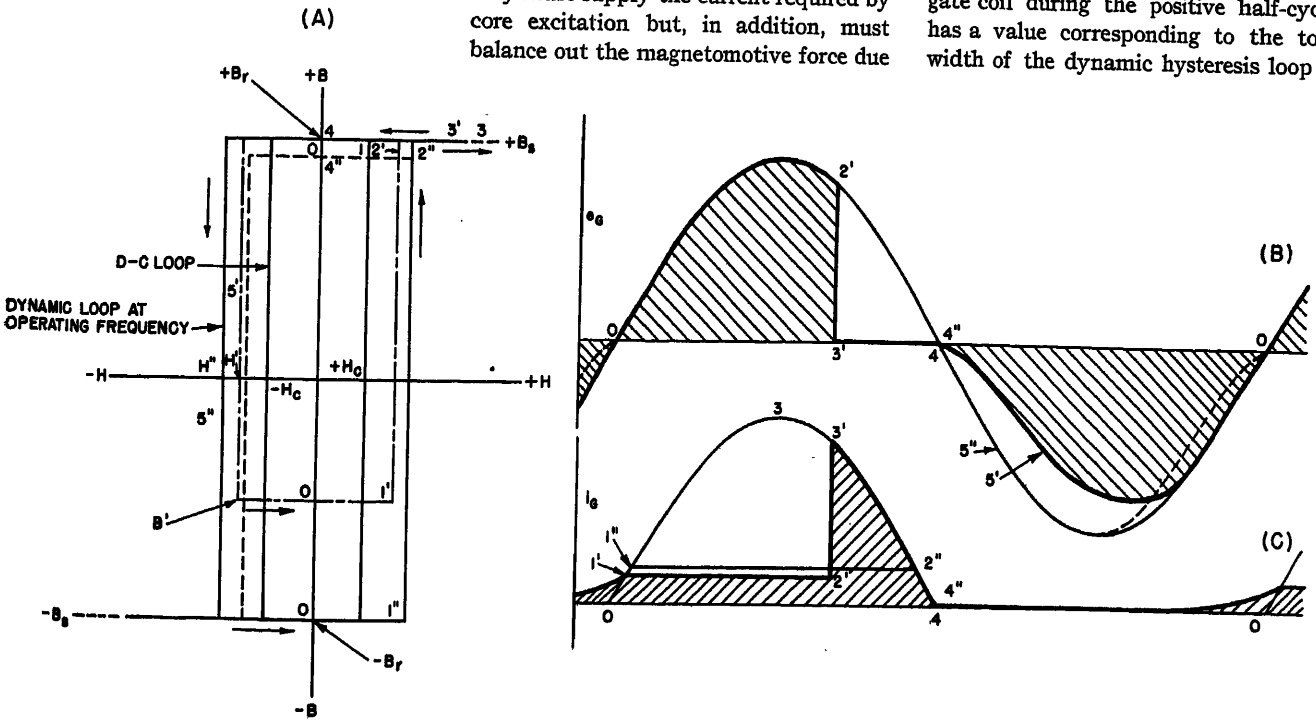

Fig. 3. Half-wave circuit operation

(A) Idealized hysteresis loops (B) Wave form of induced voltage in gate winding (C) Wave form of current in gate winding

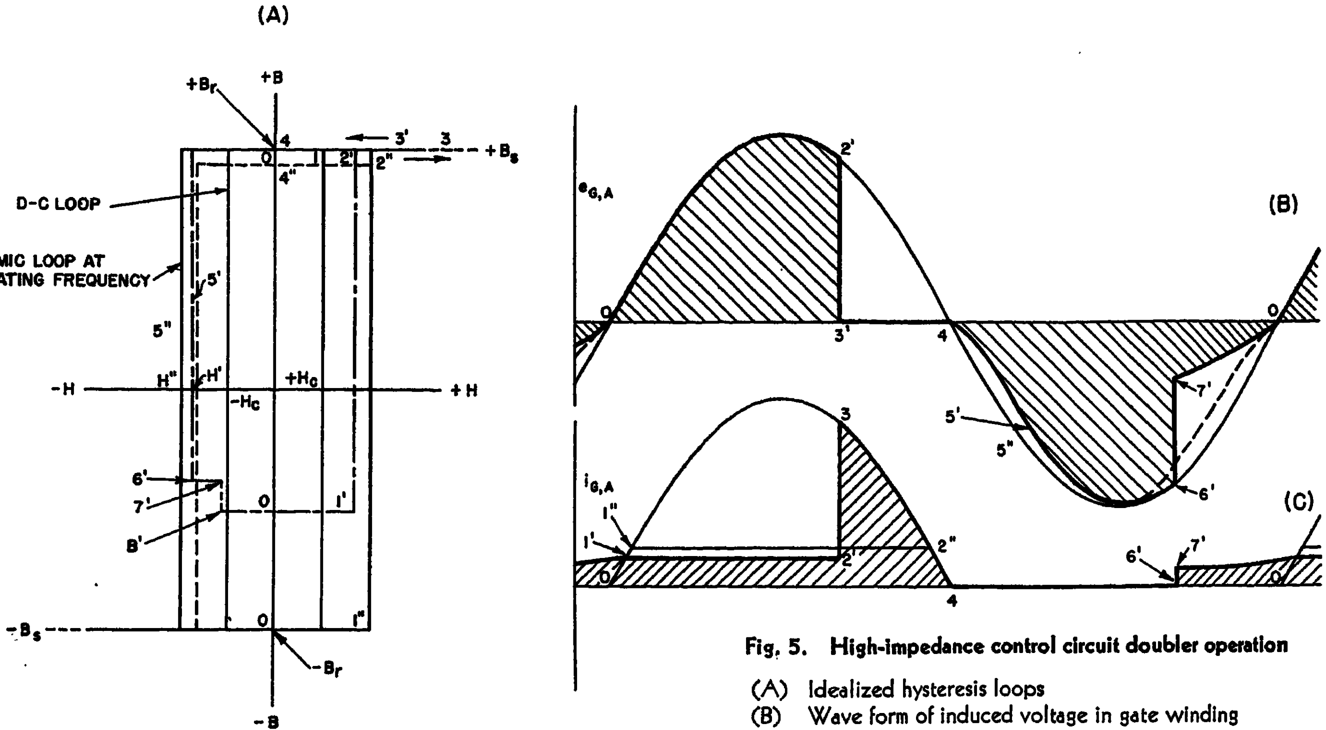

Fig. 5. High-impedance control circuit doubler operation

(A) Idealized hysteresis loops
(B) Wave form of induced voltage in gate winding
(C) Wave form of current in gate winding

the operating frequency and the control current required to establish this condition is determined by approximately one-half the width of this dynamic loop.

Consider now the effect of further increasing the control current so that it exceeds the value corresponding to $\mathbf{H}''$. There will then be a tendency for the flux to reset to the $-\mathbf{B}_s$ value more rapidly than is required by the supply voltage. However, a greater $d\mathbf{B}/dt$ will tend to induce a voltage in the gate winding which exceeds the supply voltage during the reset half-cycle. Under such circumstances the rectifier *REC* will conduct during the reset period. The $d\mathbf{B}/dt$ in the core is thereby limited to an amount which exceeds the supply voltage by the relatively small resistance drop in the rectifier and load due to the excess of current supplied to the control winding beyond that required to reset the core in 1/2 cycle. This shows that in this half-wave circuit the net magnetizing force acting upon the core, can exceed the value obtained from the major dynamic hysteresis loop by only a relatively small amount. Nearly all of the magnetizing force supplied by the control circuit in excess of this value is opposed by an equal amount in the gate winding, through conduction of the rectifier during the normally nonconducting half-cycle. In this half-wave circuit the available volt-time area during the reset period consists of 1/2 cycle of the applied alternating voltage. This amount of volt-time area is available regardless of the firing angle during the forward or conducting half-cycle.

Doubler Circuit with High-Impedance Control Circuit

When two of the simple half-wave circuits are connected so as to supply alternating current to a common load resistor, as shown in Fig. 4, the resulting circuit is called the doubler circuit. This circuit is one which often has been erroneously assumed to have control characteristics similar to the simple half-wave circuit when the control circuit impedance is relatively high. A description of the operating conditions throughout a period of 1 cycle will serve to show why such an assumption is in error. Fig. 5 illustrates the static major and operating dynamic minor loops and the gate winding voltage and current wave forms for minimum output and for firing angles of 120 degrees and 0 degrees (full output). The shaded areas emphasize the 120-degree firing angle conditions. In this case the rectifiers are assumed to be ideal in the inverse direction only and the voltage across the load due to the prefiring current is assumed to be almost negligible. The applied voltage is made just sufficient to cause the peak-to-peak flux density swing at minimum output to be a fraction less than two times the saturation density.

When the control current is zero, both cores will remain in the region of $+\mathbf{B}_s$ (swinging from $+\mathbf{B}_r$ to 3) after 1 cycle of operation following the application of alternating voltage. The induced voltage in each coil then will be substantially zero at all times. The current through each gate winding will be half-cycles of sine waves as shown by the light solid curve of Fig. 5(C), one carrying current for half-cycles of one polarity and the other for half-cycles of the opposite polarity. The load current therefore will be full cycles of alternating current, the combined circuit in series with the load resistance acting as though it were a closed switch. The current will be limited only by the sum of the load resistance and the total

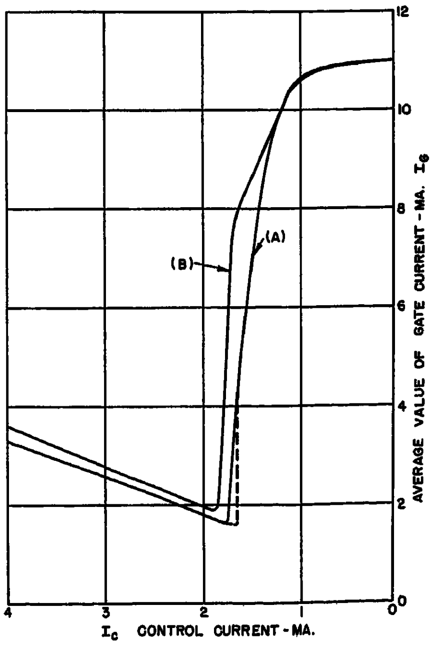

Fig. 6. Control characteristics of half-wave and doubler compared

(A) Half-wave circuit
(B) Doubler circuit with high-impedance control circuit

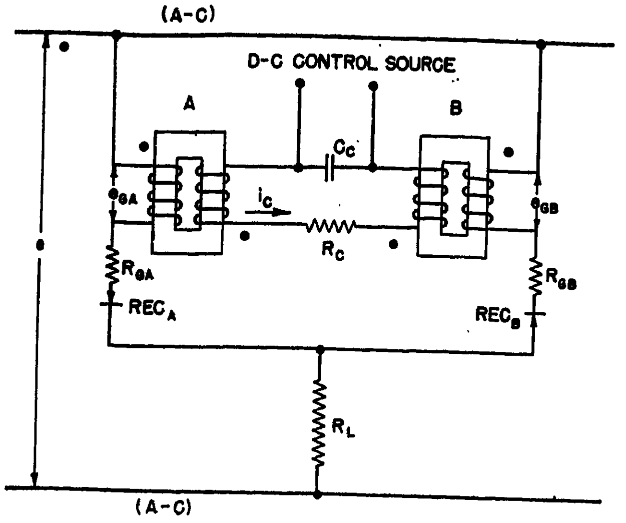

Fig. 7. Doubler magnetic amplifier circuit with low-impedance control circuit

resistance of one gate winding circuit. This latter resistance includes the forward resistance of one rectifier and the resistance of one gate winding.

Now suppose the control current is adjusted to such a value as to provide a magnetomotive force corresponding to **H′** of Fig. 5. If we consider only the final steady-state conditions for the time being, then, during the half-cycle in which a rectifier is blocking, this value of **H′** will produce in the inductor core associated with this rectifier a negative volt-time area corresponding to the shaded portion in the negative half of Fig. 5(B). The flux density in the core will therefore be reset to **B′** during this period. This negative volt-time area curve has a large nick taken out of it, starting at a point in this half-cycle at which the other core fires, and applies a large part of the line voltage across the common load resistance. For the remainder of this negative half-cycle the negative volt-time area available for reset is no longer the full supply voltage but is the relatively small amount determined by the voltage drop across R_G of the branch circuit delivering current to the load. The net magnetomotive force required by the lower $d\mathbf{B}/dt$ for the remainder of the reset period is shown as 7′ on Fig. 5(A). The excess of control current, above this value, forces conduction of the rectifier associated with the core being reset for the remainder of this reset period. This effect has been termed preconduction current.

Suppose that a given core is to be reset to a certain value of average flux density in either the half-wave or the doubler circuit. The reduced volt-time area available for reset in the doubler circuit then makes it necessary that the average $d\mathbf{B}/dt$ for the early portion of the reset period be higher for the doubler circuit than for the simple half-wave circuit. A higher value of $d\mathbf{B}/dt$ for a given core will require a higher magnetomotive force. Therefore, this concept indicates that for a given firing angle, other than one close to cutoff, a given core in a doubler circuit with high control circuit impedance should require higher values of magnetomotive force than it does in a half-wave circuit. This is in agreement with the observed results obtained when a core is first tested in a half-wave circuit and then combined with a similar core in a doubler circuit having a high-impedance control circuit. Fig. 6 shows the results of such a test.

Doubler Circuit with Low-Impedance Control Circuit

Another author[5] has recently presented an excellent and extensive mathematical analysis, of which those portions describing the steady-state conditions are applicable to this circuit. The analysis there

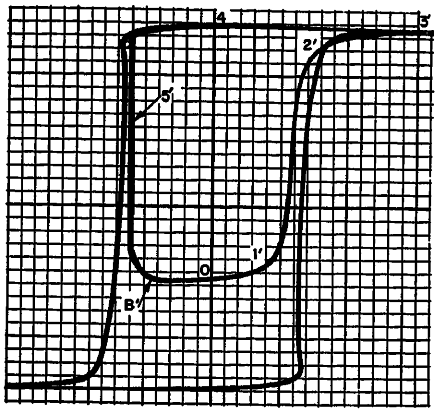

Fig. 9. Major and operating minor hysteresis loops for the half-wave circuit

presented is based upon a rectangular dynamic hysteresis loop but assumes that the control current is zero during the firing period. The description of the circuit operation which follows will include the effect of the static loop upon the control characteristic curve and the wave form of the current flowing in the control circuit. All postsaturation inductive effects will be neglected.

Fig. 7 shows schematically a doubler circuit with a control circuit made to have a low impedance to the flow of alternating currents by means of a capacitor C_c across the control source. If the control source has an inherently low impedance relative to the control winding resistance R_c, then capacitor C_c is not required.

When the control circuit impedance is such as to allow a-c components to flow freely in the control windings, the mode of operation is quite different from that described for the cases in which the control circuit impedance is so high as to suppress the flow of all a-c components. With the control windings of the inductors connected together, as shown by Fig. 7, the control circuit couples the two cores together electromagnetically. When both cores are operating within their unsaturated regions, a voltage impressed upon the gate winding of one inductor will induce a voltage in its control winding. Since the control windings are virtually connected in parallel with respect to such induced voltages, this induced voltage will be impressed upon the control winding of the other inductor. The core areas and control winding turns normally are made respectively equal for the two inductors of a particular magnetic amplifier, so this coupling effect forces the rate-of-change of flux ($d\mathbf{B}/dt$) in the two cores to be substantially the same at any given instant. The current which flows in the control circuit at any instant must therefore be such as to maintain this equality of $d\mathbf{B}/dt$ for the two cores. If the hysteresis loop is assumed to have zero slopes in the saturated regions and if all air-core inductive effects are neglected, then, when either one of the cores saturates, the $d\mathbf{B}/dt$ in the saturated core is reduced substantially to zero and no $d\mathbf{B}/dt$ is permitted in the unsaturated core.

An explanation of the manner in which this circuit operates is simplified if resistance effects are assumed negligible and if a particular steady-state firing angle be assumed. The control current amplitude and wave shape required to maintain the assumed steady-state condition then may be determined from the magnetic characteristics of the core.

If a firing angle of 120 degrees is assumed, then at the start of a half-cycle, when core A is to hold off by absorbing the applied voltage, the flux in this core will be at $\mathbf{B}'$ and point 0 on the operating minor hysteresis loop shown by Fig. 8(A). (Note that the wider loop with solid lines is the major dynamic hysteresis loop for the core at the operating frequency. The d-c hysteresis loop is the narrower loop shown with solid lines.) During the portion of the cycle that core A is holding off, the flux density in this core changes from $\mathbf{B}'$ to $+\mathbf{B}_s$ at point 2′ along the dot-dashed line. Figs. 8(B), (C), and (D) show the corresponding winding voltages and currents for inductor A. However, during this same period, core B, which has just completed its firing period, must have a similar flux density change but in the reset direction, so it swings down from $+\mathbf{B}_r$ to point 6 (slightly less than $\mathbf{B}'$ due to the effect of winding resistances) over the outer knee of the major hysteresis loop for core B. Since rectifier REC_B is blocking during this period, all of the magnetomotive force $\mathbf{H}''$ required to reset core B must be supplied by current in its control winding. The instantaneous current flowing in the control windings circuit during this period must thus be proportional to $\mathbf{H}''$ as shown in Fig. 8(A). The control winding of inductor A then acts as the secondary of a transformer to supply this excitation, and the gate winding acts as the primary. If these two windings have unity turns ratio, then, since the current in the primary or gate winding during this hold-off period will have to supply its own exciting current as well as that for core B, the current in this gate winding will be proportional to $\mathbf{H}'+\mathbf{H}''$ or proportional to the total width of the operating minor hysteresis loop.

When the flux in core A reaches saturation density at 2′ of Fig. 8, this core fires. The $d\mathbf{B}/dt$ in core A then becomes zero, so no voltage will be induced in its control winding. Since the average voltage across capacitor C is only that required to overcome the relatively low resistance of the control circuit for the average value of control circuit current, the voltage now impressed upon the control winding of inductor B is relatively small, hence the flux in core B, which has been reset to a value corresponding to point 6, continues to reset at a very low rate to $\mathbf{B}'$ during the conduction period of core A. Since the $d\mathbf{B}/dt$ in core B is very low, the current in the control circuit drops to substantially that corresponding to the static loop during this period as shown at 3′ in Fig. 8(D).

During the next half-cycle the roles of the two inductors are reversed. While core B is holding off, core A is reset by current supplied by the control winding of inductor B to the control winding of inductor A. The current required to reset core A has the same amplitude and flows in the same direction in the control winding as it did when the control winding was supplying excitation to reset core B during the preceding half-cycle. As a result, the

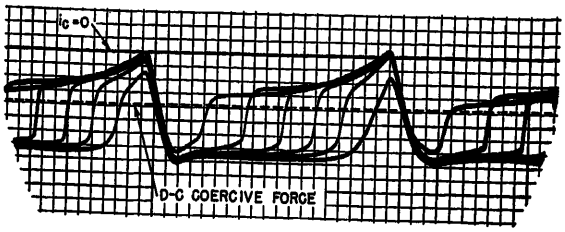

Fig. 13 (right). Composite oscillogram of current in low-impedance control circuit of doubler

current which flows in the control circuit during this half-cycle is as shown by points 4 through 7 to 0 in Fig. 8(D).

The effect of including a static hysteresis loop of finite width in the analysis of reference 5 is to shear the top of the control characteristic curve to the left by an amount which is proportional to the coercive force of the static loop. The values of load current and control current at cut-off would be unaffected. The gain would be a function of the difference between the dynamic coercive force and static coercive force.

Validity Checks

The operating minor hysteresis loops and current and voltage waveforms of experimental models of each of the magnetic amplifier circuits described in the foregoing were viewed on an oscilloscope screen. Vacuum-tube rectifiers were used for the experimental checks. The same specimen core of 0.002-inch Deltamax was used for all of these tests. Good correspondence was had between the idealized loops and experimental loops for cases employing a high-impedance control circuit.

Fig. 9 shows the major dynamic hysteresis loop and the operating minor hysteresis loop obtained for the simple half-wave circuit of Fig. 2 when firing at approximately 120 degrees. Similar shaped loops were obtained when this core was combined with a similar core to form the conventional full-wave d-c output circuits. The control characteristic curves, when normalized to an equivalent single-core basis, were practically identical with the control characteristic for the half-wave circuit. An analysis of the steady-state operation of the half-wave circuit is therefore applicable to single-phase magnetic amplifier circuits of the high-impedance control-circuit type when the normal output of the amplifier is direct current. The normal output of the doubler circuit is alternating current and the half-wave circuit analysis does not apply to it even though the a-c output is subsequently rectified.

Fig. 10 shows the major and operating minor hysteresis loops obtained for the doubler circuit of Fig. 4 when firing occurs at approximately 120 degrees. These should be compared with Fig. 5. The static coercive force of this specimen core was approximately 0.09 oersted and the dynamic coercive force at 60 cycles was approximately 0.17 oersted, a ratio of 1/1.9. The ratio of magnetomotive forces indicated between points 7' and **B**' to that at 5' as shown by the operating minor loop of Fig. 10 is 1/1.5. The lower ratio of the observed value is probably due to the slight widening, over the static loop, required in order to provide the small $d\mathbf{B}/dt$ called for during the period from 7' to **B**'.

When the doubler circuit of Fig. 7 was tested, the operating hysteresis loops were as shown by Fig. 11 for a 120-degree firing angle. Note that the bottom of the operating minor loops do not have the nick as was predicted by the assumed idealized conditions. Also, Fig. 12 shows that the control current during the conduction period of the gate winding does not remain constant as was predicted by the assumed idealized conditions. Both of these instances of poor correspondence between the predicted and actual results are due to the fact that postsaturation inductive effects were neglected. By neglecting this inductance, the voltage induced in the control coil of the saturated core was assumed to be zero during the saturation period. The control voltage was then assumed to be the only voltage acting upon the control circuit during the saturation period of each half-cycle. Fig. 12 shows that the current tends to decrease and may even reverse polarity during the saturation period. This is good evidence that during the latter half of each half-cycle the decreasing load current flowing in the gate winding induces a voltage in the control circuit which opposes the signal voltage and may be greater than the signal voltage. This actually causes the core being reset to lose a small amount of its maximum reset flux change during the saturation period, instead of gaining some as was predicted by the idealized assumptions. The amplitude of the instantaneous voltage induced in the control coil on the saturated core is a function of the slope of the **B-H** curve above the knee of the curve and of the instantaneous rate-of-change of load current. The amount of current which flows in the control circuit during this period is therefore dependent not only upon the control voltage and width of the static hysteresis loop but also upon the saturation-region inductance, load current, and inductance of the unsaturated control coil during this period. This latter inductance may be relatively low. The differential permeability of the core across the bottom of the minor hysteresis loop of rectangular loop materials is shown by Fig. 11 to be rather low. The unsaturated core is operating in this region when the saturated core is operating above the knee of its hysteresis loop.

It appears, therefore, that a rigorous analysis of self-saturated types of circuits having low control circuit impedances should include the effects of saturation-region inductance. This would include both the equivalent air-core inductance and the slope of the **B-H** curve above the knee of the curve. The differential permeability across the bottom of the minor loop also becomes an important factor to include in such an analysis. However, in spite of these limitations, the analysis of reference[5] has been shown to yield reasonably accurate results for materials such as grain-oriented silicon and overannealed Deltamax.

When the static hysteresis loop width of a very rectangular loop core material exceeds approximately 10 per cent of the dynamic loop width, a more rigorous analysis is required in order to predict with reasonable accuracy the control characteristic curve of magnetic amplifiers using such materials. Fig. 13 is a composite oscillogram of the control circuit current wave form, for representative Deltamax cores in the circuit of Fig. 7, when firing occurs at several different angles of delay. This indicates that an analysis which will predict the average value of current for each firing angle probably will be very difficult to achieve. Fig. 13 also demonstrates that both the dynamic and static hysteresis loops will be important factors in such an analysis.

Observations of the steady-state operating minor loops for other single-phase circuits of the low-impedance control-circuit type, such as the full-wave d-c output circuits, show only very minor deviations from those indicated by Fig. 11 for the doubler circuit.

Flux Preset High-Speed Magnetic Amplifiers

C. B. HOUSE
ASSOCIATE MEMBER AIEE

EARLY in 1951, R. A. Ramey prepared a paper[1] on magnetic amplifiers. In this and succeeding reports[1,2] on the same subject the theory and application of a new type of half-cycle response magnetic amplifier were developed. This amplifier depended upon square hysteresis loop magnetic materials for its proper operation, and the analysis in turn postulated square-loop materials.

Further development in the Naval Research Laboratory has resulted in the circuit being presented here. This circuit extends the benefits of the half-cycle response to circuits utilizing magnetic materials not possessing the square-loop characteristics, i.e., the ratio of remanent flux to saturation flux may possess any value between 1.0 and 0.0. The circuit therefore, removes the restriction upon magnetic materials heretofore existing, and broadens the range of application of the half-cycle response circuits to include such materials as grain-oriented silicon steels and molybdenum-nickel-iron alloys, which have previously been deemed unsuitable. As an important corollary benefit, the circuit will overcome the deleterious effects suffered in the half-cycle response circuits with square-loop materials when using rectifiers which do not possess perfect rectifying characteristics.

Background

In reference 1, Ramey discussed in detail the theory of operation and circuit details of an amplifier which inherently possesses high response speeds (essentially one half-cycle of the power supply voltage) and still permits large power gains. The complete development of that theory is not within the province of this paper but a brief resumé will be given here to provide a basis from which the reader may follow the further developments.

The basic half-wave form of the Ramey amplifier is shown in Fig. 1. The conventions used in this diagram are as given in the following:

The polarities shown for the voltage sources e_{ac} and e_{ac}' are instantaneous values.

The polarities of the windings are as indicated.

The rectangular symbol between the windings indicates that the core is composed of a magnetic material with a rectangular hysteresis loop, as shown in idealized form in Fig. 2.

The turns ratio may be any number desired, as long as the voltages e_{ac} and e_{ac}' possess the same ratio in the same order.

The voltage e_c is an unidirectional signal voltage.

In the first section of the analysis it will be assumed that e_c is zero and that the control terminals are short-circuited together. The action of the circuit will then be followed until a steady-state condition results.

In beginning a step-by-step analysis, first it may be assumed that at a time when the applied voltage wave e_{ac}, e_{ac}' is going through zero (Fig. 3, point 1) the core will possess a remanent flux of a polarity and value determined by the previous history of applied voltages. To simplify discussion it is further assumed that the core had been previously saturated in the plus direction and at time of zero applied voltage the flux level is resetting at point 1 in Fig. 2. (Further justification of this assumption is contained in reference 1.)

As e_{ac} and e_{ac}' increase with the polarities shown in Fig. 1, the current in the left-hand or control circuit will produce a magnetomotive force equal to one-half the hysteresis loop width. The applied voltage will then react upon the core and change its state (or demagnetize it). The amount of change will be a function of the applied voltage and in usual design, 1/2 cycle of applied e_{ac}' will carry the flux level to just below saturation in the negative direction (Fig. 2, point 2). During the period just discussed, the applied voltage e_{ac} on the right-hand, or load side, will be directed against the rectifier, and no current will flow on that side. This half-cycle is commonly termed the reset cycle.

The next half-cycle (which will be called the gating half-cycle) starts at point 2 of Fig. 3. At this time, the voltage polarities, shown in Fig. 1, will reverse, so that the voltage applied to the control side will be blocked by the rectifier. However, on the load side, magnetizing current will start flowing and the applied voltage will now start magnetizing the core in the plus direction. With the assumed values of voltage, the flux will be carried just to the knee in the positive direction by the end of this half-cycle of applied voltage and thus return to point 1 of Fig. 2. A steady-state condition has now been reached and this sequence of operation will continue as long as voltage is applied. Only magnetizing current will flow through the load, and the amplifier will be in the state of minimum output with the flux swinging from knee to knee

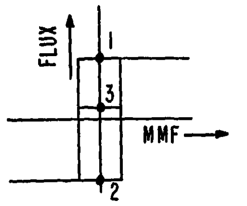

Fig. 2. Idealized hysteresis curve of a square-loop magnetic material

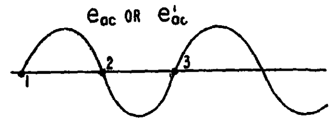

Fig. 3. Voltage wave of supply to magnetic amplifier

with no current greater than magnetizing current flowing.

Referring again to Fig. 1, it may be deduced that, during the half-cycle when e_{ac}' is applied through the control side, the total voltage applied to the core is the difference between e_{ac}' and e_c. If e_c is equal to zero, as has been previously assumed, the operation will be as explained. When e_c equals some finite value less than e_{ac}' the total voltage applied to the core on reset will be less than the voltage applied to the core in the previous half-cycle, and a new set of conditions will arise.

Under the new conditions the starting point for the analysis may remain the same; i.e., the applied voltage wave has gone through zero and the core flux is at position 1, on the hysteresis curve, Fig. 2, and the polarity of the applied voltage will become as shown in Fig. 1 in the next instant. The reset cycle is just beginning.

Since the time integral of the voltage applied to the core during the reset half-cycle will be less than the time integral of e_{ac}' the flux level will not be carried to point 2 on the hysteresis curve but will be changed only to some point part way down the loop (point 3) as determined by the net voltage time integral.

On the gating half-cycle the core will be able to absorb a voltage integral equal only to the net voltage integral applied on the reset cycle before it saturates and its impedance drops to zero. The load will then absorb the remaining voltage in the half-cycle, with current limited only by its impedance.

At point 3, Fig. 3, when the reset cycle starts, the core will again be at point 1, Fig. 2, and the cycle will repeat as before. The wave shape of the current through the load will be shown in Fig. 4.

Thus a magnetic amplifier has been described whose output power can respond to input signals within a half-cycle of the supply voltage. The time in the gating cycle at which the core saturates (or the firing angle) will be determined only by the net voltage time integral applied to the core on the reset half-cycle. If $\int_0^T(e_{ac}'-e_c)dt=0$, or a negative number, the core will not reset at all, and full output should be realized. It readily follows that the control element need not be a voltage, but that any device which controls the net voltage applied to the core on the reset half-cycle may be used.[2]

The foregoing discussion has assumed perfect square-loop core materials and perfect rectifiers. However, complications arise when magnetic materials which do not have a perfectly square hysteresis loop, and rectifiers which have back leakage, are used. L. J. Johnson has discussed these effects.[3] In his attack upon the problem he established a theoretically ideal transfer characteristic curve and compared this ideal curve with the actual curves obtained when using different core materials in otherwise similar magnetic amplifier circuits. In his discussion of the suitability of the different magnetic materials, he made the comparisons of curve shape and cited possible causes of the deviations from the ideal curve. Among the causes were the effects of low remanence and rectifier back leakage.

Low remanence permits the core to reset partially without regard to the control voltage. This uncontrolled reset will result in the core-absorbing part of the voltage integral during the gating half-cycle, and consequently the full half-cycle of the power voltage cannot be applied to the load when the control voltage dictates that it should. This effect will naturally become most prominent at the maximum output end of the transfer characteristic curve, and it manifests itself as a reduction in maximum load current available, as shown in Fig. 5.

Rectifier leakage in the load circuit during the reset half-cycle will allow a current to flow through the gating winding in such a direction as partially to reset the core, giving the same detrimental results at full output as low remanence. Again this result becomes most evident at the full output end of the curve since at low outputs the voltage in the control circuit is transformed into the load circuit in such a direction as to reduce the back voltage across the load rectifier and in turn reduce the back leakage. This result is also shown in Fig. 5. Of course, if the maximum leakage current is not as large as the magnetizing current requirements in a square-loop material, then this reset theoretically will not occur, according to this analysis.

However, during dynamic operation there are other reverse current phenomena in rectifiers that occur in addition to the rectifier leakage as measured using reverse d-c voltage. Conrath of Vickers, Inc., has suggested that there is a capacitive component of reverse current. In tests on Vickers selenium rectifiers, he established at 60 cycles an equivalent capacitance value of 0.02 microfarad per square centimeter of rectifying area. Observations at this laboratory suggest that these equivalent capacitance values may vary with manufacturers of selenium rectifiers.

Since leakage and capacity effects should increase with rectifier plate area and frequency (as qualitatively checked in experiments) it becomes evident that circuits which operate satisfactorily for small maximum load currents at 60 cycles may not give designed full output when operated at 400 cycles with large current capacity rectifiers.

Circuit Theory

As a specific remedy for some of the ills encountered in the Ramey high-speed response magnetic amplifier when using square-loop materials and to extend the benefits of that circuit to amplifiers using the nonsquare-loop material, the circuit shown in basic and general half-wave form in Fig. 6 was devised.

The notation in Fig. 6 is as follows:

The polarities indicated for e_{ac}, e_{ac}', e_{ac}'' (the alternating supply voltages) are in-

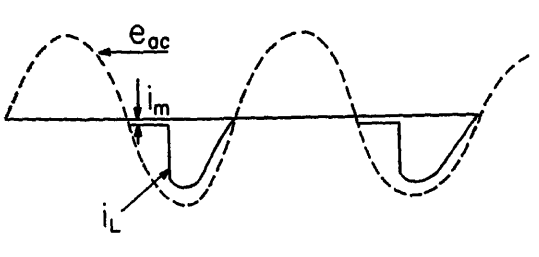

Fig. 4 (left). Current in load of half-wave magnetic amplifier

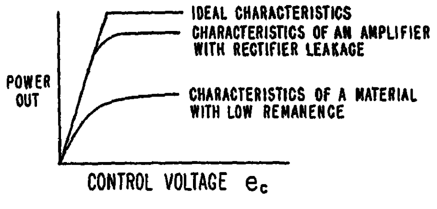
Fig. 5 (right). Transfer characteristics of half-cycle response magnetic amplifier using rectified alternating voltage control



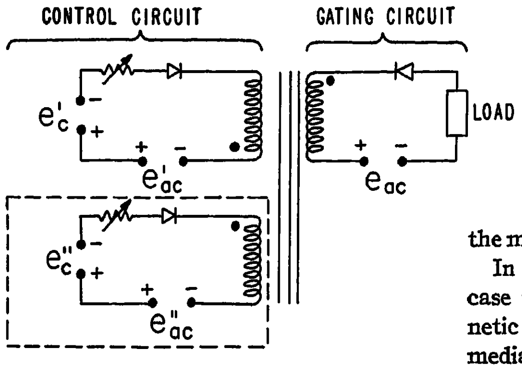


Fig. 6 (left). Half-cycle response magnetic amplifier using both resetting and presetting control circuits

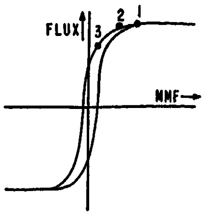
Fig. 7. Hysteresis curve for intermediate remanence magnetic material



stantaneous polarities. These voltages possess the same relation to each other as the turns on their respective windings.

The control voltages, e_c', and e_c'', may be direct current, rectified alternating current, resistance drop, or any other proposed method of amplifier control.

The polarities of the windings are as indicated.

It is apparent that this circuit, with the exception of the element contained within the dashed enclosure, is the circuit shown in Fig. 1. The power delivered to the load on the gating half-cycle is determined by the amount of reset dictated by the control circuit on the reset half-cycle.

It is also evident that the element within the dashed enclosure is similar to the Ramey control circuit in applied voltage polarity and rectifier polarity, so that it may assume functions of a control circuit. It differs, however, in that its winding polarity is opposite to that of the Ramey control circuit, i.e., current through one control circuit changes flux level in the core in a direction opposite to that produced by current flow in the other circuit.

It will become evident later that in most circuits there must be a resistance in series with both control sources. The exceptions are those cases where a fixed minimum or maximum output might be acceptable or where the ratios of remanent to maximum flux is either 1.0 or 0.0. The values of the control source resistance will be influenced by the type of core, the rectifiers, and the type of control used. The circuit is drawn as shown to present the most general case.

In discussing the operation, a specific case using a core which possesses magnetic hysteresis characteristics intermediate between square-loop material and material possessing no remanent magnetism (see Fig. 7) will be assumed. Reset will be resistance controlled (Fig. 8A). The polarities of the supply voltages e_{ac}, e_{ac}' and e_{ac}'' are shown as they will be during the gating half-cycle. In the discussion, the Ramey control circuit will be called the reset circuit and the control circuit added will be called the presetting circuit.

In the step-by-step analysis of what occurs in this circuit, it might assist the understanding of the operation if it is first emphasized that the action may be divided into five distinct stages of operation. The first stage will be postulated as the firing stage, and the next two stages merely cover the short transition period into the fourth stage where the important circuit reactions occur. For understanding the circuit, stages two and three could be ignored if certain minor anomalies in state between stages 1 and 4 were accepted. Stage 5 covers the prefiring period in the gating half-cycle. For continuity the different modes will be discussed in their order of occurrence rather than their order of importance.

In stage 1 the core has saturated and current is limited only by the load impedance. No change of the state of the core is involved. As the instantaneous voltage decreases in the gating half-cycle, the current in the load circuit decreases until it reaches a value equal to the saturation magnetizing current, point 1, Fig. 7.

Stage 2 then begins. As instantaneous a-c voltage continues to decrease there is a change of flux in the core which generates voltages e_t, e_t' and e_t'' at the terminals of the windings on the core. These voltages will have positive polarities at the undotted ends of the windings. Thus the generated voltages will be directed against the rectifier in the resetting circuit and with the rectifier in the presetting circuit. However, as long as $|e_t''|<|e_{ac}''|$ the net voltage in the presetting circuit will be against the rectifier. Since the net voltages in both control circuits are against their respective rectifiers, the only active element is the load circuit. The voltage equation for the active element during stage two will be

$$e_t + e_{a-c} - i_L R_L = 0 \tag{1}$$

During this stage the core will be partly demagnetized. When $e_t'' = e_{ac}''$ the rectifier in the presetting circuit will unblock and stage three begins.

During the third stage current flows in the presetting circuit and the load circuit as determined by the equations

$$e_t'' - e_{ac}'' - i_c'' R_c'' = 0 \tag{2}$$

$$e_t + e_{ac} - i_L R_L = 0 \tag{3}$$

$$N i_L + N'' i_c'' = N i_m \tag{4}$$

where N, N', and N'' are the turns in the power winding, reset winding and preset winding respectively, and i_m is the total magnetizing current referred to the load circuit coil. As this stage progresses, the core will continue to demagnetize with the magnetizing current shifting to the presetting circuit until the supply voltages have reversed polarity and e_{ac} rise to a value equal to e_t. By this time, the magnetizing current has transferred to the presetting circuit, so current ceases to flow in the load circuit and that circuit becomes inactive. Stage 3 now ends and

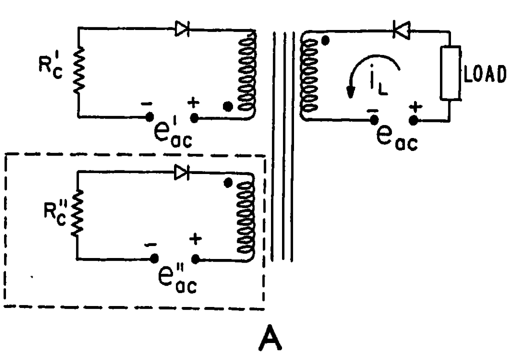


Fig. 8. Resistance controlled half-cycle-response magnetic amplifier

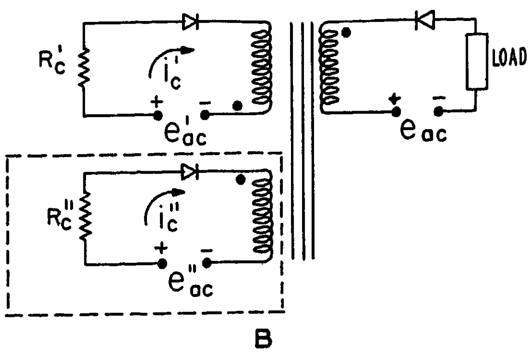
A (left). During gating half-cycle

B (right). During control half-cycle



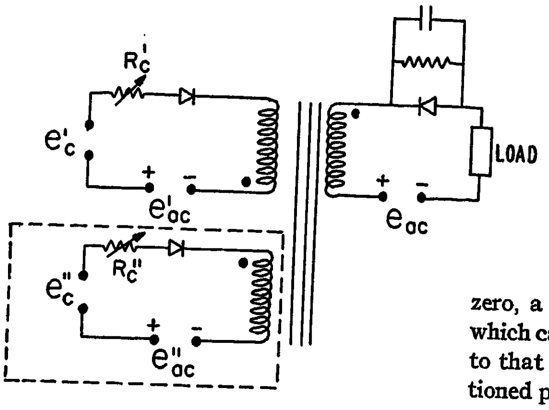


Fig. 9 (left). Magnetic amplifier with leaking power rectifier

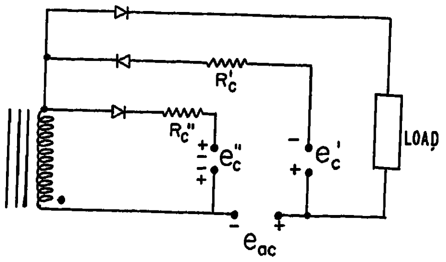
Fig. 10 (right). Single-winding half-wave magnetic amplifier incorporating both preset and reset circuit functions



the true resetting-presetting period will begin. At this time the core will be in a condition indicated by point 2, Fig. 7.

During stage 4, the polarities of the applied voltages will be as shown in Fig. 8(B). At the beginning of stage 4, $e_t' = e_{ac}'$, and e_{ac}' will continue to increase in absolute value faster than e_t' so the rectifier in the resetting circuit unblocks and starts to take part in the control of the core. Current is now flowing in both control circuits and the circuit equations become

$$e_{ac}' - e_t' - i_c' R_c' = 0 \qquad (5)$$

$$e_{ac}'' + e_t'' - i_c'' R_c'' = 0 \qquad (6)$$

$$N'' i_c'' - N' i_c' = N i_m \qquad (7)$$

From equations 5, 6, and 7, if 1:1:1 turns ratio exists and $e_{ac} = e_{ac}' = e_{ac}''$

$$e_t = e_{a-c} \frac{R_c'' - R_c'}{R_c'' + R_c'} + i_m \frac{R_c'' R_c'}{R_c'' + R_c'} \qquad (8)$$

It is in this stage that the state of the core at the end of the control cycle is determined by the relative values of the resistances. If the presetting circuit is open (R_c'' is very large), $e_t = e_{ac} + i_m R_c'$, and the resetting circuit will gain control to reset the core. This implies that e_t will not change sign during the control cycle. If the resetting circuit is open, $e_t = -e_{ac} + i_m R_c''$; and e_t will go through zero and change sign, as e_{ac} increases. Or, the core will go towards saturation. At the time when e_t goes through zero, the core state will have regressed down the hysteresis curve to point 3, Fig. 7, after which time the core will proceed towards saturation to point 1, Fig. 7. For least average current flow in the control circuit at full output, R_c'' should be chosen so that point 1, Fig. 7 is reached just at the end of the control half-cycle. Between these limits for R_c' and R_c'' the direction and amount of core flux change will be dependent upon the relative values of the control resistances.

Near the end of the control half-cycle, when the applied voltage approaches zero, a transition period will be entered which can be analyzed in a manner similar to that covered in stages 2 and 3 mentioned previously.

During this transition interval, magnetizing current will be gradually transferred to the load circuit. However, this period is so short, and the net applied voltage integral is so small, that there will be very little change of core state. At the end of this transition period the load circuit voltage will be acting upon the core, and the flux will start toward positive saturation from a point on the hysteresis curve essentially established during stage 4. When the integral of the voltage applied during the fifth stage is large enough, the core will saturate and drop out of the circuit. This returns the core to stage 1. For the more general case of resistance and/or voltage control, as shown in Fig. 6, the circuit equations developed in stage 4 will become

$$e_{ac}' - e_c' - e_t' - i_c' R_c' = 0 \qquad (9)$$

$$e_{ac}'' - e_c'' + e_t'' - i_c'' R_c'' = 0 \qquad (10)$$

$$N'' i_c'' - N' i_c' = N i_m \qquad (11)$$

So with 1:1:1 turns ratio and $e_{a-c} = e_{ac}' = e_{ac}''$

$$e_t = e_{ac} \frac{R_c'' - R_c'}{R_c'' + R_c'} + i_m \frac{R_c'' R_c'}{R_c'' + R_c'} + \frac{e_c'' R_c'}{R_c'' + R_c'} - \frac{e_c' R_c''}{R_c'' + R_c'} \qquad (12)$$

This equation is similar in form to that previously given, except that there are now four parameters which will influence the final state of the core at the end of the control half-cycle. This is now a magnetic amplifier whose condition at the beginning of the gating half-cycle has been completely predetermined in the previous half-cycle of applied voltage, and this control may take place independently of the core material used.

If the material is perfectly square-loop, the preset circuit may be open-circuited, and the reset will be controlled by the resistance (or voltage) in the reset circuit. If the material has zero remanence, the reset circuit may be omitted and the preset controlled by the resistance or voltage in the preset circuit. A material which has a remanence below maximum flux level and above zero flux level could use either or both control circuits depending upon the desired range of output and the core characteristics.

If both circuits are used, the presetting circuit can be adjusted to give maximum output power with no signal furnished, and then signal voltage in the resetting circuit can be supplied to change the output power. Or the resetting circuit can be adjusted to give minimum output with no signal, and the signal voltage in the presetting circuit will increase output power. If desired, control can be inserted in both circuits. Control of the amplifier may be by any of the commonly used methods with the restriction that under most circumstances the signal source must have either an external or internal series resistance.

Another source of benefits arising from the use of the circuit presented here is the compensation for rectifier back leakage when using square-loop material.

In many circuits with small magnetizing current requirements the back leakage through the power rectifier causes uncontrolled reset when no reset is desired. This condition is aggravated when larger power outputs are desired, as previously discussed. This uncontrolled reset is quite similar to the effect observed when the core material has a remanent flux less than maximum flux.

Fig. 9 shows the magnetic amplifier during the reset half-cycle. The d-c back leakage of the rectifier is portrayed as the resistor and the a-c dynamic leakage is portrayed as the capacitor in parallel with the power rectifier.

If it is assumed that the material is square-loop, and full output is desired, the first requirement is that the signal voltage, e_c', be equal and opposite to applied e_{a-c}' (if voltage control of reset is used).

Indicated polarities of the windings and applied a-c show that, if back leakage current of a greater value than the magnetizing current tries to flow in the load circuit, reset will occur which will not be under control of the reset winding.

But in the presetting circuit the generated voltage, e_t'', will be with the rectifier, and current can flow in the circuit, minimizing the amount of reset. In addition

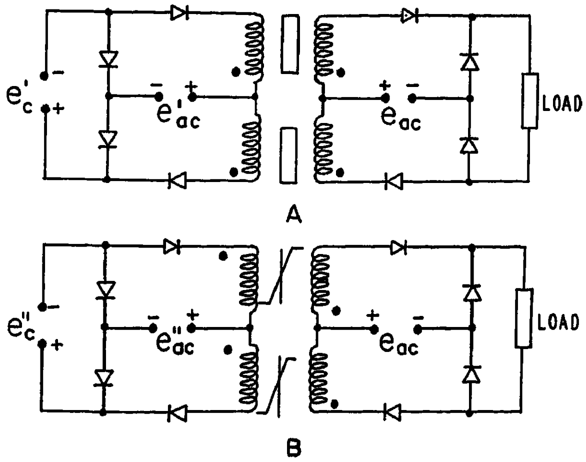


Fig. 11 (left). Full-wave magnetic amplifier

A. Using square-loop magnetic materials
B. Using zero-remanence magnetic materials

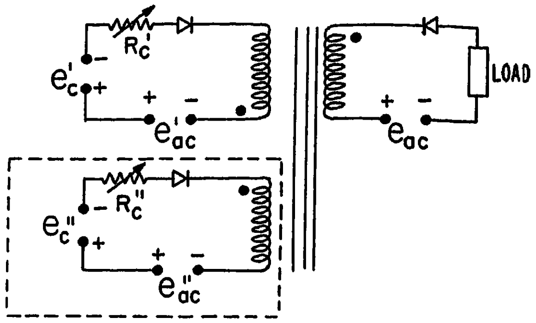

Fig. 13. Magnetic amplifier circuit used for obtaining transfer characteristics

the applied voltage, e_c'', can give a positive current flow in this winding in such a direction as to resist demagnetization of the core. If some reset of the cores does occur during the first part of the reset cycle from the capacitive component pulse of rectifier leakage, the current flow in the preset circuit, as forced by e_{ac}'', can reset the core to the saturation point and cause the core to be fully saturated when the power cycle begins. The full half-wave of voltage in the gating half-cycle will thus be made available to the load.

Although, to add clarity to the discussion, the circuit heretofore has been presented as though three separate windings were placed on the core, the circuit will operate in the same way if only one winding is used and the control circuits added to that winding as shown in Fig. 10. The circuit in Fig. 10 is not strictly analogous to that presented in Fig. 6, since e_{ac} is not placed in the presetting circuit, but its functions are taken over by e_c''. The relative polarity of the signal voltage in the presetting circuit, e_c'', appears ambiguous because it will depend upon core material and desired circuit operation; i.e., if the material is one with zero remanence, the resetting circuit would be omitted and the presetting polarity would be in such a direction as to buck the voltage generated by the flux collapse. If the material is square-loop with rectifier leakage, the polarity of the voltage e_c'' would be reversed to provide a positive presetting of the core to the saturated condition.

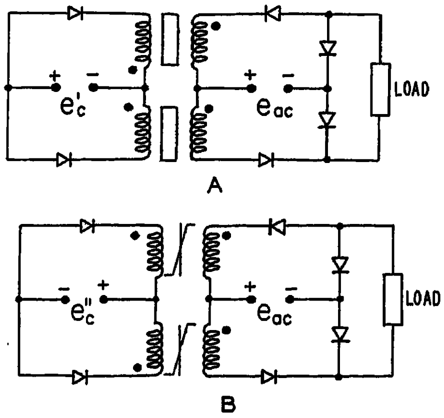

Fig. 12. Full-wave magnetic amplifier circuit

A. Using square-loop magnetic materials
B. Using zero remanence magnetic materials

The resetting-presetting circuits presented so far have been in the half-wave form. They may also be used in full-wave form with the stipulation that some types of control may require changes in the circuit configuration because of the possibility of disturbing voltages from one element acting upon the other element. It is emphasized that among other factors the approach to design of full wave circuits depends upon whether the material has square-loop or zero remanence characteristics. For example, the circuit given in Fig. 11(A) for square-loop material with d-c control appears similar to that given in Fig. 11(B) for zero remanence material, but closer examination shows different functions for the various voltages.

In Fig. 11(A), e_{ac}' will reset the core in absence of control voltage, e_c', giving zero output. However, in Fig. 11(B), e_{ac}'' has only the purpose of supplying a slight boost voltage to overcome IR losses in the presetting circuit. If zero resistance in the control circuit is assumed, e_{ac}'' should be zero.

In the absence of voltages e_c'' and e_{ac}'', in the control circuit, the zero remanence core in Fig. 11(B), which is on the presetting cycle, will generate a voltage causing the magnetizing current to circulate through the control winding. The core is now acting as an inductance with infinite time constant, and refusing to reset from the saturated condition. Maximum output current would be available to the load on the gating cycle.

As the control voltage, e_c'', increases, it will force the core to reset an amount equal to the voltage integral of the signal, until at full signal the output current would be equal to the magnetizing current.

A more dramatic illustration of the required difference in approach is shown in Figs. 12(A) and 12(B) for full-wave operation with d-c control. Although the circuits appear similar, examination shows that Fig. 12(A) will not operate because both cores are being acted upon simultaneously; and with element polarities as shown, there would be no alternation of reset between the two. However, with the circuit in Fig. 12(B), the flux collapse in one core during the time that core is being preset generates a voltage equal e_c'' (which voltage is blocked by the rectifier in the other core circuit). Thus full wave operation may be obtained with the zero remanence material with the circuit in Fig. 12(B), whereas a different circuit must be used for the square-loop material.

Reduction to Practice

As a check of the operation of this circuit, two toroidal cores of different hysteresis characteristics were wound and successively placed in the circuit shown in Fig. 13. Transfer characteristic curves were then obtained for these half-wave amplifiers.

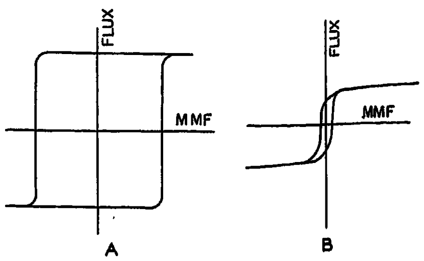

Fig. 14. Hysteresis curve

A. For core no. 1
B. For core no. 2

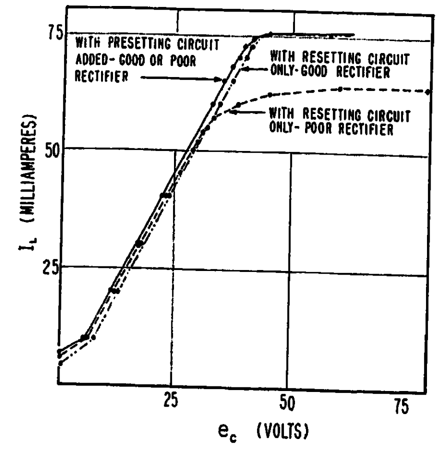

Fig. 15. Transfer characteristics for core no 1

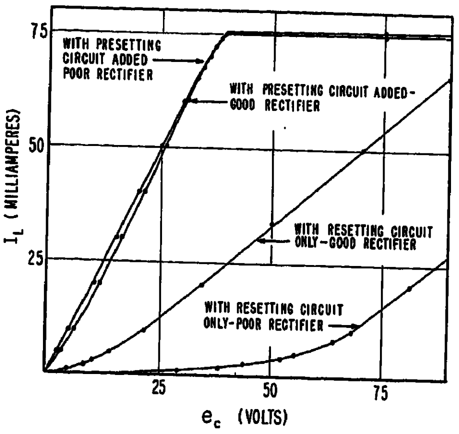

Fig. 16. Transfer characteristics for core no. 2

Core no. 1 was a grain-oriented silicon-iron material which has a relatively broad square-loop, with a published coercive force of 0.2 to 0.4 oersteds and a maximum flux density of 14,000–15,000 gauss. Core no. 2 was an alloy of 5 per cent molybdenum and 79 per cent nickel, with a relatively narrow hysteresis loop of 0.02 to 0.04 oersteds, a maximum flux density of approximately 6,600 gauss and a remanent flux density of approximately 5,000 gauss. The relative size and shape of the hysteresis loops are shown in Figs. 14(A) and 14(B).

Rectifiers were of a selenium 4-plate half-wave type, rated at 0.25 ampere. However, during the tests involving the effects of poor rectifiers a selenium rectifier of the same rating from a different manufacturer was placed in the load circuit. In this discussion "poor rectifier" means only that back leakage effects are greater, with deleterious effects on the action of the magnetic amplifier.

Each core was wound so as to saturate at 40 volts, 60 cycles alternating current. The circuits were arranged as half-wave amplifiers with rectified alternating voltage control, since this type of control gives a straight-line transfer characteristic curve when the amplifier is operating properly. Thus any deviations from the ideal curve may be easily noticed. This type of control was used in reference 3.

Tests were first run using the resetting circuit only (presetting winding open). Then the presetting circuit was closed with a resistance in series of a proper value to give full output when the net resetting voltage in the resetting circuit was zero, and the test runs repeated. The next step was to take readings using the resetting circuit only, after inserting a rectifier which was not as suitable for the circuit. This run was then repeated after the presetting winding was placed in the circuits.

Fig. 15 shows the results obtained while using core no. 1. It may be observed that the original transfer characteristic for this core approximated quite closely the ideal curve as shown in Fig. 5. However, when the poor rectifier was substituted in the power circuit, the maximum output decreased considerably and a curve was introduced at the knee. When the presetting circuit was added to the core, the curve returned to its former shape and the maximum output increased to its previous value.

Figure 16 shows the results obtained while using core no. 2. It is seen that while using the resetting circuit only the transfer characteristic does not approach the ideal curve even with good rectifiers, and it is also seen that the curve is seriously affected by the type of rectifier. When the presetting winding is added, the transfer characteristic curve again duplicates the transfer characteristic obtained using a square-loop material and good rectifiers, exclusive of the rectifier type. This is also shown in Fig. 16.

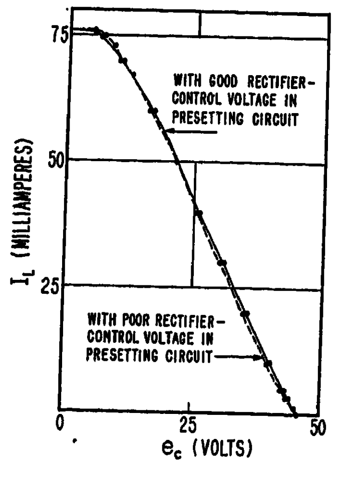

Fig. 17. Transfer characteristics of core no. 2 with control voltage in presetting circuit

The next concern was the operation of the circuit when the control voltage was inserted in the presetting circuit. The circuit is initially adjusted by varying values of R_c' and R_c'' so that no reset occurs when the control voltage e_c'' is zero and full reset occurs when control voltage is equal to e_{ac}''. With this method full output occurs with zero control voltage, as is shown by transfer characteristic curves in Fig. 17. Again it may be noted that little difference is evident in the curve regardless of whether the poor or the good rectifier is used in the power circuit.

As another example of the versatility of this circuit, it was decided to insert the control voltage in the presetting circuit so as to give zero output with zero control voltage. e_{ac}'' was omitted in the presetting circuit and the reset circuit resistance value adjusted to give full reset with zero control voltage. Then, as the control voltage was increased, the output increased (see Fig. 18). These curves have the same general slope as those in Fig. 17 with reversed sign.

As may not be surprising, these improvements have not been realized without some penalties. In this case it is evident, both from the equations and from intuition, that the input current on the reset cycle must be increased since from equation 7 $N''i''_c - N'i'_c = Ni_m$ and the relative values of i_c' and i_c'' will be determined by R_c' and R_c'' whose values in turn will depend upon core material and rectifiers used. Practically, however, the increased input power requirement is not detrimental in many cases. This is especially true where resistance control is used. If R_c' and R_c'' are caused to vary individually, the circuit requirements are such that either the reset or preset circuit

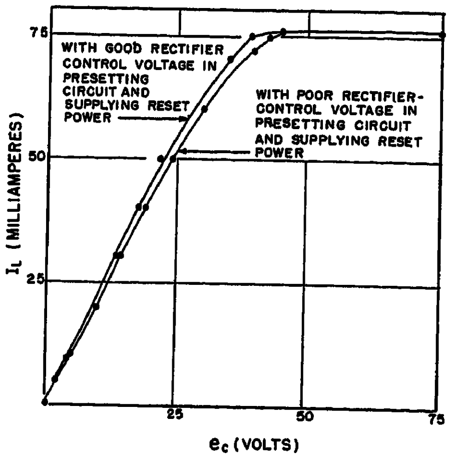

Fig. 18. Transfer characteristics of core no. 2 with control voltage in presetting circuit and supplying power

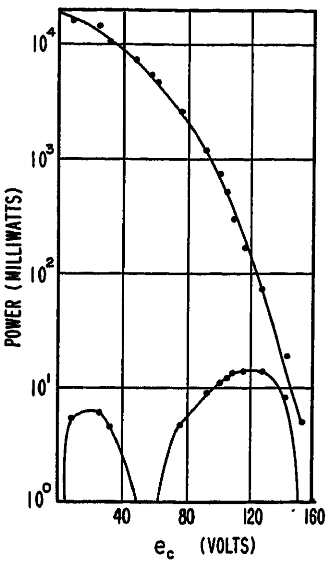

Fig. 19 (left). Power relationships in magnetic amplifier circuit

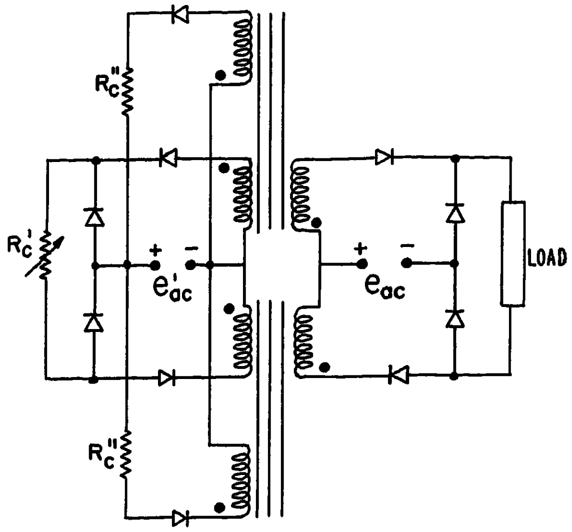

Fig. 20 (right). Full-wave magnetic amplifier circuit for exciter

will be effectively open when the other element is controlling the amplifier. Consequently the input power requirements have not been increased. However, if it is desired to leave one resistance fixed, and to vary the resistance in the other element, power requirement increases will still be well within practical limits. For outputs of many watts the input current can still be only a few milliamperes.

Rather than discuss the amplifier in terms of power gains (which can become a difficult subject when examining the half-cycle response circuit) the curves in Fig. 19 present the input power and output power for increasing signal voltage as obtained on a 5-79-molybdenum nickel alloy core with resistance load and rectified alternating voltage control in a half-wave circuit. It is realized that there are many ways of presenting power gain in amplifiers, but in this discussion input power is presented as the average current through the signal source, multiplied by the voltage generated by the signal source. Output power is calculated as average load current squared, multiplied by the load resistance. Average reading meters (d-c instruments) were used for instrumentation. The ordinate, it will be noted, is a logarithmic scale. The odd shape of the power input curve results from the method of control and the circuitry employed. The circuit was so arranged that maximum output was obtained at zero control voltage. Under the condition for maximum output the average current through the signal source was flowing in one direction. As the signal voltage was increased, the average current went through zero and reversed direction. It then increased in the opposite direction for a while before it started decreasing again to zero. No claim is made that circuit elements used were the optimum for high power gain. The results are merely presented as an example.

The circuit presented herein has proved its practicability when incorporated in a resistance controlled exciter using magnetic amplifiers with nominally square-loop materials. The circuit used is shown in Fig. 20. Originally maximum output current in the power circuit could not be obtained because uncontrolled reset occurred before addition of the presetting circuit. Maximum available current in the load circuit was increased by 70 per cent with its addition. In furtherance of the previous contention that, although input current requirements are increased, the current will remain within practical limits, it was noted in this case that when the available output current was increased to 3.4 amperes maximum, the maximum current in the control circuit was still less than 9 milliamperes at zero output. This condition entailed maximum input current requirements.

Conclusions

The circuit here presented is a general circuit for half-cycle response time magnetic amplifiers. It permits the use of magnetic materials which possess ratios of remanent flux to maximum flux of values between 1.0 and 0.0 in half-cycle response amplifiers. It may be said that this circuit presents a general class of amplifiers of which the half-cycle response amplifiers using square-loop material previously reported upon represent a special case. Another special case would be the use of magnetic materials with zero remanence in half-cycle response amplifiers. This circuit encompasses both cases, and provides for the use of materials possessing intermediate characteristics.

In addition, compensation for some defects encountered in the special case amplifiers using practical circuit elements may be achieved with this circuit. Among these defects are those caused by some loss in remanent magnetism in square-loop materials, or some residual magnetism in saturable inductance materials. Related to these effects and similar in nature are those caused by rectifier back leakage. These two effects may be simultaneously compensated for in this amplifier.

In general, the input power is an inverse function of the maximum resistances which may be placed in the control circuits. As a consequence, the input power requirements will decrease as the remanent flux level approaches either zero or maximum flux level, all other factors remaining constant.

The foregoing factor leads to the conclusion that if narrow hysteresis loop materials could be manufactured with zero remanent flux level, the half-cycle response circuits could be designed with a much lower input power requirement than the present square-loop materials. Preliminary work is being conducted on a system which will use magnetic materials with low coercive force requirements such as are commercially available. The zero remanence condition which is desirable for low input power will be simulated by introducing a constant current bias.

However, it must be realized that this circuit is not an absolute panacea. Although its use will enable full power output in amplifiers employing non-square-loop magnetic materials, and leaky power circuit rectifiers, the input power requirements may be raised.

The circuit responds best as far as power gain is concerned when resistance control is used but it is perfectly feasible to use voltage control or any of the methods of control that were previously cited.

The circuit is versatile in that the control voltage may be inserted in either the presetting circuit or the resetting circuit, with full output at either zero or full control voltage, as arranged by the designer's choice of components. The circuit may even be arranged so that different control voltages are inserted in the two circuits providing the restrictions as to source impedance are followed.

The Measurement of Random Monochrome Video Interference

J. M. BARSTOW
MEMBER AIEE

H. N. CHRISTOPHER
NONMEMBER AIEE

ONE OF the important factors in the design and maintenance of television transmission circuits is random interference, sometimes referred to as random noise. Much of this type of interference originates in the input stages of amplifiers but it may also originate in the line or in other parts of the transmission path. These noise components are greatly modified by circuit equalization which may vary from a few decibels (db) to possibly 27 or more db per octave. Thus the transmission engineer is confronted with the problem of evaluating random interference having different energy levels, per cycle, over the television bandwidth. Before noise evaluations can be made, information must be obtained by subjective tests on the interfering effect of broad, narrow, and mixed bands of random noise distributed throughout the television band.

Out of the work associated with such tests comes a reasonable question, "Cannot random interference be measured in such a way that equal measurements will mean approximately equal interfering effect, regardless of the frequency composition of the noise?"

This question may be reasonably divided into two parts:

1. What is the weighting or relative importance of random interference in different parts of the video spectrum?

2. Does the human visual mechanism sum up the interference effects of random noise in various parts of the video spectrum in such a way that the over-all effect can be uniquely related to an over-all measurement, made with equipment that is not too complicated?

Preliminary answers to these questions are given in the following sections of this paper. The answers are called preliminary because it is obvious that they depend to a large extent on the equipment used in making the judgment tests, and this equipment is undergoing constant change as the television art advances. At present, it is believed that a stage has been reached at which results of the type involved will be useful over a sufficiently long period to make publication worth while.

Others have considered this problem and have deduced approximate results by rationalizing a relatively small number of subjective measurements with related work involving photographic reproduction processes.[1,2] The test results given here, however, are purely experimental and seem sufficient in scope and numbers to warrant conclusions. Although they confirm, in part, the general characteristics of random noise weighting previously estimated, they are independent of any thus far published.

Summary of Results

The frequency weighting derived from the judgment tests is given in Fig. 1. This weighting is for use with a simple power-summing measuring device.

The general principles derived from the tests may be summarized as follows:

1. Low-frequency noise is judged much more interfering than high-frequency noise of equal power.

2. A given amount of noise power is judged more objectionable if it is concentrated in a narrow band than if it is spread out over a wider band in the same frequency region.

3. Human vision in combination with the present television monitors does not precisely sum weighted noise powers in arriving at an over-all assessment of the interfering effect of random noise bands. However, a reasonable compromise can be obtained with weighting applied to a power meter. In the region of 7 db above threshold, average errors of the order of 1 db with maximum errors of 2 db will obtain.

4. At frequencies above 4.5 megacycles (mc) an unexpected effect was observed called sparkle effect. When the total noise power is contained in the region above 4 mc, sharp points of light of very brief duration appear on the raster. It is believed that this effect is the result of the random occurrence of high peak potentials in the random noise which produce the sharp points of light on the raster before the extremely fine-grain noise effect becomes visible. The sparkle effect tends to flatten the weighting above 4 mc.

Subjective Test Conditions

The objective in setting up the test conditions was to simulate somewhat more severe viewing conditions than are usually encountered in the home. The test results were obtained by a jury of observers viewing the raster from a distance of four times the picture height. The raster was adjusted to 6 by 8 inches and was viewed in almost total darkness (ambient about 0.0025-foot lambert). The jurors were subjected one at a time to the test conditions, and for most tests three juries of 10 observers each were employed. The three juries had members in common, there being 14 different jurors used in all.

The test setup is illustrated schematically in Fig. 2. A test consisted of having the juror compare the judgment criterion (7.22 mc low-pass band of flat noise at about 7 db above the threshold of visibility) with a test noise obtained by

Paper 53-356, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B.C., Canada, September 1–4, 1953. Manuscript submitted June 3, 1953; made available for printing July 13, 1953.

J. M. Barstow and H. N. Christopher are with the Bell Telephone Laboratories, Inc., New York, N. Y.

The authors wish to acknowledge the very able assistance given by A. D. Fowler of the Bell Telephone Laboratories, Inc., in reviewing the test results and providing valuable comments during the preparation of the material for this paper.

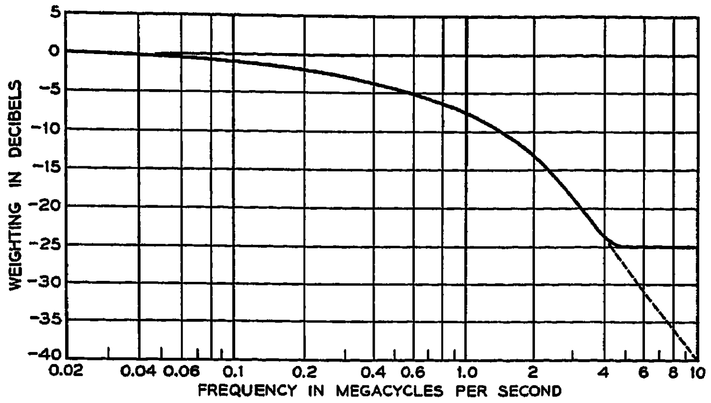

Fig. 1. Random noise weighting for monochrome television

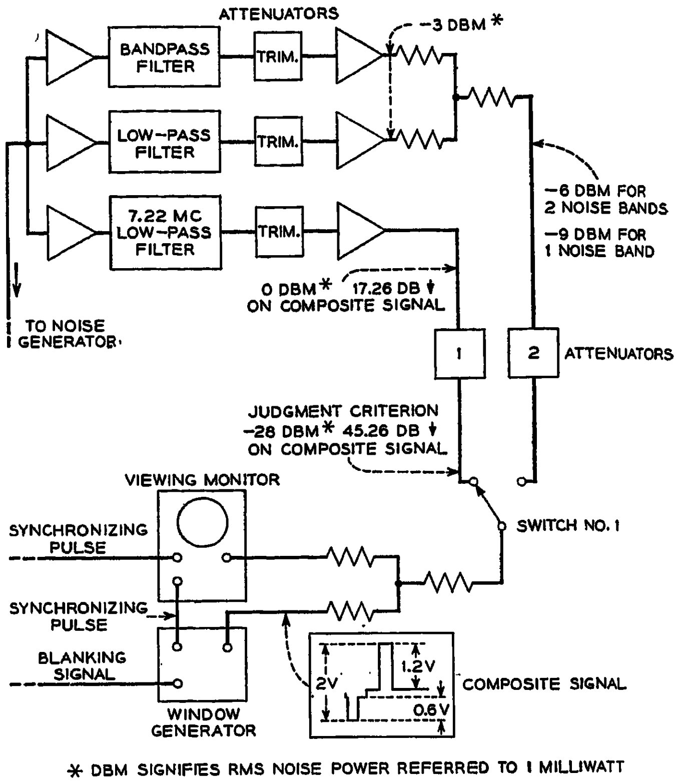

Fig. 2 (right). Circuit used to determine the relative interfering effect of discrete bands of random noise

passing a wide band of flat noise through either a bandpass or a low-pass filter. The test level of about 7 db above the threshold of visibility (45.26 db below peak-to-peak composite signal) was chosen for the reference condition because it is in the region of a tolerable noise level, and therefore information on methods of measurement which apply to it would be most useful. (Zero db obtain when the ratio of rms noise volts to composite signal voltage, peak to peak, =1). The observer was permitted to switch (switch 1, Fig. 2) from one condition to the other at will, and was instructed to ask the test operator to raise or lower the level of the test noise as required to obtain interference equality in his judgment. The circuit arrangement of Fig. 2 also permitted the mixing of two noise bands in different parts of the video spectrum for test.

In the early stages of noise tests, picture slides were used as subject material. It was soon observed, however, that the jurors were basing their judgments on the noise in middle gray areas of the picture and check tests were made on wholly gray areas to corroborate this observation. Subsequently the tests were made on wholly gray areas without the picture. This technique permitted the raster to be generated electronically without the use of a scanner, and thus provided essentially a noise-free raster, a feature greatly desired in noise studies.

It was found that about equal results were obtained over a range of gray areas varying in brightness from about 0.3-foot- to 0.6-foot lambert.

The types of random noise tested varied from very wide-band noise (7.22-mc reference condition) to narrow bands only 40 kc wide. Although no band used was narrow enough to produce definite line patterns on the raster, some bands were sufficiently narrow to produce fleeting appearances of herring bone patterns.

The tests on noises having two bands in different parts of the spectrum were made, to obtain additional evidence on the rule of combination of interfering effects as summed up by human vision. Noises typical of those encountered on standard transmission facilities were also included in the tests.

All viewing was on a laboratory monitor equipped with an *1816 P4* kinescope. The kinescope anode was operated at 11 kv and the associated video amplifier was substantially distortionless to above 15 mc. The simulated picture signals were in accordance with the present United States standard of 525 lines, 60 fields per second, 30 frames per second, with alternate field interlace.

The electrical transmission circuits were uniform in their response up to about 8 mc. This means that the monitor was superior to present-day broadcast television receivers in its response in the 0-4.3-mc range, and very much more uniform in response in the range of 4.3-8 mc. The monitor and associated circuits were made good in this high range to permit extension of the information on relative interfering effect toward 8 mc. Hence, it is believed the weighting and measuring methods to be described apply to the present standard monochrome system up to 4.3 mc, and give some indication of the weighting which should be applied to interference on wider circuits used for kinescope recording and wide-band theatre television employing 525-line 15,750-lines-per-second standards.

Discussion of Results

The results of the tests are shown in Figs. 1, 3, 4, 5 and 6, and Tables I to III.

* The indicated powers were judged to have the same interfering effect as the 7.22-mc flat noise band used as a judgment criterion $20 \log_{10} \frac{\text{Rms noise volts}}{\text{Peak-to-peak composite signal volts}} = -45.26$ db

Fig. 3 shows the magnitudes of unweighted noise powers in the bands of noise which were judged to be equally interfering. The bandwidths indicated were selected to be narrow with respect to the full band but not narrow enough to cause bar pattern effects. The total power in each band is shown plotted near the center of each band. The point representing the total power in each band is the integral of the power per kilocycle over the area defined by the frequency boundaries of each band. For simplicity and ease of computation, the filter characteristics have been idealized. This figure shows that more power is required at high than at low frequencies to produce a given interfering effect. The inverse of the shape revealed by the total power points is very nearly equal to the shape of the weighting given in Fig. 1.

The unweighted power in the low-pass reference band is indicated in Fig. 3 by a point plotted at 7.22 mc, the upper edge of this band. This level is 45.26 db below the peak-to-peak composite signal. Because of the unsymmetrical nature of television video signals, it has become customary to refer to the signal in terms of the peak-to-peak magnitude (picture plus sync) while the noise is expressed in rms magnitudes.

Figs. 4 and 5 show the unweighted powers in low-pass noise bands which were judged to be equally interfering. These data were obtained approximately 1 year apart and, although two setups and slightly different noise bands were used, the data are in very good agreement. The total unweighted powers are plotted at the upper edge of the low-pass bands in these figures. Considering the rate of increase in the total noise power required to produce the reference interfering effect as the bandwidth is increased, these data show again that on a per-cycle basis, high-frequency noise power does not contribute as much to interfering effect as does low-frequency noise power. In these figures the inverse shape formed by the total power points does not approximate the best weighting shape. This may be better understood when it is pointed out that in an area where a positive slope of 3 db per octave is attained, the noise powers in that area would be contributing nothing to the interfering effect. This slope is very nearly attained in the 2-to-7-mc region.

The horizontal lines showing the noise power per 10 kc in each band may be used to yield information on weighting also. A negative slope of 3 db in power level indicated by these lines, per octave of total

bandwidth would indicate a frequency region in which the weighting is constant. The lower two or three low-pass bands approach such a region.

It is interesting to observe the powers per 10 kc in the low-pass bands having upper edges above 1 mc. These powers per 10 kc are nearly constant, indicating that, in the presence of the low-frequency noise power, the high frequencies are contributing little to the observed interfering effect. In some of the earlier work on the interfering effect of flat random noise, tests were made by starting with a 4-mc band and gradually reducing its width towards 1 mc, maintaining the power-per-kc constant. The observations showed that no appreciable change in interfering effect was produced. The present data of Figs. 4 and 5 are in complete accord with these findings but they also show a marked increase in the interfering effect of noise in the region below 1 mc. The early tests were not carried far enough to divulge this information.

Table I shows the magnitudes of the unweighted noise powers plotted in Figs. 3, 4, and 5.

Fig. 6 shows three weighting curves, one derived from the bandpass data, another derived from the low-pass data and a third or compromise curve drawn in between the other two. An explanation of the derivation of the top and bottom curves is given in the Appendix.

The uppermost curve, derived from bandpass noises, extends down to only about 300 kc, since adequate data were not taken on bands below this frequency. The bottom curve, derived from low-pass data, is not shown beyond 1.3 mc because in the presence of low-frequency interference, the determination of the position of the high-frequency end of the curve is subject to large errors, and hence there is considerable uncertainty as to its proper level, based on the low-pass data alone.

The curves are so placed on the db scale that if the top curve is used for the bandpass noises and the bottom curve for the low-pass noises, computed weighted noise powers turn out to be approximately equal when the interferences were judged to be equal by the jury of observers.

It is obviously impracticable to employ one weighting and calibration for low-pass interference and another weighting

† The power in the combined bands was judged to equal the interfering effect of the 7.22-mc low-pass band used as a reference or judgment criterion.

and calibration for bandpass interference. Hence, a compromise is necessary if the summation of weighted power is used as an indication of interfering effect.

At this point it should be noted that the different positions of the two curves reveal that for the interference levels tested, human vision does not sum the weighted interference powers over the band in assessing over-all interfering effect. The relative positions of the curves indicate that a given amount of noise power is more interfering if it is concentrated in a narrow band (bandpass data) than if it is spread out over a wider band (low-pass data) in the same frequency region.

Consideration of the interfering effects of narrow- and wide-band noises, having the same power, in the same general frequency region, indicates that the average observer saw something that caused him to rate the narrow bands more interfering. It is a fact that narrow bands tend to produce fleeting patterns not very unlike herringbone effects. If the band could be made progressively narrower until only a single frequency was passed, bar patterns would result. In other words, the narrower the band, the less random the noise effect and hence the more objectionable it becomes. This is apparently one of the causes for the displacement of the two weighting curves, derived for low-pass and bandpass noises, shown in Fig. 6.

Theorizing further on the observations, and noting that they were made at levels only a few db (about 7) above threshold, it appears reasonable that if the noise power in a narrow band at this level were redistributed over a much wider band, the resulting noise power per cycle might easily be so low as to be barely above threshold, or even slightly below threshold. Under these conditions a balance between the interfering effects would be obtained only by raising the power in the wide-band noise relative to that in the narrow-band noise. This reasoning offers a further explanation of the observed results.

The curve plotted between the two outside curves in Fig. 6 is a compromise weighting which produces nearly constant computed weighted powers when different shapes of random interference are adjusted to be equally interfering by competent jurors. The philosophy involved in drawing this curve between the other two may be described as follows: At low frequencies, where the only evidence available is from noise obtained through low-pass filters, the compromise curve is near the low-pass curve. At high frequencies where the low-pass data gives very poor evidence of what the weighting should be, the compromise curve is drawn near the bandpass curve. This is done not only because the best evidence on what the weighting should be at high frequencies is obtained from the bandpass data, but also because in actual practice most random noises are tipped up to some extent, and therefore approach, in the limit, bandpass noise having high noise power per cycle near the upper edge of the band. It would appear that full weight should be given to high-frequency noise when it occurs in this manner.

Fig. 7 shows the computed interference magnitudes for the series of random noises that were used in the course of these experiments. Each position along the abscissa presents a given noise, which is briefly described as regards frequency composition. A more complete description of each noise is given in Table 2, together with numerical magnitudes of the data plotted in Fig. 7. The computed magnitude using the compromise weighting is shown as the ordinate. Since all noises were judged to be equally interfering by jurors, the departure of the respective computed values from a constant average value represents the errors which might be expected from a meter designed to sum the weighted power according to the compromise weighting in Fig. 6.

An examination of Fig. 7 shows that narrow-band noises will in general be underweighted (the meter will read too low), and broad bands will be overweighted (the meter will read too high).

The rms deviation of the db magnitudes shown in Fig. 2 from the average value is 1.42 db. This may be compared to the rms deviation from the mean of all observer judgments on the various noises. The latter figure is 1.45 db. From this it may be seen that the meter error (assuming the mean judgment of the jurors to be correct in every case) is of about the same order of magnitude as the observer deviation.

Sparkle Effect

Fig. 1 shows two weightings for the area above 4 mc. The lower weighting is an extrapolation of the weighting determined by the judgment tests for frequencies below 4 mc, while the upper weighting more nearly represents the weighting determined by judgment tests on the noise band in the 4–8-mc region.

The appearance of noise as observed on a picture tube varies enormously, depending upon the frequency composition. Very low-frequency noise creates a streaky, nebulous effect that is judged most annoying. As the frequency increases, the disturbance resembles photographic grain in which the individual grains have random motion and become finer and finer as the frequency increases. As the grain becomes finer, the input noise level must be increased to keep the fine grain visible. In the vicinity of 4.5 mc an abrupt change occurs. The face of the picture tube now appears specked with minute points of light that endure for a fleeting instant and then disappear. This sparkling causes the observer evaluation to flatten out above 4.5 mc. It occurs only when the total noise energy is contained in the area above 4.5 mc. This effect appears related to the random oc-

currence of peak potentials in the random noise source and to the effect of these potentials on the kinescope. The output of the noise generator was examined periodically with an oscilloscope for evidence of clipping. These measurements indicated the output of the noise generator to have a peak factor of 14 db (peak noise volts to rms noise volts) and showed no evidence of clipping.

Overloading of the amplifiers external to the viewing monitor, Fig. 2, tended to change the appearance of the sparkling. The minute bright areas became elongated and more nearly resembled short dashes of light. This change in character made it possible to differentiate between the true sparkle effect and overloading of the amplifiers. Three different *1816 P4* kinescopes showed the sparkle effect. This suggests that the effect is characteristic of the kinescope.

The interpretation of this result on design standards is of importance. If a situation arises in which the expected noise is all in the region above 4 mc, the upper weighting curve should be employed, since the noise cannot be permitted to break through the threshold of the sparkle effect. If the expected noise is spread out over the low as well as the high frequencies, it would be permissible to use the lower curve, since the contribution of the high frequencies (when they are below the threshold of the sparkle effect) is negligibly low and is probably most accurately assessed by application of this weighting. As a practical matter, on general types of noises, it would probably not matter what curve is used, since the sparkle effect begins at levels over 25 db higher than the threshold of interference in the low-frequency regions.

Two-Band Noise Tests

Each 2-band noise was made up of a low-pass band (cutoff low on the frequency scale) and a high-frequency bandpass band. The levels of each were adjusted to be equally interfering. The observations were made in the same manner employed for the 1-band tests described earlier and shown schematically in Fig. 2. Ten observers were employed. Table III gives the results of these tests and indicates the weighted power in the 2-band noises were from 1 to 1.4 db smaller than the weighted power in the judgment criterion. These results substantiate the general results presented here as regards the magnitudes of the deviations expected. More specifically, the added bands fall in the category of narrow bands and thus should be underweighted by the compromise weighting, as shown in Figs. 6 and 7, and as is evident in the results.

Conclusion

The results of the experiments described have indicated that random television interference can be measured with a power meter having frequency weighting, with sufficient accuracy to be of value in the design and maintenance of television transmission circuits.

The relationship between the quantity measured and the subjective effect is not precisely unique but the order of magnitude of the errors is about the same for the weighted power meter as were the rms deviations of the observer data. Useful design and maintenance standards can be set up in terms of meter readings at given level points on transmission circuits.

Appendix. Weighting from Bandpass and Low-Pass Data

Bandpass Data

The derivation of a frequency weighting from the bandpass data shown in Fig. 3 is given in Table IV. In the table, column 1 shows the mid-frequencies of the respective bands, and column 2 the full bandwidths. Column 3 gives the total power in each band in db relative to the power in the first band when each noise was adjusted to have the reference interfering effect. In column 4 corrected frequency figures are given. These figures are very nearly the same as the figures in column 1 (mid-band frequencies) but slightly different because, if an appreciable slope in the weighting occurs over one of the given bands of noise, it is apparent that the center-of-interference of that band is not the arithmetic center of the band. Since it was desired to plot the weightings at the center-of-interference of each band, a small frequency correction was calculated whenever the db weighting across the band changed by 2 db or more. The figures in columns 3 and 4, when plotted, give the desired shape of the weighting. This is the shape given in the top curve of Fig. 6. As indicated in the text, the position of the curve on the db scale was determined by adjustment, to produce calculated magnitudes of noise from the bandpass data that were equal to the magnitudes of the low-pass noises calculated from the bottom curve.

Low-Pass Data

The calculation of weighting from the low-pass data yields results which are considerably more inaccurate than those obtained from the bandpass data, especially in the frequency regions above 500 kc. This is because all the judgments from which weightings may be calculated were made in the presence of low-frequency noise which has been shown to be more interfering, per cycle, than high-frequency noise. Hence, small differences in the opinions of observers in the levels producing equal interfering effects result in very large differences in the estimated weightings for the frequency regions above the very lowest employed.

A very effective method of weighting derivation is the cut-and-try method. This, however, usually involves several unsuccessful attempts and is correspondingly tedious because of the computations involved. Hence, a method of obtaining an initial curve from the data was worked out and a sample is carried out in Table V for the data given in Fig. 4.

The principle involved in making the calculation was that each noise should be required, through the application of a calculated weighting, to produce a weighted power sum of unity, since each was judged to be equally interfering. A weighting of 0 db was assumed to apply all across the lowest band (40 kc wide). In the next wider band a 0-db weighting was assumed to hold over that portion common to the lowest band, and a lesser weighting calculated for the remainder of the bandwidth such that the total weighted sum of the power for the noise came out to be unity also.

For the third band the portion common to the second band was effectively treated with the two weightings previously derived and the remainder, in excess over the width of the second noise, was operated upon by a third weighting calculated to make the weighted sum of the powers unity. This method was carried on for bands up to 2.3 mc wide. For wider bands the calculation indicated that practically no contribution to interference was being made by the high frequencies and hence no evidence could be adduced as to where the weightings should be.

In Table V, column a gives the bandwidths of the low-pass noises employed. Column b gives the excess bandwidth, for any particular low-pass band, over that of the adjacent lower band. Column c gives the frequency factor in db, of the excess bandwidths given in column b. Column d gives the relative powers per 10 kc in db for the bands when they were adjusted in level to produce equal interfering effects. These data are obtained from Fig. 4, making the db figures relative to that for the narrowest band (40 kc). Column e gives the weighted power in that portion of any band common to the next lower adjacent band. These are power units and are obtained by reducing unity by the difference between the db figure in column d and the corresponding figure in the row immediately above. For example, the figure 0.525 in column e corresponds to unity reduced by 2.55 db. Column f gives the power figure of unity to which the calculation in each row is directed. Column g gives the difference between the figures in columns e and f. Column h is the db figure corresponding to the power figures in column g. Column i gives the desired weighting. This figure is obtained by combining the figures in columns c, d and f according to the equation $i = h - (d + c)$.

Column j gives the frequencies corresponding to the weightings. These frequencies are approximately the mid-frequencies of the portion of a given low-pass band not common to the next adjacent lower band.

The smoothed curve drawn through these points, averaged with a similarly derived smooth curve for the data shown in Fig. 5 gives the shape of the bottom curve shown in Fig. 6.

Fast Response with Magnetic Amplifiers

D. G. SCORGIE
MEMBER AIEE

FOR MANY years the use of magnetic amplifiers was confined to those applications where extreme reliability was required, but where speed of response was not particularly important. Under the pressure of greater reliability and weight-saving requirements in higher power installations, important advances have been made in magnetic amplifier circuitry and components to achieve higher gain-to-time-constant ratios. It was not until the work of R. A. Ramey,[1] however, that attention was focussed on the fact that magnetic amplifiers could be made with extremely fast response (i.e., one-half cycle of the power frequency) more or less independently of the power gain.

Self-saturating magnetic amplifiers, in which positive feedback is achieved by passing the rectified load current through the output windings, are known to give high gain-to-time-constant ratios. Recent work[2,3] has shown that, with suitable combinations of external positive and negative feedback, it is possible to achieve extremely high input impedances when using the self-saturating magnetic amplifier. W. A. Geyger has shown how to increase the speed of response considerably by delaying the negative feedback through the use of linear low-pass filters.[2]

With a view toward achieving extremely fast response without sacrificing power gain, the present paper will explore the use of positive and negative feedback in self-saturating circuits. Half-cycle response is attained without recourse to rectifiers in the control circuit, thus in many cases removing a lower level limitation upon the signal voltage. The half-cycle response amplifiers to which we refer reach 100 per cent of their final steady output one-half cycle after a transient signal voltage is applied.

Analysis of an Idealized Self-Saturating Amplifier

The conventional bridge-connected self-saturating magnetic amplifier is shown in Fig. 1. The symbol designating the wire-wound cores shows a rectangle, signifying the idealization of a perfectly square hysteresis loop core material. For simplicity we call the element a remanator because it is characterized by 100-per-cent remanent flux. The amplifier shown in Fig. 1 has been discussed at length in the literature.[4,5] Seemingly, it would be needless repetition to review its operation again. However, certain of the results achievable depend upon the adoption of a new point of view. Ramey[1] attributed his results to "a recognition of the fact that the magnetic amplifier is a voltage-sensitive device and not, as generally believed, a current-sensitive device." Taken from context, the statement has very little consequence, for surely Ohm's law holds, and the control current and voltage are linearly related as determined by the control circuit resistance. However, when we perform the thought experiment of setting the control circuit resistance R and voltages e_c and e_b, Fig. 1, equal to zero, the control circuit current i_c assumes various values about which Ohm's law can provide us with no information. Therefore, this thought experiment is an appropriate beginning from which to exhibit the dependence of the control current upon the magnetic amplifier operation, rather than vice versa.

With the terminals of the control circuit windings short-circuited and zero-winding resistances, it follows that the winding voltages must be instantaneously, equal and opposite. On the half-cycle shown in Fig. 1, core I is the gate, and it will absorb a certain voltage-time integral from the supply prior to saturation.

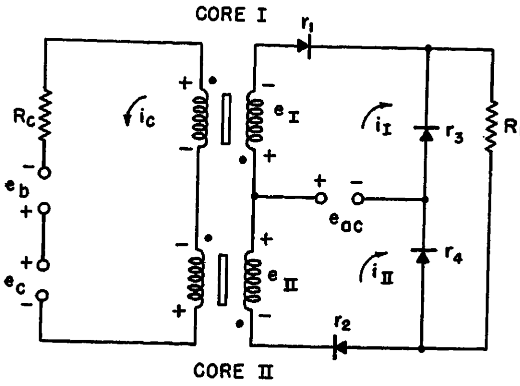

Fig. 1. Conventional bridge-connected self-saturating magnetic amplifier

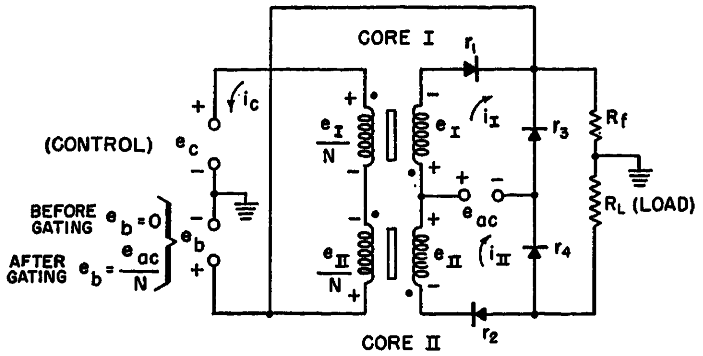

Fig. 2. Amplifier with full response in one-half cycle of power supply

After the saturation of core I, the supply voltage, e_{ac} is delivered to the load. Because of the short-circuited control windings, the voltage e_{II} on core II is of necessity equal to e_I, resulting in a reduction of the core-II flux from its fully saturated condition. The same operation is repeated on subsequent half-cycles, with the same flux reduction being transmitted to the resetting core. Since the initial flux reduction and supply voltage completely determine the output voltage, a steady-state average output current must flow. For a fixed supply and load, the value of this average output current depends only upon the history of the cores. Specifically, it depends upon the initial flux reduction of core I on the first half-cycle and the assumption that core II was initially saturated.

No mention of control currents was necessary above in showing how the various outputs arose. The voltage supply e_{ac} was the only source of power. e_{ac} and the physical circuit, including the history of the cores, will completely determine the dependent control winding current. By definition, the control current i_c flows through the signal element. In other circuitry i_c is not necessarily the same as the control winding current, although of course these currents are identical in Fig. 1.

During the period of time prior to saturation of the gating core the instantaneous magnetizing current i_m of the resetting core must be such as to allow the transfer of the volt-second integral from one core to the other. In this interval the currents will be determined primarily by core materials and output rectifier leakage. After firing, or gating, however, if we assume core materials with a square hysteresis loop, the control current would drop to zero unless back leakage through rectifiers r_1 and r_2 were large (the saturation current I_s or more). In general I_s is defined as that magnetizing current which just saturates the core. For perfectly square loop material, this is the half width of the hysteresis loop and is equal to the instantaneous magnetizing current i_m. Using square-loop cores with the control windings short circuited and no independent control over the control current, the average control current, i_c is determined by the percentage of the cycle during which saturation current I_s is allowed to flow.
That is

$$i_c = I_s\frac{\theta_f}{\pi} \tag{1}$$

where θ_f is the angle at which gating occurs. The average output current I_L and firing angle θ_f are related cosinusoidally

$$I_L = \frac{\hat{E}_{ac}}{\pi R_L}(1+\cos\theta_f) \tag{2}$$

so that

$$I_L = \frac{\hat{E}_{ac}}{\pi R_L}\left(1+\cos\pi\frac{i_c}{I_s}\right) \tag{3}$$

If, through a separate bias winding, a percentage, $1-K$, of the saturation current is passed prior to gating, then the right-hand side of equation 1 is multiplied by K and equation 2 becomes

$$I_L = \frac{\hat{E}_{ac}}{\pi R_L}\left[1+\cos\pi\left(\frac{i_c/K}{I_s}\right)\right] \tag{4}$$

The control current necessary to achieve the full range of output values is therefore made, by adding bias, as nearly zero as we wish.

Passing from one steady state to another was seen to be impossible with the control windings short circuited. However, if suddenly e_c of Fig. 1 is applied, the resetting core will no longer change level of induction at as rapid a rate as the gating core, although with no bias, the control current remains unchanged at I_s prior to gating. After gating the control current reverses to $(-I_s)$ and the direction of change of flux level in the resetting core reverses again toward saturation. Over a period of several cycles, the change of output will be proportional to the integral of control voltage (integrated over the several cycles). The integration process would continue to saturation output unless the control voltage were removed, leaving matters in some steady state described by equation 3. This idealized arrangement is an integrator and is useless as an amplifier. Yet we see that due to the integration action very little power was necessary to change from one steady state to another. Practical considerations enter the actual physical circuit to govern the extent to which the integration process is allowed to proceed, hence making the circuit controllable with a steadily applied input.

But first let us continue a bit further with the idealized circuit with perfect rectifiers and perfectly rectangular hysteresis loop core material. This time include resistor R_c in the control circuit along with voltages e_b and e_c. We saw the circuit before as an integrator of the control voltage. Now we modify matters by saying that any change of the circuit output will be the integral of whatever voltage it sees looking back from the control winding terminals, thus including the i_cR_c voltage drop and e_b in addition to e_c. A steady state is therefore defined when

$$\int e_c dt + \int i_c R_c dt - \int e_b dt = 0 \tag{5}$$

integrated over each half-cycle of supply frequency. That is, of course, self-evident in the equivalent statement that a steady state exists when

$$\int N_I\frac{d\phi_I}{dt}dt + \int N_{II}\frac{d\phi_{II}}{dt}dt = 0 \tag{6}$$

integrated over each cycle. (ϕ_I and ϕ_{II} are the fluxes linking the control windings of cores I and II respectively.)

The statement of control, equation 5, was set up in this fashion to emphasize two modes of control which are significantly different.

First is the usual case where e_b and R_c are constant. When a change of control voltage e_c is introduced after equation 5 has been first satisfied, a steady state is impossible until the average I_c has changed enough to balance equation 5 once again. The natural inference has been drawn that the current I_c is the controlling variable.

Curiously enough, the idealized circuit of which we are speaking is still not controllable with a steadily applied control voltage. With cores of rectangular hysteresis loop of half width I_s, $e_b=I_sR_c$ and $e_c=0$, equation 5 balances when gating never occurs and the output current is zero. If e_c is applied, equation 5 can balance only after gating. Prior to gating $i_c=I_s>\left(\frac{e_b-e_c}{R_c}\right)$ so that equation 5 cannot balance until full output current is reached. The transient will be similar to an exponential rise, since the time interval prior to gating gets shorter, contributing less to the increase of output each half-cycle.

Any form of negative feedback, which either increases e_b or decreases i_c with output current, will stop the output from running to saturation. If, as in practical core materials, the sides of the hysteresis loop are not perfectly vertical, but have some finite positive slope, then the average value of the magnetizing current I_m of the resetting core decreases as gating comes earlier in each cycle. Therefore, it constitutes the additional negative feedback term in equation 5 necessary for control.

If, secondly, however, we allow R_c to be negligible and instead vary e_b following a change of control voltage, equation 5 can be easily balanced. In this mode of operation, when predicting the output current, what happens to the control current is a matter of complete indifference. Positive and negative current feedback do not affect the control characteristics. Voltage feedback, as manifest in e_b, completely determines control.

Current feedback and bias, taken together, are useful in reducing the control current, hence the control power, to a minimum throughout the control range. Notice particularly, however, that negative voltage feedback also plays a role in minimizing the a-c components of control currents. Following gating in the amplifier of Fig. 1 (with R_c small) the control current is no longer forced to its upper limit I_s, imposed by the control winding of the resetting core. If e_b, the negative voltage feedback, is introduced after gating, and is instantaneously greater than e_c, it will force I_s to continue to flow, still limited by the resetting core. With perfectly square loop cores, therefore, the control current will differ from the constant I_s only at the instant when the supply voltage passes through zero. It is easy to reduce this form of current to nearly zero with d-c bias, since it is relatively free of harmonic components.

Transient Response

The idealization of components in the amplifier as discussed in the foregoing gives an unrealistic picture of performance when applied to practical circuits. We were led, for instance, to the conclusion that the amplifier with square loop core material, operating in its normal mode, had virtually infinite power gain. Recitation of the departures from idealized components and the study of their effects are extremely important but will more properly be the subject of another paper. The main theme of this paper is the speed of response and improvement of power gain.

It has been argued in the foregoing that a change from one steady-state average output voltage to another is proportional to the left-hand side of equation 5, integrated over the intervening time interval. If we assume the output voltage to be that impressed across the whole output circuit resistance, this constant of proportionality is simply the turns ratio N between the output and control winding on each core. The output is cyclically pulsing. If a change of control voltage e_c' is impressed at $t=0$, then during the ensuing transient, changes of the amplifier variables (expressed as primed quantities) are related as shown by equation 7

$$e_o'(t_n)=N\left[\int_0^{t(n-1)}e_c'dt+\int_0^{t(n-1)}i_c'R_cdt-\int_0^{t(n-1)}e_b'dt\right] \quad (7)$$

$e_o'(t_n)$ is the net difference between the volt-second area of the output voltage during the nth half cycle, which ends at the instant t_n, and that which ended at $t=0$.

Dornhoefer[4] states with reference to the gating core that "an assumption that the voltage-time integral absorbed by the reactor is given by the integral of the supply voltage from zero (i.e., beginning of nth gating half-cycle) to the firing instant is a relatively good one." The voltage-time integral that the reactor was capable of absorbing was, of course, determined during the previous $(n-1)$ half-cycle during which the same core was reset. The change of this latter quantity during a transient is described by the three terms on the right-hand side of equation 7. If the first term is positive, the others are normally negative quantities which gradually increase in magnitude as some function of the output voltage pulses. As Geyger points out, the response is faster if the buildup of the last two terms of equation 7 is delayed.[2] One might go further and suggest that it is possible to speed matters further by briefly introducing the last term of equation 7 as a positive quantity.

We will inquire here into the specific case where a step function of e_c' is applied at $t=0$, and the second and each succeeding half-cycle voltage $\int e_b'dt=\int e_c'dt$ is fed back from the output circuit without changing i_cR_c. This is a sufficient condition to assure an amplifier with full response in one-half cycle of the supply frequency. Direct application of equation 7 shows that for the first half-cycle $e_o'(t_1)=0$. On the second and every succeeding half-cycle $e_o'(t_n)=N\int_0^{t_1}e_c'dt$, so that an amplifier with half-cycle

response is obtained. The power gain is determined only by how effectively control current can be reduced to a minimum by bias and current feedback.

D-C-Controlled Amplifiers with Half-Cycle Response

Fig. 2 shows the simplest embodiment of an amplifier which responds in the manner described in the previous paragraph. The quantity e_b is simply derived from the load by feeding back approximately e_{ac}/N to the control circuit instantly upon saturation of the gating core. The simplest method is the direct coupling through ground and terminal, *A* of Fig. 2. The circuit diagram shows the use of remanators, or square loop core materials. Theoretically the response time and voltage transfer characteristics are equally satisfactory with any saturable magnetic material, because there is nothing in the control circuit to upset the required voltage relationships when the magnitude or direction of the control current changes. The substitution of various core materials will alter only the control current-output voltage relationship, as discussed later.

Fig. 3 shows the double-bridge self-saturating circuit of Ramey,[1] which also responds fully in one half cycle of the supply frequency. Using remanators for cores I and II, the feedback action is identical to that of the circuit of Fig. 2, although not readily apparent. While core I is on its gating half-cycle and core II is resetting, the effective portion of the double-bridge circuit is shown in Fig. 4. Prior to gating rectifier r_3' might just as well be open-circuited, so that Figs. 2 and 4 are identical. After firing, core I voltage drops to zero, activating the branch comprising E_{ac}' and r_3'. In effect, then, the same feedback e_{ac}/N has been introduced at the moment of gating. Because the feedback voltage appears in parallel rather than in series with the gating core, rectifier r_1' is necessary to prevent destructive currents from flowing in the control winding after gating. The double bridge, Fig. 4, requires remanators for satisfactory operation.[6] However, with additional circuitry its use has been shown to extend to other core materials.

When properly designed, the voltage transfer characteristics of the circuits of Figs. 2 and 3 have the identical form for pulsating d-c (rectified sinusoid) control, as shown in Fig. 5. For pure d-c control, the transfer characteristics of the circuit of Fig. 3 are altered somewhat but usually not to an important extent. The linear portion in any case is practically independent of supply voltage, but in the saturation (horizontal) portion, the output voltage is of course directly proportional to the supply voltage.

A-C Controlled High-Speed Amplifier

The circuit of Fig. 6 without the shunting elements R_{s1}, R_{s2}, r_{s1}, and r_{s2} is an a-c controlled self-saturating magnetic amplifier with an alternating voltage instantaneously equal to e_{ac}/N fed back to the terminals (*A* and *B*) in the control circuit at the instant load current flows. $2e_{ac}'$ is a fixed supply voltage equal to $2e_{ac}/N$. We find that especially where core materials with high flux remanence are used, there is a certain fairly large minimum output current for either polarity or any magnitude of the alternating control signal e_s. The reason for this high quiescent current can be seen by examining the voltage distributions in the circuit of Fig. 6 without shunts R_{s1}, r_{s1}, R_{s2}, r_{s2}. With the polarities as shown, core I is on its gating half-cycle. Kirchoff's law applied to the control circuit demands that

$$e_I + e_{II} = (2e_{ac}' - e_s)N = 2e_{ac} - Ne_s \tag{8}$$

Prior to saturation, the only limitation imposed by the output circuit is that if and only if forward current flows in either output winding, that winding voltage must equal e_{ac}. From this it follows that when, for any reason, forward currents do not flow in the output windings, there are many possible voltage values which satisfy equation 8. The only limits are

$$e_I \geqq e_{ac} \text{ and } e_{II} \leqq e_{ac} \tag{9}$$

In practice, there are cumulative small effects such as unbalance of magnetizing currents, forward voltage drops in the output rectifiers r_3 and r_4, etc., which produce the inequality relationships of equation 9 at least a portion of the time when $e_s = 0$. Here we see that if the elements R_{s1} (assumed that $R_{s1} >> R_L$) and r_{s1} are inserted when core I is on its forward half-cycle, the source e_{ac} delivers a small amount of power to R_{s1} and unequivocably fixes the voltage e_1 at e_{ac}. Therefore, under all conditions the resetting core voltage e_r must be unequivocably fixed at

$$(e_r) = (e_{ac}) - (Ne_s) \tag{10}$$

in the $(n-1)$ half-cycle.

In the *n*th half-cycle the area of the output voltage pulse $\int_n e_0 dt$ is given by

$$\int_{t(n-1)}^{tn} e_0 dt = \int_{t(n-1)}^{tn} e_{ac} dt - \int_{t(n-2)}^{t(n-1)} e_r dt \tag{11}$$

From equations 10 and 11, and the assumption that e_{ac} is constant

$$\int_{t(n-1)}^{tn} e_0 dt = N \int_{t(n-2)}^{t(n-1)} e_s dt \tag{12}$$

Equation 12 says not only that we have a linear magnetic amplifier which responds fully in one half-cycle of the supply frequency, but that the output (quiescent) is zero when e_s is zero. Experimentally, it is found that the quiescent output current is on the order of twice the saturation magnetizing current of the core.

Control Currents

Our earlier statements derogating from the effectiveness of the control current as the controlling variable did not minimize its importance in other respects. By making i_c as small and constant as possible, power gain and input impedance of the amplifier can be maximized with suitable biasing. In order to calculate

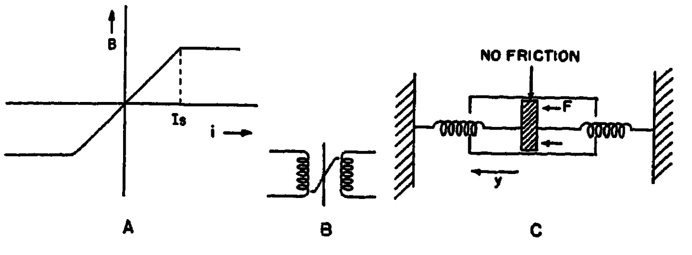

Fig. 7. A. Idealized saturable inductance characteristic. B. Symbol for saturable inductor. C. Mechanical analogy for saturable inductor

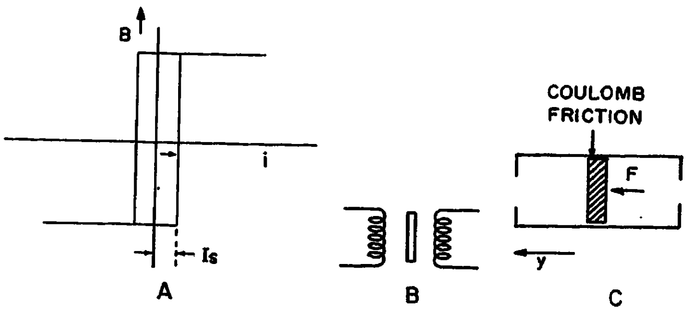

Fig. 8. A. Idealized remanator characteristics. B. Symbol for remanator. C. Mechanical analogy for remanator

transient response of the amplifier by equation 7 i_c must be known, unless $R_c=0$. The degree to which we can assume R_c negligible in the amplifiers with half-cycle response, is also dependent upon how successfully i_c is held constant. Of course R_c is always finite, so that the latter point is important.

The component which dominates the determination of control current is the saturable core and its magnetic material. To determine the current at a given instant one must know the limiting impedances and also be able to recognize the independent sources of energy. We know, of course, that e_{ac} and e_c represent sources. Fig. 7 shows idealized characteristics of saturable inductors, in which energy can be stored, and Fig. 8 shows those of remanators which are purely dissipative magnetic elements. The remanator is characterized by the high value of remanent induction which gives it a square hysteresis loop. We can get a mechanical analogue for both a remanator and saturable inductance with a weightless piston sliding in a cylinder with mechanical stops at both ends. Plot the linear displacement from the center as the vertical or y axis and the force F applied to the piston on the horizontal axis. With no friction and a spring attached to the piston, the saturation characteristic is identical to Fig. 7(A). When the spring is stretched energy $\int \mathbf{F}\cdot d\mathbf{y}$ is stored (as is $\int \mathbf{H}\cdot d\mathbf{B}$ for the magnetic case) and can be recovered by releasing the piston. Detach the spring and introduce coulomb friction, and saturation characteristic will change approximately to that of dissipative remanator of Fig. 8.

When Saturable Cores Are Remanators

If perfectly square loop remanators are used in Fig. 2, the control current takes an extremely simple form. When core I is on its gating half-cycle, as shown, core II is completely passive. That is, it can deliver no energy. The dominant source of energy is e_{ac}; core II and rectifier r_2 are the principal elements limiting control current. Prior to firing, e_{ac} is impressed across the output windings of core I, and e_{ac}/N appears across its control windings. Assuming $(e_{ac}/N)>e_c$ the control current i_c rises until limited by the resetting core II. The limitation imposed by core II is that the sum i_c+Ni_{r2}, where i_{r2} is the leakage current of rectifier r_2, be equal to I_s (the half width of the hysteresis loop). After gating e_b becomes the primary driving source and core II, as its resets, continues to limit the control current. Fig. 9(B) shows the control current for all outputs in the case where rectifiers r_1 and r_2 have infinite back resistance. The control current will be reduced by rectifier leakage. The voltage Ne_c is impressed instantaneously in the back direction across r_1 or r_2, whichever core is resetting. Therefore as E_c (hence output current) gets larger, the average control current decreases somewhat from its initial value of the magnetizing current I_s.

The simplicity of the form of the control current shown in Fig. 9(B) suggests that its reduction is not difficult. The major portion of the control winding current can be prevented from passing through the control source simply by shunting the control by a constant current source, I, which delivers I_s constantly. Fig. 10 is the circuit of Fig. 2 with this constant current source and an auxiliary winding added. The auxiliary winding is to compensate for the decrease in control winding current as output rectifier leakage increases. The auxiliary winding can also be shown as a few turns in series with the d-c load, in which case, however, smoothing with a filter is more difficult. When low quiescent current is important, it is often necessary either to insert an additional d-c bias voltage in series with the control windings to compensate for I_s flowing through the control winding resistance,

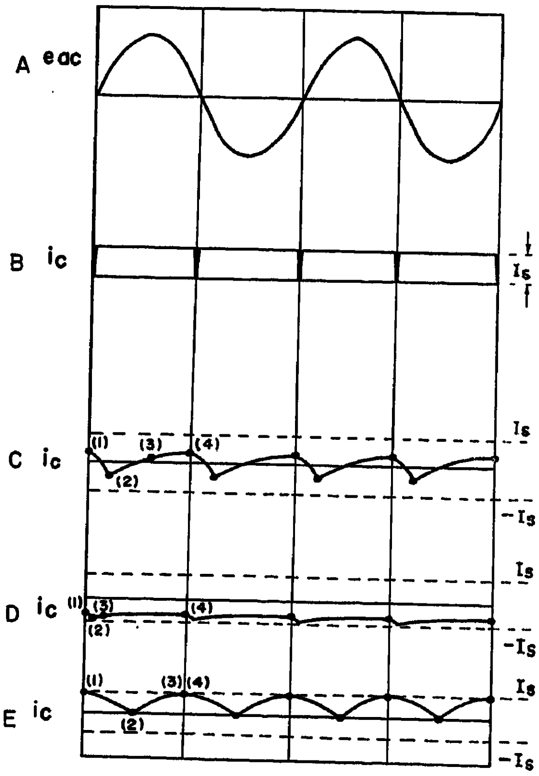

Fig. 9. Variables in circuit of Fig. 2. A. Supply voltage. B. Control current, all outputs, using remanators. C. Control current using saturable inductors, intermediate output. D. Fig. 10. One-half-cycle response amplifier, with compensation for rectifier leakage

or to allow I_s to flow through separate windings.

Fig. 11 shows a typical set of curves taken on an amplifier (set for one half cycle response) which has a turns ratio, (output winding)/(control winding), of 5,700/1,540 or nearly 4. Deltamax 1-mil toroidal cores were used. Where thicker magnetic tape is used the bowing of the control current versus output current curve is more pronounced because of eddy currents in the core. It does not necessarily follow that improved over-all performance can be obtained by using still thinner grain-oriented nickel-irons, for a deterioration of the high remanance characteristics accompanies further rolling. However, it could be that other materials such as the newly developed Alfenol with its high electrical resistance and rectangular hysteresis loop, or 4-79 molybdenum Permalloy, for which the B_r/B_s ratio increases in the thinner tapes, will provide more satisfactory results.

In supermalloy the B_r/B_s ratio is on the order of 0.7. However, satisfactory results can still be obtained with its use because of the extremely small coercive force. Fig. 12 shows the characteristics of a low-level amplifier adjusted for full response in somewhere between one-half and one cycle of the supply frequency. It appears curious indeed to have included the inductance L in series with the control signal. However, L has no effect upon the time constant of the amplifier because of the fact that it is unnecessary to change the average control current appreciably. The addition of an inductance has the effect of reducing the harmonic currents which must flow through the control. It is particularly effective in reducing the average control current in the region of low output currents.

The control characteristics of Fig. 12 illustrate particularly well the fact that, at least in some instances, a magnetic amplifier must be considered as a voltage-controlled device. The output current is seen to be a many-valued function of the control current, but is stable and uniquely determined by average control voltage. The control current transfer curve has a characteristic S-shape when positive feedback is used. The central portion can be made nearly vertical by decreasing the positive feedback, but the curve at the bottom of the S remains unchanged. More accurate compensation can be effected by introducing suitable nonlinearities in the positive feedback loop. However, it is more satis-

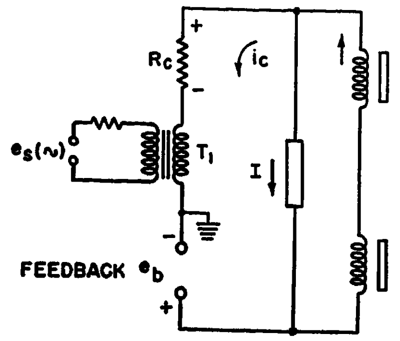

Fig. 14. Control circuit of Fig. 10, modified for driving a 2-phase a-c motor

factory to introduce means of reducing the average control current in the region of low outputs as, for instance, with the series inductance L mentioned in the foregoing.

The reason for the effect of L upon the average control current is that the a-c components of control current must pass through terminals A and B, which are conductively coupled to the output rectifier bridge. The slight rectifying action, which is greatest for low output currents, gives rise to a d-c component of voltage at terminals A and B. Thus a decrease in a-c component control current gives rise to a decrease in the d-c component. Three additional factors contribute to the curvature of the control current characteristic in the region of low outputs.

Unbalance Between Cores

The output current is reduced by increasing the voltage impressed upon the resetting core. Ideally, the resetting core voltage should be instantaneously equal to e_{ac} for zero output. In practice, however, a slight difference between the turns ratios of the two cores brings about a condition where the resetting core voltage tries to rise above e_{ac}. As a consequence, a small current flows in the forward direction through the output rectifier r_1 or r_2 in series with the resetting core. This occurs at a time when the resetting core is limiting the control winding current, so that i_c rises by the same amount multiplied by the turns ratio.

Excess of Negative Feedback Voltage

At the instant of gating, the voltage e_{ac}/N is fed back into the control circuit. If too great a feedback pulse is introduced, particularly when the control voltage is small, the resetting core voltage rises above e_{ac}. The limitation on the control current imposed by the resetting core is then removed just as when the cores were unbalanced.

At the full output end of the characteristic, Fig. 12, the control current drop sharply. This can be improved by increasing and linearizing the back resistance of the output rectifiers by derating. However, the basic difficulty remains that the core materials are never possessed of perfect remanence. The pulse of energy delivered by the core as it begins to reset decreases the control current. The effect becomes more important percentagewise when we wish to prevent reset altogether and produce full output.

Excess Supply Voltage

Where the supply voltage is sufficiently high to swing the flux level of the cores from one knee to the others in a single half-cycle, there is the danger of saturating the resetting core. This removes the current limitation imposed upon the control current by the resetting core. The situation is corrected by decreasing the supply voltage.

When Cores Are Saturable Inductors

Once again, we will determine the control currents in the circuit of Fig. 2. This time replace cores I and II by the idealized saturable inductances of Fig. 7, wherein energy can be stored. We can no longer assume that the supplies for e_c and e_{ac} are the only sources of energy; instead one or the other or both of the cores will in general also be delivering energy.

Fig. 13 shows the traversal of the saturation curve of the saturable inductors during a single half-cycle of operation. Assuming that the magnetic induction will swing from knee to knee with the application of the full supply voltage, the case shown would represent the condition of about one-third maximum output current.

The half-cycle begins at point 1, Fig. 13. At this point the resetting core has its maximum stored energy. In an effort to dissipate this energy, it raises the voltage e_{II} to the value of e_{ac} and causes a small current i_{II} (Fig. 2) to flow in the output circuit. The control voltage is added to the resetting core voltage, so that the gating core voltage rises to $e_I = e_{ac} + Ne_c$. Thus rectifier r_1 will block and no current flows in the output winding of core I. In direct contrast to the case where remanators were used, we now see that core II is the primary energy source, and core I the limiter of control current. Between points 1 and 2 of Fig. 13, the control current is determined by core I, and it changes at a rate proportional to $(e_{ac} + Ne_c)$. Point 2 of Fig. 13 is reached at the instant the total magnetizing current requirements of the two cores become the same. The current i_{II}, which has been diminishing, disappears and i_I begins to flow in the output winding of the gating core. At point 2 it can be seen that i_c has reversed polarity Fig. 9(C). Beyond point 2, the situation reverts to that which was normal with remanators, namely, the resetting core limits the control current, $e_I = e_{ac}$, and $e_{II} = e_{ac} - Ne_c$. The rate of change of i_c is proportional to e_{ac}. At point 3 gating occurs, but i_c is unaffected and continues at the same rate until the end of the half-cycle, point 4.

Fig. 9(C) showed an example of control current with some intermediate output, Figs. 9(D) and 9(E), respectively, show the control current wave shape for nearly full output and zero output. The contrast is evident between this and Fig. 9(B) which represents the control current for all values of output current when remanators are used. Preventing the control winding currents from flowing through the control sources is obviously less formidable and more effective when remanators are used.

Methods of Control

Unique methods of control of magnetic amplifier have been proposed.[7] Their novelty rested chiefly on the point that where remanators are used, the control current flows backward through the control voltage source, Figs. 2 and 9(C). A fixed amount of power, supplied by the voltage source e_{ac}, is transformed through the gating core and delivered to the control circuit, where it must all be absorbed by the control element and the resetting

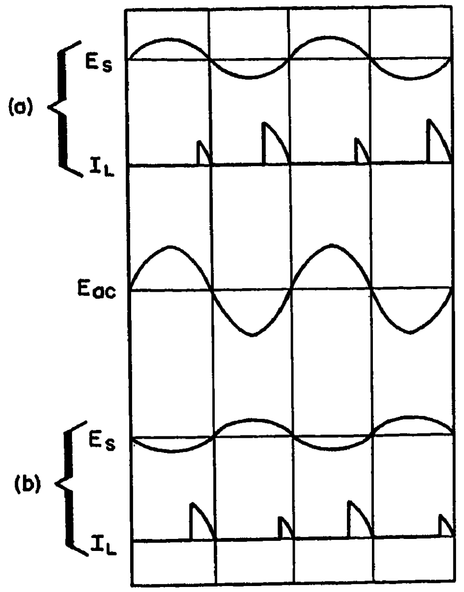

Fig. 15 (left). Output current I_L, when control voltage e_s, is introduced as shown in Fig. 14. A. Forward phase of e_s. B. Reverse phase of e_s

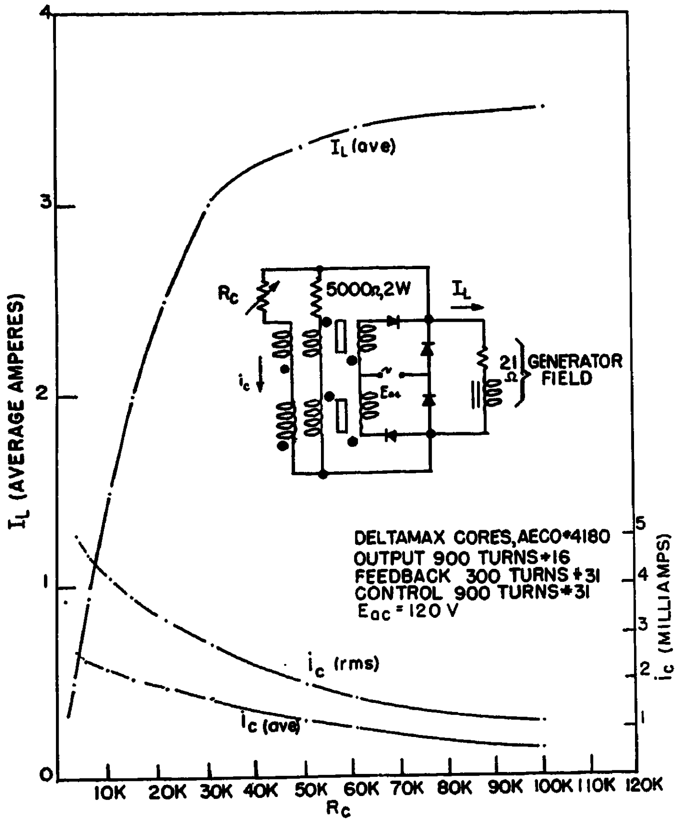

Fig. 16 (right). Operating characteristics of high-speed resistance-controlled amplifier with inductive load

core. Increased output is obtained by absorbing a greater percentage of this power in the control element. Therefore, any variable dissipative element can be used for control.

We shall discuss two examples, the first illustrating the utility of combinations of passive and active control elements.

Fixed Resistor Plus Variable Voltage Control

Resistance control has been discussed by Ramey.[7] Subsequently, Geyger showed the advantages of using superimposed a-c and d-c components in the output of a magnetic amplifier to drive a 2-phase motor with poor damping characteristics.[8] Lufcy, Schmid, and Barnhart disclosed circuitry in which a fixed resistor and variable control voltage were combined to control a high-speed magnetic servo amplifier.[9] The combination of the two central ideas[8,9] is achieved as shown in Fig. 14. There, only the control circuit of Fig. 10 is shown, wherein the control voltage e_c has been replaced by the combination of resistor R_c and a transformer T_1 through which an a-c signal of reversible phase is introduced.

Fig. 14 shows a constant current source I which, if included at all, must be set at some value less than the saturation magnetizing current I_s of the remanator control windings. A unidirectional current flows through R_c giving an effective d-c control voltage. The value of R_c is chosen so that this effective control voltage gives about one-half full output from the amplifier. When the alternating signal e_s is introduced, it alternately adds to and substracts from the voltage across R_c on successive half cycles. The value of i_c is unchanged except as e_s effects output rectifier leakage or eddy currents in the resetting core. Fig. 15 illustrates how a change in phase of e_s brings about a reversing phase fundamental a-c component in the amplifier output.

Resistance-Controlled Amplifier with Inductive Load

This example is included to illustrate several points which have not been specifically mentioned. Chief among these is a reaffirmation of the proposition that amplifier performance can be profitably analyzed in terms of voltages as the principal variables. However, in this instance the statement applies to the output circuit as well as to the control.

Fig. 16 shows the transfer characteristic of an amplifier which is controlled by a variable resistor R_c and has a highly inductive load. The load voltage responds fully, one half cycle after a step change of control resistance. However the load current rises exponentially with a time constant determined by its inductance and resistance. The negative voltage feedback pulses which have been used throughout the paper to achieve half-cycle response cannot be obtained in this example from a resistor in series with the load. It would be necessary to provide an instantaneous voltage divider across the load terminals for feedback if the output-to-control winding turns ratio N were greater than one. With resistance control the turns ratio can be one and the whole load voltage acts as the feedback voltage E_b. In practice the turns ratio N should be greater than one because of the internal resistance of the output windings.

Summary

The bridge-connected self-saturating magnetic amplifier can be made to respond fully to a signal in one half cycle of the supply frequency. A number of types of input have been considered: a-c, d-c, and combinations of the two for performing a variety of functions. Analysis of the circuits, assuming either current or voltage as the control variable, is useful, but examination of the control voltages is generally the more so. Remanators, in which no energy can be stored, lead to circuitry in which most of the control winding current can be prevented from passing through the control source.

A Magnetic Amplifier for Synchros

R. L. VAN ALLEN
ASSOCIATE MEMBER AIEE

Basic Single Core Magnetic Amplifier

THE SYNCHRO magnetic amplifier was developed at the Naval Research Laboratory (NRL)* to eliminate some of the difficulties and failures of the electronic synchro amplifier. At the same time, it provides a demonstration of a system utilizing magnetic circuits of a type which was developed at the Laboratory.[1,2,3]

Since the system draws directly upon a circuit developed within the past few years, it will be worth while to review the principles, first, as applied to proportional amplifiers, and second, as used to sense an error or difference between isolated signals.

To simplify the discussion, let us assume a core material possessing an ideal rectangular hysteresis loop and a circuit with ideal rectifiers and windings with negligible resistance. A basic single-core half-wave magnetic amplifier is shown in Fig. 1. For purposes of this illustration, the power and control windings have a unity turns ratio and are wound in the sense indicated by the dots adjacent to the windings. Voltages E_{ac} and E_{ac}' are sinusoidal, of equal magnitude, and have instantaneous polarity as shown. The magnitudes of the supply voltages E_{ac} and E_{ac}' are such that if either were applied directly to one winding on the core, the time integral of this voltage would cause the core flux to change from knee to knee on the hysteresis loop. The control voltage E_c is rectified alternating current of the same frequency and phase as E_{ac}'. When the polarities are as shown in Fig. 1(A), voltage E_{ac} will appear across the power winding and load in series, while a back voltage is across the control rectifier and I_c is zero. For these voltage polarities the flux will change in the direction marked FIRE.

When polarities of the supply voltage are as shown in Fig. 1(B), the current path is restricted to the control winding, and flux changes on the hysteresis loop will be in a direction marked RESET. This mode of operation resets the flux of the core to a value determined by the time integral of the voltage $E_{ac}'-E_c$. The magnitude of the control voltage E_c will determine the amount of reset and establish the flux of the core at the end of the RESET half-cycle, as shown in Fig. 2(A). During this half cycle, I_c will be the magnetizing current of the core, and I_L will be zero because of the power-circuit rectifiers. During the next half cycle, designated FIRE, voltage E_{ac} will at first appear across the power winding and produce a flux change in the core proportional to the integral of this voltage. As the core flux proceeds to saturation, the current in the load will be only magnetizing current until the instant of time T_x. At the time T_x, the core flux reaches saturation and voltage E_{ac} will then appear across the load, so that I_L suddenly becomes equal to E_{ac} divided by the load impedance for the duration of this half-cycle. Since the change in core flux is proportional to the integral of the voltage across the windings, then during the RESET half-cycle the voltage integral producing a flux change will be

$$\int_0^{T/2} E_{ac}'dt - \int_0^{T/2} E_c dt$$

For the next, or FIRE half-cycle, the voltage integral producing a flux change in the reverse direction will be

$$\int_{T/2}^{T_x} E_{ac}dt = \int_{T/2}^{T} E_{ac}dt - \int_{T_x}^{T} E_{ac}dt$$

Since the total change in flux was the same for both the RESET and FIRE half-cycles, where $E_{ac}'=E_{ac}$, and there is 1 to 1 turns ratio, it follows that

$$\frac{1}{T/2}\int_0^{T/2} E_c dt = \frac{1}{T/2}\int_{T_x}^{T} E_{ac}dt \qquad (1)$$

when averaged over a half-cycle. Thus, voltage is transferred to the load proportional to the applied control voltage and, in the case of a 1 to 1 turns ratio on the core, the average control voltage equals the average load voltage.

Fig. 2(B) shows what happens when the output of the amplifier is minimum, or $E_c=0$. It is true that the load current I_L is not zero during the FIRE half-cycle, because magnetizing current must exist while the flux is changing. However, this minimum load current in the practical amplifier is usually negligible, being several orders of magnitude less than full-load current.

RESPONSE TIME

The integral of the voltage appearing to the load on the FIRE half-cycle depends upon the integral of the signal voltage during the previous half-cycle. So, in order to have steady-state output on the FIRE half-cycle, it is necessary to have steady-state input on the previous RESET half-cycle. Therefore, the response time to reach steady-state output will be the time from initiation of the signal, to the end of the next complete RESET half-cycle. This means the minimum response time will be 1/2 cycle when E_c is applied at the beginning of a RESET half-cycle. Also, the maximum response time will always be less tha $1^1/_2$ cycles, reaching a maximum when E_c is applied immediately after a RESET half-cycle has begun. It should be noted that this response time refers only to steady-state output. Actually, when E_c is applied during a RESET half-cycle, a portion of steady-state output will be obtained on the next FIRE half-cycle, an amount depending upon what percentage of steady-state input was reached during this first RESET half-cycle.

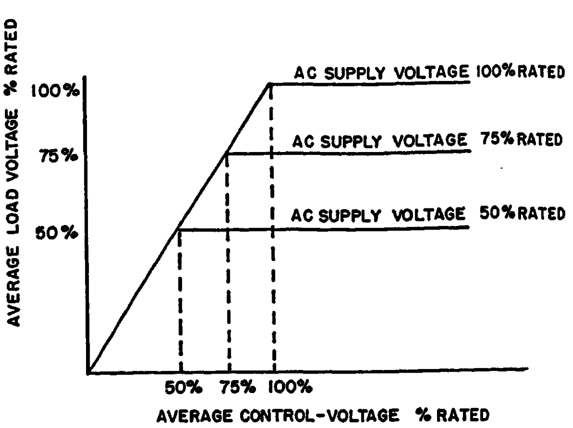

Fig. 3. Transfer characteristics of magnetic amplifier for different supply voltages

Control Element

In addition to the fast time of response of this magnetic amplifier, there are other characteristics which make this circuit especially adaptable for control purposes. For example, the controlling element may be a source of d-c voltage, or a variable resistance, as well as a rectified a-c voltage as shown in the preceding example. The basic requirement of any of these control elements is that they will pass magnetizing current to permit resetting action in the control circuit. Since the controlling element provides an electromotive force which bucks the supply voltage E_{ac}', the output power is proportional to the control voltage. This is a new concept in the field of magnetic amplifiers, which for years have been considered primarily as a current-amplifying device.

Transfer Characteristics

The transfer characteristic (or plot of output versus input) for conventional magnetic amplifiers is a plot of average output current versus average input or control current. In contrast, the NRL-developed magnetic amplifier, having as the control element a source of electromotive force, establishes a linear transfer relationship between average control voltage and average load voltage, see Fig. 3. This linear relationship holds for a range of control voltages from $E_c=0$ to $E_c=E_{ac}'$, providing rectifier leakage is not excessive. It is very significant, in regard to the synchro amplifier, that, provided the ratio E_{ac}/E_{ac}' remains constant, this linear transfer characteristic is not affected through the control range by changes in the supply voltage. Of course, the maximum power-handling capacity for a given load of the amplifier is reduced as the supply voltages are reduced, as shown in Fig. 3.

Special Circuit Characteristics

It is shown in Fig. 3 and by equation 1 that the average voltage applied to the load is proportional to the average control voltage E_c. This voltage output to the load is a direct result of E_c opposing E_{ac}'. Similarly, in the absence of E_c, a reduction in E_{ac}' will produce an output voltage, $\int V_{out}dt=\int(E_{ac}-E_{ac}')dt$. This characteristic of the circuit to transfer to the load a voltage proportional to the difference between the supply voltages E_{ac} and E_{ac}' is unique and bilateral. To illustrate this bilateral action, assume a single-core circuit having the parameters indicated in Fig. 4. When E_{ac} is greater than E_{ac}', circuit no. 2 fires, owing to saturation of the core at one end of the hysteresis loop, and a voltage proportional to $E=E_{ac}-E_{ac}'$ is applied to R. Conversely, when E_{ac}' is greater than E_{ac}, circuit no. 1 fires, owing to saturation of the core at the opposite end of the hysteresis loop, and the voltage across R' is proportional to $E=E_{ac}'-E_{ac}$. This simple circuit, in addition to exhibiting a bilateral voltage transfer proportional to the difference between E_{ac} and E_{ac}'

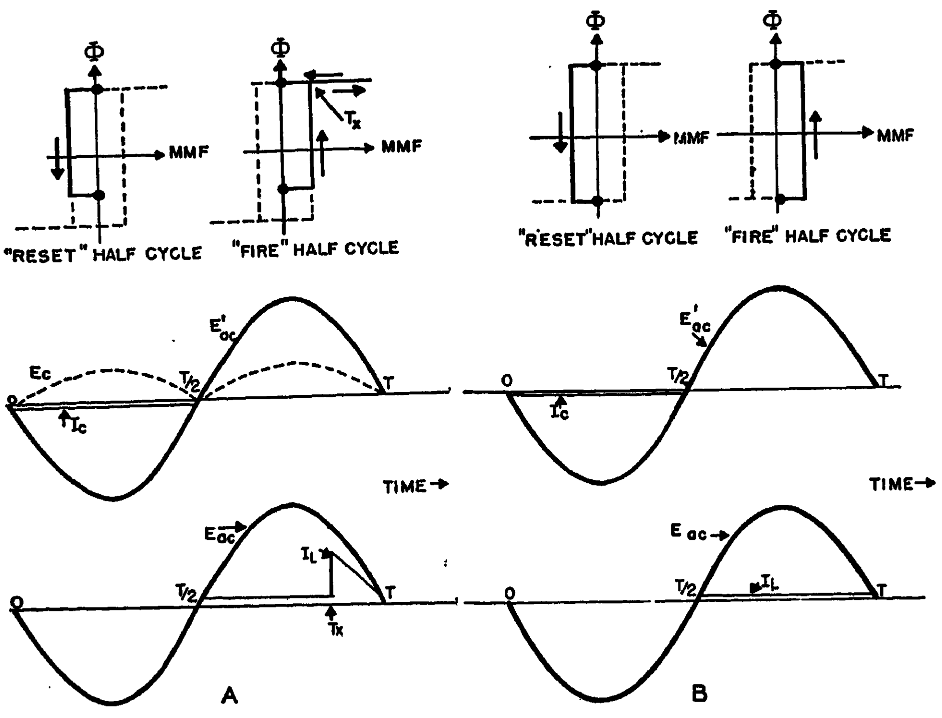

Fig. 2 Voltage and current wave forms and flux change of single-core magnetic amplifier

A. With signal voltage B. Without signal voltage

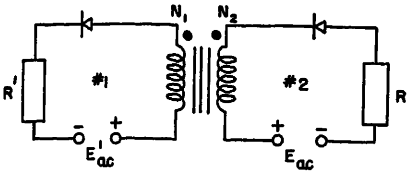

Fig. 4. Single-core bilateral network
Square-loop core material

$N_1 = N_2$ $R = R'$ $E_{ac} = E_{ac}'$

also possesses another unique property of error sensing. Error sensing is due to the high remanence flux of the square-loop material, which exhibits a memory action, so that E_{ac} in circuit no. 2 will act upon R during one half-cycle, depending upon how E_{ac}' in circuit no. 1 acted upon the core in the preceding half-cycle. Conversely, E_{ac}' will act upon R' in accordance with the action of E_{ac} upon the core in the preceding half-cycle. Thus, an output is obtained as a result of error sensing or a comparison that is made between E_{ac} and E_{ac}', with an inherent delay of 1/2 cycle introduced.

Application to Synchro Amplifier

The application of magnetic amplifiers to function as a synchro amplifier may be accomplished in several ways. However, in order to have accuracy, fast response, high sensitivity, and stability, one circuit was chosen from several alternatives. This circuit is a multiple application of the basic Ramey magnetic amplifiers.

Fig. 5 is a block diagram of the complete system showing full-wave magnetic amplifiers. In the block diagram, it is indicated how the control voltages for the six units are obtained from the stator of a synchro generator, with each pair of stator terminals controlling two magnetic amplifiers. Thus:

1. Voltage S_2S_3 controls magnetic amplifiers A and A'
2. Voltage S_1S_3 controls magnetic amplifiers B and B'
3. Voltage S_1S_2 controls magnetic amplifiers C and C'

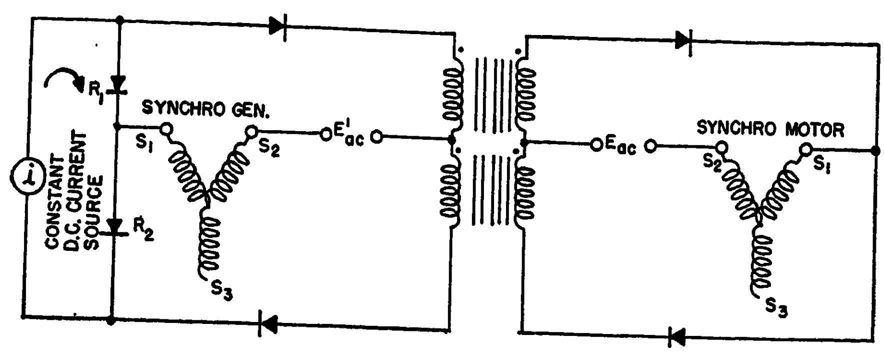

Fig. 6. Full-wave synchro magnetic amplifier

The output of each pair of amplifiers supplies the respective synchro motor terminals. Thus:

1. Amplifiers A and A' supply synchro motor terminals S_2S_3
2. Amplifiers B and B' supply synchro motor terminals S_1S_3
3. Amplifiers C and C' supply synchro motor terminals S_1S_2

The apparent duplication of amplifier units for each input and output serves a specific purpose, which will be explained later.

Each of the amplifiers A, A', B, B', C, and C' is an identical full-wave amplifier, as shown in Fig. 6. A constant current source i and two additional rectifiers, R_1 and R_2, are in the control circuit, see Fig. 6, to insure that the control current will not rise above the magnetizing current of the core. As was previously shown, it is necessary to permit magnetizing current in the control winding only during the RESET half-cycle. The output load on the synchro amplifier unit, see Fig. 6, consists of the winding between a pair of terminals on the synchro motor bus, in which a voltage is induced varying in magnitude and polarity with the position of the rotor. This presents a problem in magnetic-amplifier loading, since the impedance of the load varies with the number of synchro repeaters used, and the voltage induced in the load varies with the angular position of these repeaters.

When a synchro shaft is rotated through 360 degrees and the rotor is energized with a single-phase voltage, the stator terminal voltages will appear as shown in Fig. 7. Thus, during one complete revolution the stator terminal voltage (for example $V_{S_1S_2}$) will change in magnitude and polarity, having the same polarity as the rotor voltage for 180 degrees rotation and reversing polarity for the other 180 degrees. Since the magnetic amplifier is to respond to the difference between motor and generator terminal voltage, it must also respond to a change in polarity of this voltage. To provide for polarity reversal, the magnetic-amplifier circuit shown in Fig. 8 is used.

In essence, this circuit has two full-wave Ramey magnetic amplifiers connected for parallel operation, except that E_{ac} and E_{ac}' of one unit are in reverse polarity with E_{ac} and E_{ac}' of the other unit. This is arranged by supplying E_{ac} and E_{ac}' from two center-tapped windings of a transformer. By making $E_{ac} = E_{ac}'$ and equal to or greater than the maximum synchro terminal voltage, the direction of current through the synchro stator windings will be determined by the instantaneous polarity of voltages E_{ac} and E_{ac}'.

Since it is the voltage available to the core that we are concerned with in both

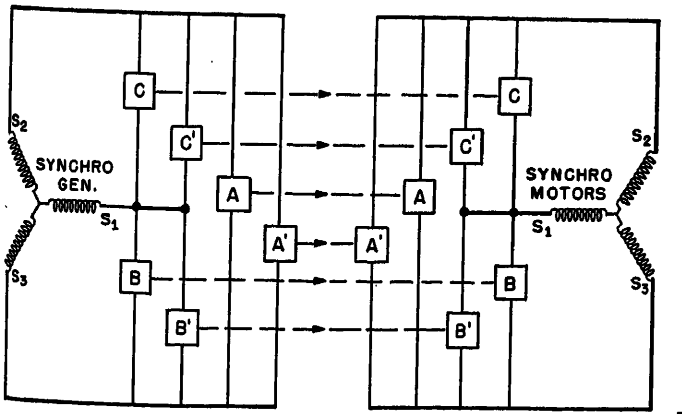

Fig. 5. Block diagram of synchro magnetic amplifiers

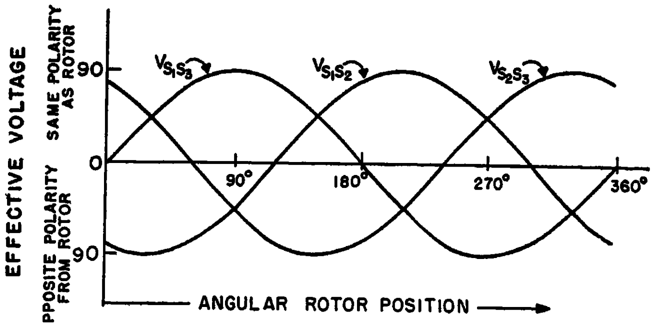

Fig. 7. Synchro stator voltage as a function of angular position of the rotor

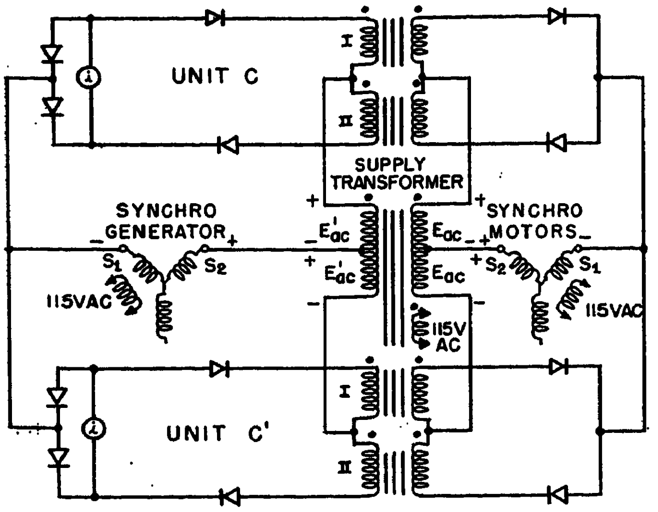

Fig. 8. Two full-wave magnetic amplifiers arranged to accommodate change in polarity of synchro stator voltage

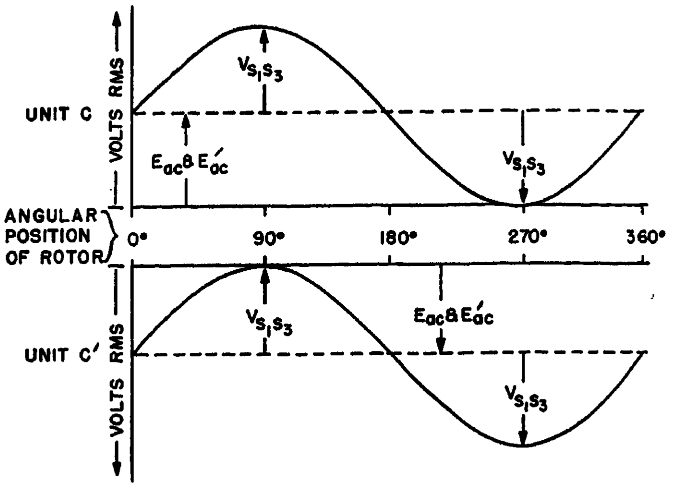

Fig. 9. Voltage available to the synchro magnetic-amplifier core as a function of the angular position of the rotor

the power and the control circuit, let us examine Fig. 9. In this figure, root-mean-square voltage is plotted versus rotor displacement. It should be noted that this a volt-displacement plot rather than a volt-time plot. The voltage available to the core is the algebraic sum of the supply voltage and the synchro terminal voltage. This is equivalent to having a single supply voltage $V_t = E_{ac} + V_{S_1S_2}$ (motor), in the power circuit, and $V_t' = E_{ac}' + V_{S_1S_3}$ (generator), in the control circuit. As long as the ratio of V_t/V_t' remains a constant equal to the turns ratio of the windings, the magnetic amplifiers are quiescent, which is equivalent to E_{ac}/E_{ac}' remaining constant and with no signal voltage, in the basic circuit shown in Fig. 1. Also, in Fig. 3, the values of E_{ac} and E_{ac}' may change, but as long as the ratio E_{ac}/E_{ac}' remains constant, the magnetic amplifier operates along the same linear transfer characteristic. This is the condition that exists in the synchro amplifier as the motor and generator assume the same angular position through a complete revolution of 360 degrees. If the angular position of both are the same, V_t and V_t' will change proportionally and all magnetic-amplifier units will remain quiescent. However, let us consider what occurs when the voltages V_t and V_t' change independently. Referring to Fig. 8 and assuming instantaneous polarities as shown, we have for initial quiescent conditions (assuming unity turns ratio for simplicity):

Unit C

$V_t = V_t'$
$V_t = E_{ac} + V_{S_1S_2}$ (motor)
$V_t' = E_{ac}' + V_{S_1S_3}$ (generator)

and

Unit C'

$V_t = V_t'$
$V_t = -E_{ac} + V_{S_1S_2}$ (motor)
$V_t' = -E_{ac} + V_{S_1S_3}$ (generator)

Now assuming the synchro generator is displaced so as to increase its terminal voltage, $V_{S_1S_3}$ generator, we have

Unit C	Unit C'
$V_t' > V_t$	$V_t' < V_t$

Neither core of unit C fires because of blocking by the constant current source and rectifiers. Core I of unit C' will reset a smaller amount, so that on the next half cycle an excess voltage equal to the difference between V_t' and V_t will appear across the motor synchro terminals S_1S_2. Since the amplifiers are full-wave, core II of unit C' will fire on the second half-cycle following initiation of the signal. The current through the synchro motors will be in such a direction as to produce torque to position the rotors and to restore quiescence again. As soon as the motor rotor is positioned, the magnitudes of V_t and V_t' will have changed to new steady-state values and then

Unit C	Unit C'
$V_t' = V_t$	$V_t' = V_t$

Next, assume that the synchro generator is displaced such as to decrease its terminal voltage, $V_{S_1S_3}$ generator; for the same instantaneous polarities, see Fig. 8, we have

Unit C	Unit C'
$V_t' < V_t$	$V_t' > V_t$

Core II of unit C will reset a smaller amount, and this core will fire on the next half-cycle. Similarly, core I of unit C will fire on the second half-cycle and torque in the synchro motors will be in a direction to restore quiescence, until again

Unit C	Unit C'
$V_t' = V_t$	$V_t' = V_t$

It is evident that the two units C and C' act to provide torque in opposite directions irrespective of the polarity of the synchro's terminal voltage, with the direction of torque dependent on the polarity of the synchro terminal voltage. In other words, for one half revolution of the generator rotor relative to the motor rotor, unit C will provide clockwise torque, and for the other half, counterclockwise.

When there is a displacement of the motor shaft with the generator in a locked position, a torque is produced resisting this displacement. The action of a core firing is again a function of the voltages V_t and V_t' and, since a displacement of

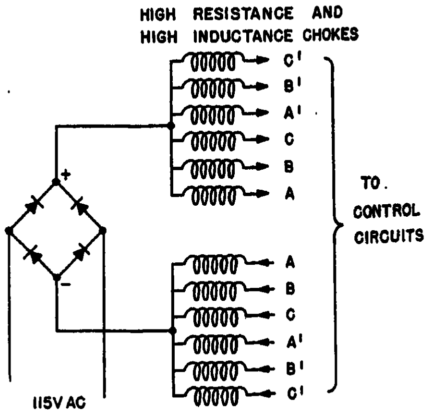

Fig. 10. Diagram of constant-current d-c supply

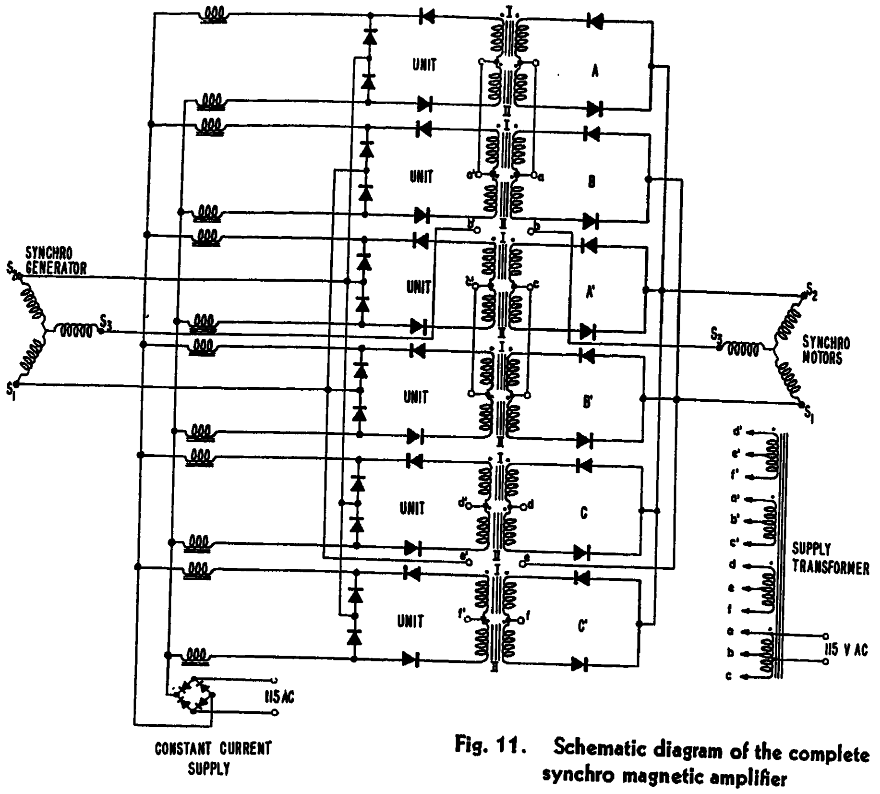

Fig. 11. Schematic diagram of the complete synchro magnetic amplifier

the motor rotor causes a change in the synchro motor terminal voltage, there is a consequent unbalance produced by a change in V_t instead of V_t'.

In going through the step-by-step analysis of the operation of the synchro amplifier, the main purpose of the constant-current sources becomes readily apparent—that of blocking other than magnetizing currents in the control circuit. For the case of a generator-initiated signal in the circuit, Fig. 8 the voltage V_t' is seen to increase in one unit and at the same time to decrease in the other. Dependent on past history and upon the operating point along the hysteresis loop, an increase in V_t' may cause saturation on the reset half-cycle. This tends to produce large currents in the control circuit, which are prevented by the constant-current source and associated blocking rectifiers.

All of the constant-current sources are supplied from a single full-wave bridge rectifier using the 115-volt a-c supply, Fig. 10. In both the positive and negative leads, high-impedance chokes are used, so that the d-c current is maintained nearly constant because of the high-d-c resistance of the chokes, and a-c isolation between units is assured by the large inductance of the chokes.

Complete System

Fig. 11 is a schematic diagram of the complete synchro amplifier. For the sake of clarity, the power and control circuits are diagrammed separately, since the two circuits are electrically isolated except for inductive coupling through the cores. This circuit is a composite of three magnetic amplifier circuits of the type shown in Fig. 8. A simplification of the complete system is obtained by eliminating two of the center-tapped transformer windings. Here, Units A, A', B, and B' are seen to share common a-c supplies, E_{ac} and E_{ac}', whereas units C and C' require different a-c supplies. Therefore, the whole system uses eight a-c supplies, in the form of four center-tapped windings. These four center-tapped windings are provided from a single transformer, with its primary supplied from the 115-volt line.

Results of Tests

In the investigation of this magnetic amplifier, an attempt was made to determine the accuracy, time of response, and gain. Measurements were made with satisfactory precision on static and dynamic accuracy and time of response. No satisfactory measurement of gain was obtained because of practical problems involved.

Accuracy

The static and dynamic accuracy of the synchros was tested both with and without the magnetic amplifier. As a basis for comparison, both static and dynamic accuracy checks were made on a

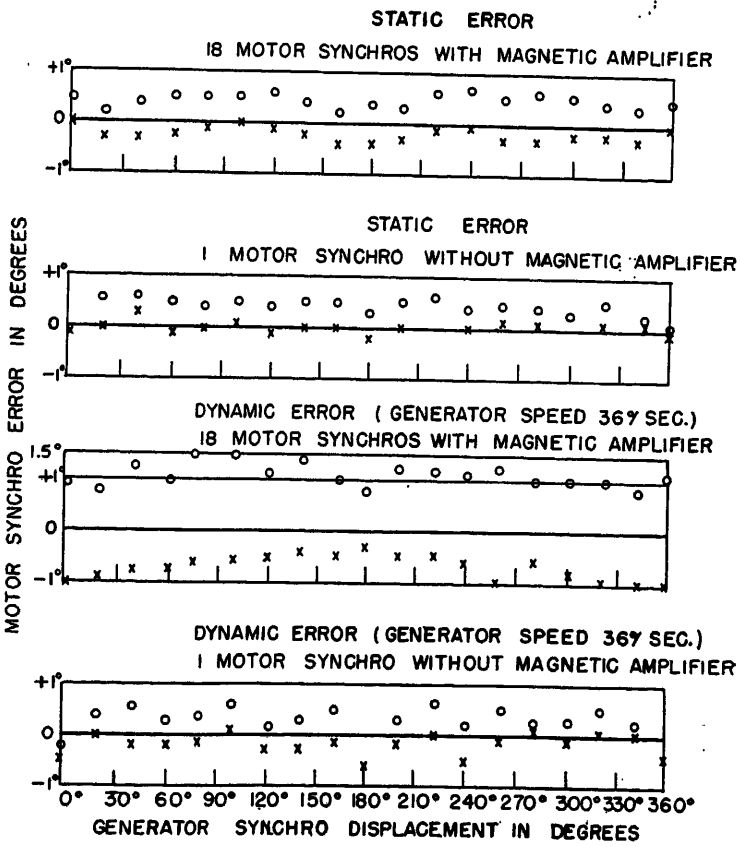

Fig. 12. Static and dynamic accuracy of the system
O—Rotation clockwise
X—Rotation counterclockwise

Bureau of Ordnance *5-G* synchro generator driving a single *5-F* synchro motor, direct-coupled without magnetic amplifiers. Both of these units were matched synchros selected to have an accuracy of ±0.5 degrees. This same motor-generator pair was tested for accuracy with the magnetic amplifiers in service, and with 17 additional synchro motors of the same size paralleling the *5-F* synchro motor under observation. Of the 18 synchro motors, only 6 were provided with external magnetic dampers and dials; the remaining 12 had free shafts.

The dynamic accuracy test was made by driving the *5-G* synchro generator from an external motor at a constant speed, and photographing the dials of the motor-generator pair simultaneously. Light flashes from a Strobolux were used to make exposures on a moving film to make a point-by-point accuracy check between the motor-generator pair while in rotation. The results of static and dynamic accuracy tests, both with and without the magnetic amplifiers, are shown in Fig. 12.

RESPONSE TIME

The response time of the system was determined for step displacements initiated in either the synchro generator or the synchro motor. Here again, as in the accuracy tests, a comparison was made between the response time of a single motor-generator pair connected directly, and the response time of 18 synchro motors using the magnetic amplifier.

To obtain the transient oscillograms, see Fig. 13, an oscilloscope was connected across one pair of motor stator terminals, for example, S_2S_3, and the sweep triggered at the same instant a step displacement was initiated. Oscillations of the motor rotor or rotors in coming to rest were recorded as a change in amplitude of the 60-cps a-c voltage appearing at the stator terminals of the synchro motor. By choosing the proper rotor position to initiate the transients, the 60-cps voltage $V_{S_2S_3}$ was amplitude-modulated to be very nearly proportional to displacement; the 60-cps voltage peaks provided a convenient time reference.

Generator-initiated transients were produced by switching from one to the other of two locked generators having appropriate angular displacement. Motor-initiated transients were made by displacing a single motor rotor and triggering the sweep at the same instant the displaced rotor was released.

The response time of the amplifiers alone, without the influence of the natural period of the synchro motors, was obtained as follows. The synchro motors were positioned by a generator (no. 1) and then all motor shafts were locked. The control was then switched to another generator (no. 2), displaced 20 degrees,

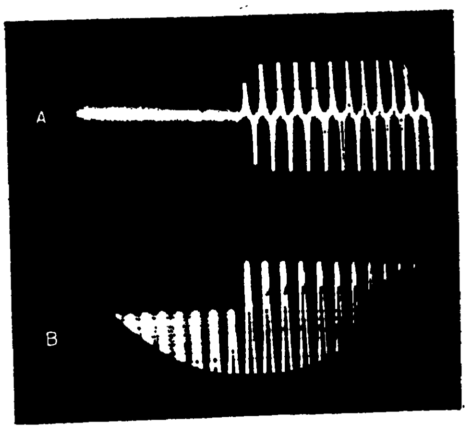

Fig. 14 (right). Transient response of magnetic amplifiers obtained with blocked synchro rotors

A. Current supplied to motor synchros with blocked rotors

B. Transient introduced in generator synchro voltage and the oscilloscope sweeps triggered a short time before the instant of switching. One y-axis of a dual-beam oscilloscope was connected across a small resistance in one synchro-motor lead, so that motor current was recorded as a function of time. The other y-axis was connected across a pair of control circuit terminals to record the time that the generators were switched.

Fig. 14 shows the result of this measurement, and it may be noted that the response time is essentially one cycle. This response time correlates with the dynamic accuracy tests made on the system, which show an average angular lag of the motor synchros of approximately 3/4 degree for each direction of rotation, see Fig. 12. Since the speed of rotation for this test was 36 degrees per second, then 3/4 degree corresponds to a time lag of 0.02 second which, in terms of 60-cycle power-supply frequency, is a response time of 1.2 cycles. When the speed of rotation is reduced one half, or 18 rpm, the dynamic error is correspondingly reduced by one half.

GAIN

One of the greatest advantages of this particular magnetic amplifier is that gain and time of response are not interrelated. Furthermore, the output current is not necessarily a function of input current, as it is for conventional amplifiers; instead, the gain of this circuit is more of a function of the ratio of input to output circuit impedances. Of course there are practical limitations to this type of magnetic-amplifier circuit, such as winding resistance, a-c power-supply impedance, rectifier back-leakage, and the fact that even the best core materials do not have their remanent flux density equal to their saturation flux density. In spite of these practical limitations, the results obtained with the synchro magnetic amplifiers are good.

Table I. Design Data

Item	Specifications
Magnetic-amplifier cores	20-gauge Hypersil toroidal strip wound $2^{7}/_{8}$-inch outside diameter; $2^{1}/_{16}$-inch inside diameter; 1-inch height
Magnetic-amplifier windings	2,000 turns no. 22 (power circuit) 2,000 turns No. 29 (control circuit)
Supply transformer	Primary: 115 volt Secondaries: two 180-volt center-tapped windings for E_{ac} supplies, two 170-volt center-tapped windings for E_{ac}' supplies
Rectifiers	Power: each rectifier shown schematically in the power circuits is made up of two *G-10* power germanium rectifiers in parallel Control: all rectifiers are *1N39* germanium diodes Constant current source: (Fig. 10) four 100-milliampere 120 volt selenium rectifiers
Chokes	Constant current source: (Fig. 10) twelve 5,500 ohm, 250-henry chokes

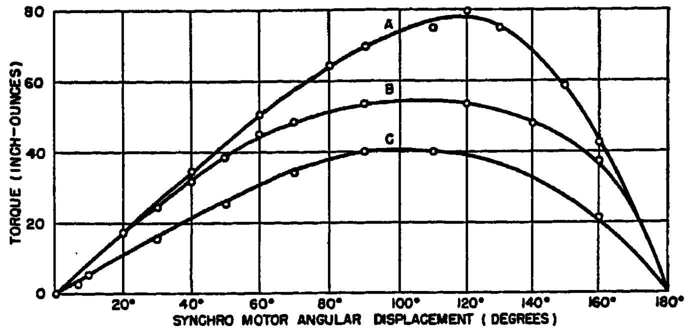

Fig. 15. Static output torque with and without magnetic amplifiers

A. Eighteen motor synchros with magnetic amplifier

B. Two motor synchros with magnetic amplifiers

C. Two motor synchros without magnetic amplifiers

To obtain measurements of the gain of the complete synchro magnetic amplifier under operating conditions posed a problem. Since the output of the amplifier is, in the final analysis, intended to provide torque through the respective motor synchros, it was believed that gain measurements could be obtained from torque measurements. Although output torque could be readily measured, the input torque was essentially zero, because of current limiting in the control circuit of the synchro amplifier. This limiting action kept the generator stator current to 11 milliamperes or less, regardless of the torque exerted on the motor shafts. This is not surprising, since the system is not designed to function as a torque amplifier, but to deliver an output torque based on a comparison of motor and generator terminal voltages. Nevertheless the small generator stator current which is necessary as magnetizing current for the magnetic amplifiers does produce an extremely small reacting torque (which was impractical to measure, because approximately 10 milliamperes are required to overcome static friction alone). Owing to the presence of static friction in the generator synchro shaft, which would swamp out measurement of input torque, overly optimistic figures of gain would result from torque measurements. Fig. 15 gives the results of static torque measurements and, for purposes of comparison, the torque displacement curve of a single *5G* generator synchro, supplying two *5F* motor synchros, is included. It can be seen from this graph that the maximum output torque obtained from a motor synchro, with the magnetic amplifier supplying 18 motor synchros, is twice that obtained when two motors and one generator are connected directly, and also that there is an increase in the maximum torque available when more motor synchros are added in parallel, as a load on the magnetic amplifiers. This results from one characteristic of this magnetic-amplifier circuit, which performs more efficiently when coupled to a low-impedance load (in this case, a number of synchro-motor impedances in parallel).

Conclusions

The magnetic amplifier described in this paper provides power amplification, so that the signal obtained from a single synchro generator may be used to position a large number of synchro motors connected in parallel.

This particular magnetic synchro amplifier was not designed as a replacement for any specific electronic synchro amplifier, but rather to demonstrate a principle. However, the size and weight of this particular magnetic amplifier and its performance indicate that a system designed to replace certain electronic amplifier systems would offer considerable saving in weight and space. The minimum size and weight of a magnetic synchro amplifier of this type designed for any particular installation will depend upon:

1. Type and number of synchro motors;
2. Mechanical load on the synchro motors;
3. Static and dynamic accuracy requirement;
4. Speed of response desired.

Table II. Space and Weight

Item	Weight
Twelve magnetic-amplifier cores with windings at $2^{1}/_{4}$ pounds each	27 pounds
Supply transformer	11 pounds
Twelve chokes, at $1^{1}/_{2}$ pounds each	18 pounds
Rectifiers	4 pounds
Total weight (excluding chassis and hardware)	60 pounds

Entire system may be conveniently housed in a volume of $2^{1}/_{2}$ cubic feet (approximately 12 by 10 by 30 inches).

Although the magnetic amplifier provides good torque isolation between synchro generator and the synchro motors one disadvantage of this type of system is that there is no torque isolation between parallel-connected motors. This is typical of any synchro system with several synchro motors connected in parallel, and driven from a single synchro generator. Another disadvantage is that the temperature limitations on the magnetic amplifier are dictated by the germanium rectifiers, which have a restricted operating-temperature range.

Discussion

L. J. Johnson (D and R, Ltd., Santa Barbara, Calif.) and **Dr. S. E. Rauch** (Associate Professor, University of California, Los Angeles, Calif.): The author has presented details in his discussion of the synchro system which lead the reader to expect equivalent center-tap power transformers in both the control and load side of the amplifiers. For example, in Table I it is shown that the number of turns in the power and control circuits are equal. In addition, it is necessary that the control voltage equal the output voltage, since this condition would have to exist if the synchro generator and synchro motors were used without the magnetic amplifier. However, Table I shows a 180-volt center-tap winding for E_{ac} supplies, and a 170-volt center-tap winding for E_{ac}' supplies. This 10-volt difference between the power- and control-circuit voltages has not been explained in the paper. Since the voltage difference is a vital requirement in obtaining the stability of the synchro system, it is of general interest to have this phenomenon discussed in detail.

Let us first consider the bilateral amplifier shown in Fig. 4. It can be seen that if $E_{ac}'>E_{ac}$, then circuit no. 1 will fire and circuit no. 2 will not fire. Thus, the magnetic flux will traverse an asymmetrical hysteresis loop. The major portion of this loop will be in the flux direction determined by the magnetomotive force produced by the currents in circuit no. 1. Now suppose that a reversal of voltage difference occurs, such that $E_{ac}>E_{ac}'$. Then the minor loop must progress towards the opposite end of the major loop. The rate of progress is determined only by the voltage difference $E_{ac}-E_{ac}'$. Thus, the time to reach steady state is a function of the difference voltage. It is possible for the time delay to be of the order of magnitude of a second or more to reach steady state.

Let us examine in detail the effects of the voltage difference in the circuit of Fig. 8, using the supply voltages as listed in Table I (namely, $E_{ac}'=170$ volt center-tapped transformer, $E_{ac}=180$-volt center-tapped transformer). Assume the magnitude of voltage between the terminals S_1 and S_2 for the synchro generator and synchro motors to be 50 volts, with polarities as marked in Fig. 8. The voltage applied to unit C in the control circuit will be synchro generator voltage, plus E_{ac}', or $50+85=135$ volts. The voltage to unit C on the load side is equal to E_{ac} plus synchro motor voltage, namely $90+50=140$ volts. It is to be noted that equal turns exist in the control and power windings. Since there is a 5-volt difference in favor of the load circuit, and the amplifier employs the Ramey principle, the 5 volts must be absorbed while the amplifier is firing.

Now consider the control and load circuits which contain unit C'. The voltage to the control circuit equals E_{ac}' minus synchro generator voltage, or $85-50=35$ volts. Similarly the voltage to the load circuit is E_{ac} minus synchro motor voltage, or $90-50=40$ volts. Again, there exists a 5-volt excess in load circuit which is absorbed when unit C' is firing. From these observations it follows that unit C and unit C' fire simultaneously with equal magnitudes when the synchro motors and synchro generator are in perfect alignment. As the circuit in Fig. 8 is in triplicate for the complete synchro-amplifier circuit, it must be concluded that all amplifiers fire simultaneously with 5-volt magnitudes when the synchro generator and synchro motors are in perfect alignment. This phenomenon ensures that all cores work around minor loops which are located at the firing end of the major loop. As a result, there is no time delay involved in affecting a change of flux from the reset end to the firing end of the major loop when a transient error is encountered. This would not necessarily be the case, if $E_{ac}=E_{ac}'$. Thus, the significance of the voltage difference has been established. Furthermore, stability of the circuit has been improved by eliminating the possibility of pure time delays which arise when the flux must drift from the reset to the firing end of the major loop. It is well known in the servo field that pure time delays are very detrimental to the stability of systems.

The designer will immediately raise the question concerning the process in which the 5-volt differential was established for the specific synchro system reported upon by the author. In general, the required magnitude of the voltage differential is empirically obtained and is dependent upon core material characteristics. The permeability in the saturated region must be of sufficient magnitude to limit peak current values when all amplifiers are firing in equal magnitudes; namely, during the steady-state quiescent condition. During this period the firing currents do not necessarily flow through the synchro motors, but may flow directly from one amplifier unit to the other. For example, in Fig. 8 currents may flow out of unit C into unit C' and through the entire supply transformer winding. It may be noted further that the resistance is very low, and thus a small reactance exhibited by the windings on the saturated core will significantly limit the peak values of these currents. As the required voltage differential is always proportionally small in comparison to supply transformer voltages, it is only necessary that the core characteristic exhibit sufficient permeability magnitude for current limitation near the knee for small firing angles. It is highly desirable for the permeability beyond the knee to rapidly decrease to its minimum value for larger firing angles.

Hypersil provides characteristics which appear to be the most desirable for the application reported in this paper. Deltamax is less desirable, since its permeability change at the knee is too abrupt and would necessitate a much closer control of the voltage difference herein discussed. A more detailed analysis of the effects of core materials on circuits employing magnetic amplifiers can be found in the references.

R. L. Van Allen: The author wishes to thank Mr. Johnson and Dr. Rauch for an interesting discussion. However, it should be stated that this article was submitted as a technical paper to demonstrate the workability of a principle set forth by Dr. Ramey. There are many design problems which may arise in adapting this principle to a specific synchro system. This paper was not intended as a guide to the designer, but since several questions have been raised regarding design, the author would like to add to the discussion some notes obtained from his experience with the system.

Early work with this magnetic synchro amplifier was performed on a model which incorporated the use of selenium rectifiers in the load circuits, and although the selenium rectifiers were the best available, they adversely affected the performance of the system. Using selenium rectifiers, it was found to be necessary to establish a quiescent firing angle by making the load power supply E_{ac} much larger than the control-circuit power supply, E_{ac}'. In addition to preventing pure time delays, this quiescent firing angle also served an additional function of biasing all magnetic amplifiers up on the transfer characteristic curve. The ideal transfer characteristic, see Fig. 3, does not truly represent the practical amplifier transfer characteristic. Because of imperfect core materials and forward resistance of rectifiers, the practical transfer characteristic curve exhibits a toe at the base of the curve. For small output currents at small values of control voltage, the slope of the curve is not as steep as the rest of the curve. Therefore, unless some means of biasing is provided, the magnetic synchro amplifier will be insensitive to small angular changes of the generator. By operating in the linear regions of the transfer characteristic, sensitivity, static accuracy, and stability are improved. There is a disadvantage in biasing for a quiescent firing angle;

that is, all cores in each amplifier unit must be carefully matched, or else static accuracy will be impaired. In the paper, it was mentioned that alternate units such as C and C' provide either clockwise or counterclockwise torque. It is evident that when all units have a quiescent firing angle, all counteracting torques must be equal, or else the motor synchros will seek a position not in alignment with the generator, thus impairing the static accuracy of the system. It was found that most of the quiescent current does pass through the motor windings, and hence must be taken into account.

During the course of the investigation of this system, germanium power rectifiers became available, and when they were used in the power circuits of the magnetic amplifiers, stability of the system could be obtained with E_{ac} nearly equal to E_{ac}' because of an increase in the slope of the transfer characteristic. It was found, however, that for small angle sensitivity, static accuracy, and improved time of response, a quiescent firing angle was still desirable, for these reasons as well as for the elimination of pure delay time. The amount of voltage difference between E_{ac} and E_{ac}' was arrived at empirically, but the absolute value of this difference is not extremely critical and may vary several volts. But, it is best to use as little voltage difference as possible to keep quiescent current low and still maintain good sensitivity and time of response.

The problems of stability and speed of response are closely related, and it was found in the course of the investigation that factors which influenced the speed of response of the individual amplifier are most important in establishing a stable system. If we carefully examine the basic amplifier of Fig. 6, it becomes apparent that it is not inherently a half-cycle response amplifier, as is the more basic circuit invented by Dr. Ramey, see Fig. 1.

Referring to the circuit which is illustrated in Fig. 6, let us assume for initial conditions that the motor and generator are in alignment and their terminal voltages are each 50 volts with polarities aiding E_{ac} and E_{ac}'. In the control circuit, the resetting voltage is $E_{ac}'+50$ volts, and in the load circuit, $E_{ac}+50$ volts. Further, let us assume that instantaneously the generator voltage is increased to 70 volts at the beginning of a cycle in which the top core will fire and the lower core reset. The step increase in generator voltage will cause a voltage $E_{ac}'+70$ to appear across the control windings of the lower core, and transform to the power winding of the lower core $E_{ac}'+70$ volts. Since, in the power circuit, the source voltages are $E_{ac}+50$ volts (and with E_{ac} 5 volts greater than E_{ac}), there is still a net of 15 volts excess in the direction of the load rectifier of the resetting core, so that the lower power rectifier will conduct and reduce the resetting voltage to $E_{ac}+50$ volts. Thus the required amount of reset does not occur in 1/2 cycle, but must take several cycles to reach steady state. If either the synchro motor impedance or the impedance of E_{ac} supply is appreciable, and the current through the firing core causes a drop in the terminal voltage, then there will be a greater excess of voltage transformed by the resetting core, further increasing the time of response. For this particular system, it was found that six type-5*F* synchro motors in parallel reduced the effective impedance of the load for minimum time of response, which is of the order of 1 cycle. When more than six motors are used, no appreciable decrease in response time can be realized, but when less than six motors are connected, the time of response increases, and consequently more overshoots will result from a generator-initiated transient, unless the load impendance is reduced. It is impractical to use this system for fewer than six motors synchros of this size, so this is not considered a serious disadvantage.

In summary, the most important factors which must be considered for good performance of the system are:

1. Low internal impedance of E_{ac} supply and load;
2. Power rectifier should have low forward resistance;
3. Biasing for quiescent firing angle;
4. Careful core matching.

Type-*N* Carrier Telephone Deviation Regulator

E. H. PERKINS
NONMEMBER AIEE

J. J. MAHONEY
NONMEMBER AIEE

THE type-*N* carrier system[1] was introduced into the field 3 years ago to satisfy the increasing demand for short-haul toll telephone trunks. The system provides flat regulation for the group of 12 channels at each repeater and the receiving terminal. Individual channel regulation is provided only at the receiving terminal. The flat group regulation is adequate for longer systems, but for system lengths greater than about 150 miles, the transmission variation caused by temperature change could exceed the individual channel regulating ability of the receiving terminal. If this were to occur, the channels would not meet the severe standards specified for them as a component of a multilink toll connection.

To prevent this condition, a regulator has been designed which can be inserted into the line and which provides the additional transmission regulation required. The regulator performs the function of re-establishing correct channel levels as would the insertion into the line of two terminals back-to-back, but at a much lower cost. This regulator is activated by all of the transmitted channel carriers. It determines the departure of each channel carrier from its nominal value and regulates the line transmission by thermistor-controlled networks, so as to produce a minimum residual departure from nominal transmission. The correction includes four shapes designated slope, bulge, cubic, and quartic. Various combinations of these shapes very closely approximate the departures experienced in the cable and repeaters. This regulator controls the transmission variations sufficiently well so that temperature changes are no longer the controlling factor in limiting system length.

Transmission Requirements

The transmission variations occurring in a system are proportional to the length of the system, the number of repeaters involved, and the extent that transmission through each of these components varies with operating temperature. Thus, the amount of transmission variation is a function of the temperature range of the area where the system is used. This range varies considerably over the country. Fig. 1 presents data compiled by the United States Weather Bureau to show the normal annual temperature variations in the United States. A near maximum figure, not this normal variation, must be used for circuit design so that service standards will not be deteriorated on more than a few extreme days that exist each year in both winter and summer. An analysis of Weather Bureau data for many cities shows that a factor of three times the normal variation is representative of the near maximum figure desired, and accordingly that value has been considered as a basis for the regulator performance. This establishes, for example, a temperature swing of about 75 degrees

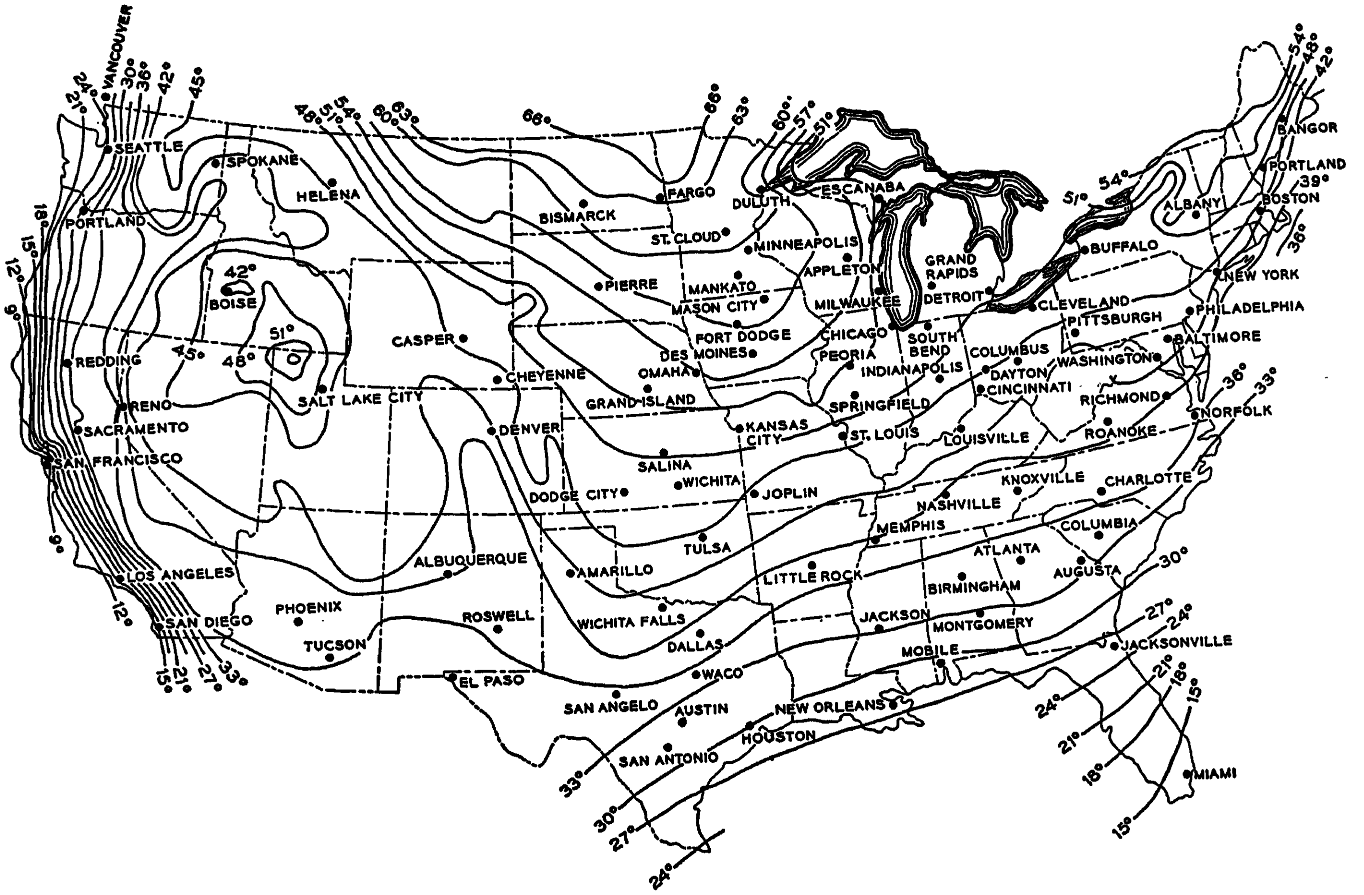

Fig. 1. Normal annual temperature variation in United States, compiled by the United States Weather Bureau

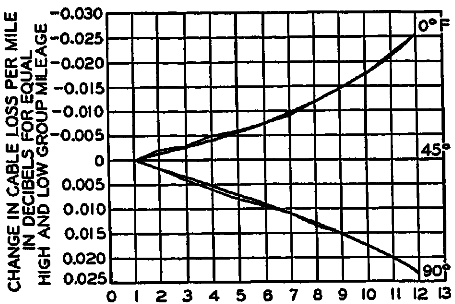

Fig. 2. Transmission loss variation with temperature in 19-gauge cable

for Vancouver, 150 degrees for Chicago, 125 degrees for New York, 80 degrees for New Orleans, and 50 degrees for Los Angeles. It is interesting to note that the smallest figures are for the California coast line, which has a range of only about 40 degrees Fahrenheit. An average value of about 100 degrees Fahrenheit seems to be a representative figure for the United States as a whole and has been chosen for this study.

The transmission change with temperature for the 19-gauge toll cable is shown on Fig. 2 for equal mileage of the two line frequency groups. The flat component of transmission change has been neglected as it is corrected for by the flat gain regulation in each repeater and thus is not cumulative. The change in loss is plotted as a function of channel number, not frequency, to reflect the partial canceling of the slope and bulge components. It may be noted that a 45-degree temperature change results in a net residual slope change of about 0.025 decibel (db) per mile and a net residual bulge change of about 0.003 db per mile.

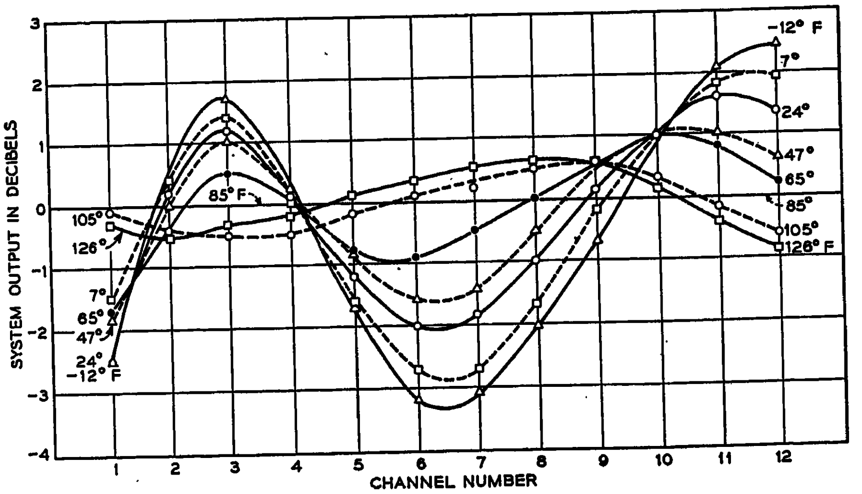

Fig. 3. Repeater gain change with operating temperature (12 repeaters in tandem)

The transmission variation with temperature for the repeaters is shown in Fig. 3. It is based on laboratory tests on 12 repeaters and is plotted as a function of the system channel number. The data are presented as departures from the value at 85 degrees Fahrenheit which is considered a representative ambient condition.

To analyze the transmission changes in a long system, the effect of the representative temperature swing of 100 degrees Fahrenheit has been calculated for a 200-

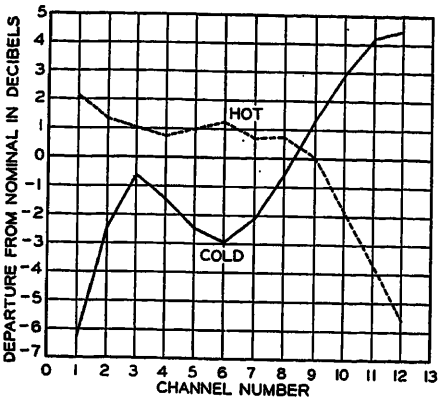

Fig. 4. 200-mile aerial cable system—deviation due to 50-degree change (hot or cold) from line-up temperature. Line-up temperature is 45 degrees Fahrenheit for cable and 85 degrees Fahrenheit for repeaters

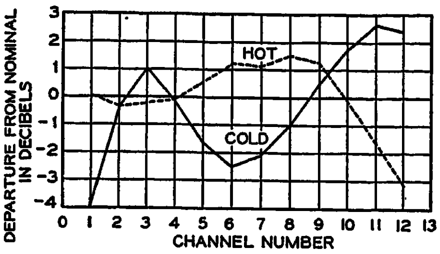

Fig. 5. 200-mile buried cable system—deviation due to 50-degree change (hot or cold) from line-up temperature. Line-up temperature is 45 degrees Fahrenheit for cable and 85 degree Fahrenheit for repeaters

mile system. These calculations have been made for both aerial and buried cable and the temperature change has been assumed to be 50 degrees both above and below line-up temperature. These variations are taken as typical of the magnitude of correction to be supplied by the regulator and are shown on Figs. 4 and 5. It will be noted that the requirements presented are based on information for channels 1 through 12. Since these requirements were formulated, channel 13 has been made available for general use in type-*N* systems as a substitute for a channel with excessive interference or marginal signaling. For long systems especially it became apparent that channel 13 was preferable to channel 1 from a transmission standpoint. Accordingly the regulator has been designed to use the channel carriers 2 to 13 inclusive. Considering Figs. 4 and 5, neglecting the transmission at channel 1, and projecting the curves to include channel 13, the maximum channel range requiring correction by the regulator is about 12 db at channel 13 for aerial cable and about 7 db at channel 13 for buried cable.

Description

The deviation regulator is a complete unit. It is connected into the transmission line directly following a low-high repeater. It provides shape changes only and has a negligible effect on the level of transmission. Each deviation regulator corrects for one direction of transmission so that two are required for both directions of a system. As each regulator employs 23 tubes it must be used at a power point.

The regulator consists of four main blocks which are shown schematically in Fig. 6. The regulator is shown connected into the transmission circuit between the low-high repeater output and the line. The four blocks of the regulator are indicated by the dotted lines which segregate the unit into the thermistor-controlled shaping networks, the regulator amplifier consisting of the line amplifier and pickoff amplifier, the channel filters, and the computer and control circuits.

Regulating Networks

The thermistor-controlled shaping networks are four separately controlled units. Each is continuously variable throughout its range under the control of its associated thermistor. The four network shapes are called slope, bulge, cubic, and quartic. The slope and bulge networks are basically required by the cable changes while the cubic and quartic networks compensate principally for the repeater changes. Flat regulation is provided by the low-high repeater and thus the regulator is relieved of this duty.

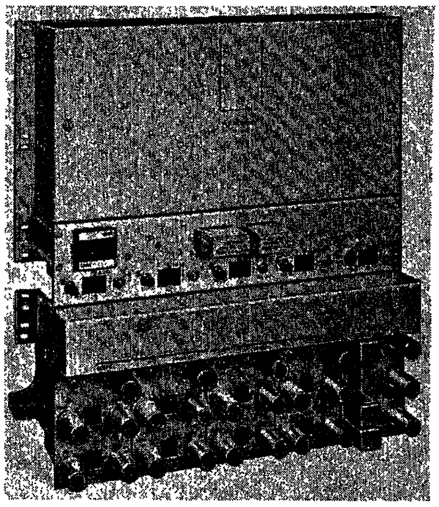

Fig. 7. N deviation regulator

As the thermistor resistance is changed the networks diminish the magnitude of their change from one extreme, pass through a mean condition where no shaping is introduced, and continue to an extreme inverse shaping. The slope network provides ±10 db of slope change. The other three networks provide only ±5 db of change.

Each network component acts independently and simultaneously with the others. This independency of action of the components obviates the need for having a different time constant for each shape and thereby permits the same type of thermistor unit to be used throughout.

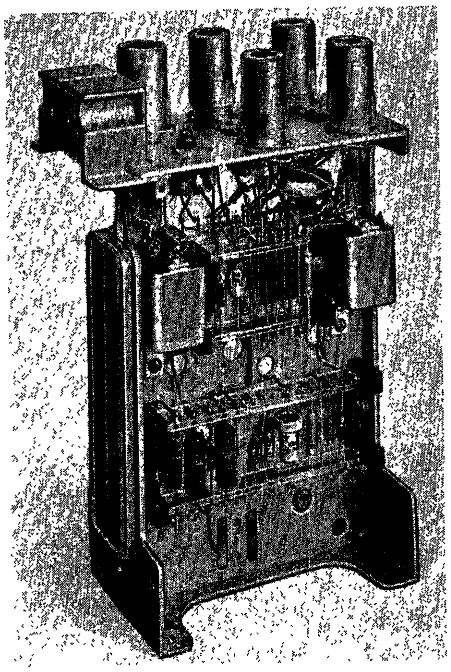

Fig. 10. Regulator control unit

Regulator Amplifier

The second box in the block schematic is the regulator amplifier which uses three *408A* vacuum tubes and is a plug-in device. It performs two functions and may be considered as composed of a line amplifier and a pick-off amplifier.

The line amplifier portion provides about 60-db gain to compensate for the mean loss of the regulating networks and thus restore the system signals to their proper level for transmission over the line. It is a 2-tube feedback amplifier very similar to the amplifier portion of the low-high repeater. It functions at the same signal levels and has similar transmission characteristics.

The pick-off amplifier portion provides a source of power to activate the control circuits. It is a 1-tube amplifier with local feedback to stabilize its gain. Its input is derived from a tap on the output transformer of the line amplifier.

Channel Filters

The output of the pick-off amplifier connects to the bank of 12 channel filters. These are the standard type-*N* channel band filters for channel carriers 2 through 13. At the output of each filter there is a potentiometer used primarily to adjust for manufacturing variations in the individual filters so that as the signals enter the computer they are a replica of those that are transmitted from the line amplifier.

Computer and Control Circuits

The function of the computer and control circuits is to deliver current to the four network thermistors under control of the signals from the 12 channel filters. The computer consists of 48 resistors, one for each channel carrier for each network shape. Four control circuits, in conjunction with the computer, adjust the thermistor currents until only a small residual regulation error remains.

Equipment Features

The regulator has been designed using the same basic equipment features that are employed for the other components of the type-*N* and type-*O* systems. It uses plug-in units, die cast frameworks, and the standard type of miniature parts throughout. The equipment has been segregated so that all components employing vacuum tubes are plug-in units. The remainder is a consolidated unit ready for relay rack mounting except for a small power panel which is completely detached.

The complete regulator, less the power panel, is pictured in Fig. 7, and in Fig. 8 with the dust cover removed. The regulating networks, channel filters, computing network, and miscellaneous apparatus are arranged on a filter and network panel. This panel is assembled with the type-*O* slide shelf at the bottom to mount the plug-in units. The regulator-amplifier unit is at the right side and the four identical control units are mounted to the left of it. These units use one of the basic type-*O* die-castings but with different face plates to accommodate the

variations in tube and transformer requirements.

The regulator-amplifier unit is pictured in Fig. 9 and the control unit is shown in Fig. 10. These figures show the mode of construction and the accessibility of the parts for inspection or repair.

Performance

Extensive calculations and tests of the regulator performance have been made in the laboratory. The tests in every case verify the predicted performance within the accuracy of the experiment. Thus it appears that with any applied input characteristic within the capability of the regulator the output characteristic can be determined by calculation. The calculation consists of analytically performing the same function that the computer performs electrically and although the method is straightforward, it is laborious and requires accurate computation.

200-Mile System

The correcting ability of the regulator for the four sample variations established for the 200-mile system in Figs. 4 and 5 is shown in Figs. 11 through 14. In each of these latter figures the plot shows the input and output characteristic of the regulator. The input characteristic is that shown in Figs. 4 or 5. The output characteristic indicates that in each case good regulation has been achieved. The uncorrected residue in the output characteristic is small and for most of the channels is less than 1/2 db. The shape of this residue is beyond the ability of the four network shapes provided, and consists largely of higher order components. This conclusion is supported by the observation that the residue has five or six axis crossings. It will be noted that the average of the output characteristic does not fall precisely on the zero-db axis. This indicates a small flat gain component resulting from regulating action. This flat component is absorbed by the following repeater.

The excess regulating range in each of the four networks could be used to equalize for the manufacturing variations that will occur in the repeaters. The engineering rules required to take advantage of this equalizing ability are still under study.

An analysis of Figs. 11 through 14 shows that most of the slope and bulge network ranges are used, but only about a third of the cubic and quartic. The remainder provides an allowance for equalizing manufacturing variations.

The stiffness of this regulator is measured by the ratio of the amount of a given network shape in the input characteristic to the amount in the output characteristic. For these circuits this ratio is about 15. In the test measurements of the output characteristics this residual of the four corrective shapes is negligibly small compared to the magnitude of the higher order shapes.

Missing Channel

A circuit condition that is of particular interest in an operating system is the functioning of the regulator when a channel carrier is removed. This will happen whenever a channel unit is removed for test or repair. When such a condition prevails the regulator tries to correct for a very low carrier. The amount of change introduced into the transmission characteristic varies with the particular channel missing, but is a maximum of only 2 db in the worst case. Fig. 15 shows the calculated and observed performance for channels 4, 5, and 6, which is representative of all the channels. As this change is slower than the action of the individual channel regulator no serious system problem usually exists.

Program

The use of schedule-*A* or -*B* program channels over a system with a regulator imposes another particularly difficult operational problem. When using the program channel the normal distribution of channel powers is materially altered. The carrier of channel 6 is 5 db high, that of channel 7 is entirely missing, and that of channel 5 may be either 5 db low or missing. Tests on the regulator under these conditions show that it will perform satisfactorily, not distorting any channel by more than 1 db from ideal.

Hunting

One of the problems encountered when using several regulators in tandem is that of hunting. If appreciable interaction existed between regulators, an abrupt change in transmission could cause a sustained oscillation in shape change as the regulators attempted to correct the initial shock. This condition has been calculated and shows that for an impressed unit step signal on a system long enough to have three regulators, the response is a small decaying transient of about 1 cycle over a 20-minute period.

Modulation

The use of a regulator in a system does not have any measurable effect on the system modulation products. From a modulation standpoint the regulator is equivalent to a single repeater and for a long line the addition of one repeater should not increase modulation appreciably.

ON Regulator

The facilities offered by the type-*N* and type-*O* systems are being combined to form the type-*ON* system. This system uses 10 carriers instead of 12 but otherwise the cable portion of the system is similar to that for an *N* system. As some of the carrier frequencies are different from those used on type *N*, a somewhat different regulator is required. This new type-*ON* regulator will work in the same manner as that for type *N* but its regulating networks and channel filters will be adjusted to different frequencies, and it will have a slightly different computer.

The correcting ability of this regulator will not be as sensitive and when channel equipment is removed or fails two adjacent carriers may be lost at the same time. Also as this is a "stackable" system the full complement of ten carriers may not always be present. Such conditions impose special hardships on the regulator but when the design details are formulated it is expected that adequate circuit control will be provided.

Conclusions

1. The use of one or more regulators permits the length of type-*N* systems to be extended severalfold and effectively removes temperature swing as the controlling factor in limiting system length.
2. The line variations indicate that a regulator will be used at 100- to 200-mile intervals depending upon the section of the country where the system is used and the proportion of aerial and buried cable.
3. The small uncorrected residue and the lack of interaction between regulators indicate that several may be used in tandem.

Heat Dissipation from Toll Transmission Equipment

J. A. COY
MEMBER AIEE

THE liberal use of vacuum tubes in toll transmission equipment, the miniaturization of this and other component apparatus, and the assembly of the components into cubic units rather than on flat panels, for the purpose of realizing the potential space saving, has presented a new problem in heat dissipation. The necessity of designing for safe heat disposal has long been recognized in radio transmitters and similar high-power equipment. Now it is apparent in low-power equipment as well.

The situation is typified by *N* carrier terminals,[1] but is not by any means limited to this type of equipment. The latest telegraph and telephone transmission equipments all present a similar problem, and this trend will continue and expand as miniaturization is extended and components become even smaller. Conversion from vacuum tubes to transistors will reduce the heat developed per individual circuit, but the transistors must be kept relatively cool, (140 degrees Fahrenheit (F) is a presently accepted limit except for phototransistors, for which the accepted maximum is 130 F). The rapid increase in number of circuits to meet the present demands for toll service, and to take care of dialing to replace manual operation, will tend to increase the total heat per office to be dissipated.

A rather vivid illustration is found in an installation of 120 *N* carrier terminals which can easily be contained in a room 20 by 30 feet. In such an installation 42 kilowatts of energy will be released, equal to that obtained from the combustion of 720 gallons of fuel oil per month, enough to heat two ordinary houses in midwinter. Several installations are now approaching this size, and space is being reserved, for as many as 300 terminals in one room.

This example and the methods of treating it will be discussed in some detail, since it is typical of the conditions which we can expect in the future. In Fig. 1 the heat generation in *N* carrier terminals and various other types of telephone equipment is compared on the basis of watts per square foot of assigned space, and also watts per cubic foot of room volume. The assigned space includes reasonably liberal allowance for good working aisle widths and room for storage lockers, work bench or desk, and similar accessories. It will be noted that the more recent developments, such as type-*N* and type-*O* carrier, *E2* repeaters, the telegraph service board, and 2,600-cycle

ringers are all heavy producers of heat, while the older types of toll transmission equipment, together with switching and associated equipment, are relatively light producers in terms of heat per unit space. Considered alone, *V3* voice-frequency amplifiers are heavy producers but they are likely to be associated with inert equipment to compose *V3* telephone repeaters, which appear further down the list.

The satisfactory disposal of the heat generated falls naturally into two stages. First, the heat must be removed from the point where it is generated, without impairing the operation or reducing the life of any component apparatus mounted in the same unit and, second, the total heat generated must be disposed outside the office without too much increase in the room temperature.

Removal of Heat from Hot Spots

In the *N* carrier terminal, nearly all of the heat originates in the vacuum tubes, and so these have been mounted on the front of the unit, as in Fig. 2, where the maximum amount of heat is carried away by conduction and radiation, and the minimum amount reaches the body of the unit. Within this body are mounted elements which do not produce heat, as in Fig. 3, including the thermistors and varistors whose operation is most affected by temperature. The units are plugged into a mounting framework to form a complete terminal as in Fig. 4, which shows the lowest of three terminals mounted in one relay rack bay.

The design objective for the terminal was to keep the temperature of the critical elements such as the varistors of the compandors and modulators below a maximum of 140 F. This also was the temperature above which the potting compound then used for some of the transformers began to soften. Subsequently this was replaced with a compound good to 155 F. To facilitate heat dissipation, the tube shields were omitted from all but a few of the vacuum tubes, and the covers on the rear of the units were made of perforated metal. In the cover visible in Fig. 2, for example, 65 per cent of the sheet metal is removed. The temperature rise of critical apparatus above ambient was thus reduced by perhaps 10 F but it was still around 40 to 50 F, measured in an installation of only a few terminals. To insure adequate margin for large installations with lines of *N* carrier terminals back-to-back and facing one another across the aisle, and for operation in hot climates, it was decided to introduce bay blowers.

A small blower is mounted just below the bottom terminal in each bay as shown in Fig. 4. Air from this blower is conducted through two rectangular ducts up the sides of the bay and discharged in jets just below the concentrations of vacuum tubes which may be identified in groups of five near the center of each unit. These jet discharge openings may be seen in the left-hand duct. The velocity of the jets (2,700 to 4,100 feet per minute) is sufficient to spread the air well across the bay.

The blower delivers about 100 cubic feet per minute total for the bay, 5 to 8 cubic feet per minute in each of the 15 jets, of which there are 9 in the left-hand and 6 in the right-hand duct opposite the channel units. The temperature rise in the units is reduced by this means to half the amount which would occur with only natural cooling. With this arrangement, good operation of the equipment may be expected with an ambient temperature up to 105 F measured 6 feet above the floor in the center of the aisle in front of the *N* carrier terminals. Permanent injury of the equipment is unlikely if the room temperature should rise as high as 130 F with the blowers operating, or 100 F with the blowers stopped. With the adoption of the bay blowers, it was possible to revert to the use of solid, in place of perforated, rear covers for better mechanical and dust protection.

In order that the blower may operate only when needed, it is controlled by a thermostat located in the mounting shelf nearest the top of the bay. Fig. 5 shows the operating temperature of the apparatus inside the channel unit with the blower off, with the blower being controlled by the thermostat, and with the

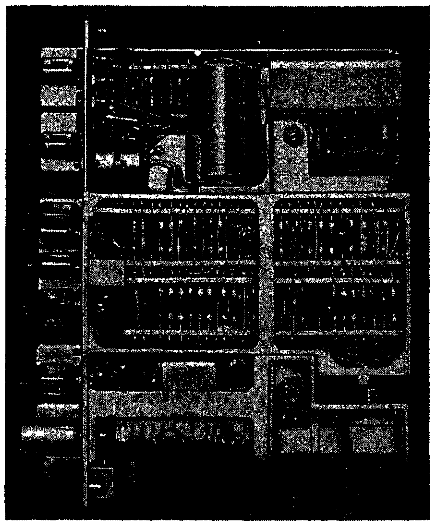

Fig. 3. Channel unit, side view

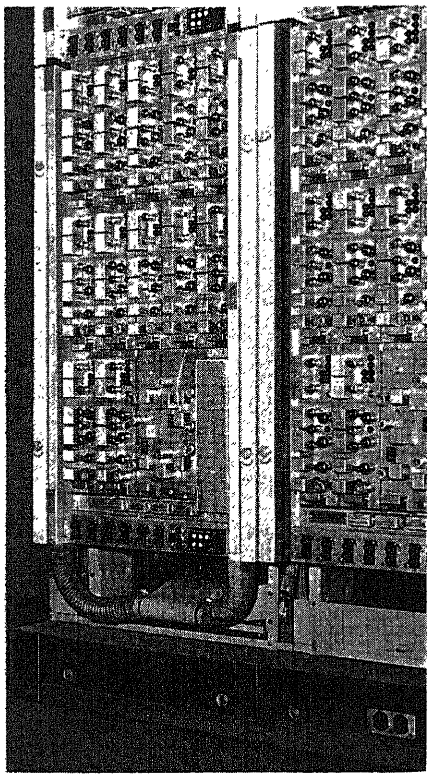

Fig. 4. N1 terminal, lowest unit of 3, with blower for cooling the bay

blower on continuously, plotted against the ambient temperature at the 6-foot level in the room. A temperature band is shown rather than a single line, to indicate the temperature spread within the units. The temperature measurements were made by placing thermocouples on the surface of several important elements. Since no heat was being generated in these elements the surface temperature so measured was the same as the interior temperature of the component.

If both the terminals and the blowers were operated only from commercial power supply, a power interruption would both stop the blowers and stop the generation of heat. In the usual case, however, the terminals are operated from storage battery reserve when power fails so that heat continues to be produced. In most of the larger offices, engine alternators are available for emergency supply, and the period of battery operation is short. In these offices transfer of the blowers to the emergency alternator is desirable. It does not appear necessary to provide such an emergency source for the blowers alone or to introduce the added complication of d-c operation from the batteries, since the rate of temperature rise in the room and in the equipment will be slow enough to cover a considerable period of power failure. Fortunately, long power outages are least likely in summer.

The *N* carrier repeaters generate only about half as much heat in a given space as the terminals, about 500 watts per relay rack bay for repeaters instead of 1,000 watts per bay for the terminals. When these repeaters are installed in buildings, blowers are not required because the temperature rise is only about half as much, and because the apparatus will operate well at somewhat higher temperature.

In general, it may be assumed that bay blowers or similar means of direct cooling can be avoided unless the heat production exceeds 500 watts per bay. This assumes that the room temperature is kept down to about the maximum of 105 F at the 6-foot level, that the heat producing elements are separated, as in *N* carrier, from the heat sensitive components, and that these components have good temperature characteristics.

Dissipation of Heat from a Vacuum Tube

In considering the general problem of heat disposition in toll offices, the way in which heat is dissipated from a vacuum tube is of interest. For this a *407A*-type vacuum tube mounted in a working *N* carrier channel unit, for example, one of the unshielded tubes in the right hand row of Fig. 2, was chosen for study. It is a miniature double-triode with two 20-volt 0.050-ampere heaters, 1 watt each, and a combined plate dissipation of about 2 watts, making a total dissipation of 4 watts. The plate structures surround the heaters so that the energy from the heaters is dissipated through the plate structures. The ambient temperature was 80 F, the glass envelope temperature measured with a thermocouple was 160 F. The plate temperature was estimated to

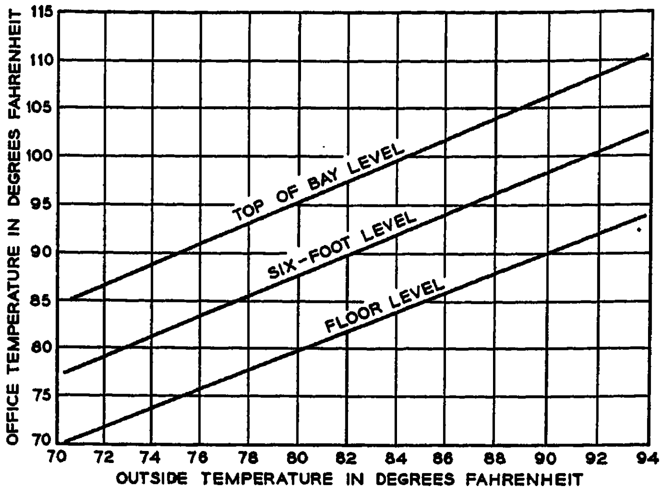

Fig. 8. Observed temperatures in an office with approximately 50 changes of air per hour

be 480 F. From this the following data were calculated or estimated: Radiation from plates and envelope, 0.7 watt; convection from envelope, 0.3 watt; conduction through socket and wires, 0.3 watt. The conduction through the socket and wires was found to be surprisingly small. The temperature difference between them and the face of the unit or the connected apparatus was scarcely measurable.

Somewhat more than half of the radiation sphere around the tube is subtended by the panel and the transformers on the front of a channel unit like that shown in Figs. 2 and 3. Perhaps a quarter of the convected heat is transmitted to the face of the unit. All of the conducted heat enters the body of the unit. Of the total of 4 watts, then, from a *407A* tube, about $2^1/_4$ watts reach the body of the channel unit. If it is assumed that the heat from a *408A* tube (2 watts) is distributed in the same way as that from a *407A* vacuum tube, then of the 24 watts generated in all the tubes of a channel unit, about 13.5 watts will reach the body of the unit.

The heat assumed to have thus entered the body of the channel unit must be dissipated from the front and rear areas since, as is apparent in Fig. 4, each unit is surrounded on the top, bottom, and sides by other units. From the front of the unit with an effective area of 70 square inches and a measured temperature rise of 45 F, the dissipation by radiation and convection is 11 watts. From the rear with equal area and a 20-degree rise, the dissipation is 3 watts. A small dissipation occurs through the framework, probably less than 1 watt. This total of about 15 watts is in fair agreement with the 13.5 watts estimated in the foregoing to be transmitted from the tubes to the unit.

Removal of Heat from Offices

The heat generated in the equipment must eventually be removed outside the building. There are three possible ways of doing this: first, by natural dissipation; second, by forced circulation of outside air through the room by means of an exhaust fan or a combination of exhaust and intake fans and, third; by refrigerative cooling. The method and extent of action to be taken will depend on the amount of heat generated per unit volume of room space; the type, arrangement, and usage of the building; and the climate; the final criterion, of course, being the relative cost.

The heat generation of *N* carrier terminals and various other types of equipment, as shown in Fig. 1, is repeated on the left-hand side of Fig. 6, for comparison with heat dissipation from the room, shown on the right-hand side of Fig. 6. The particular installation of *N* carrier terminals selected for this study is that of Fig. 7.

Obviously, natural heat dissipation becomes ineffective as the outside temperature approaches the maximum temperature to be allowed within the office, particularly when the windows are closed. This is indicated by the lowest curve on the right-hand side of Fig. 6. The curves in this figure are based on the room of Fig. 7, with two outside walls of substantial brick construction, insulated, and with windows as indicated. A still August day is assumed in the latitude of Washington, D.C., closed windows and room temperatures of 100 F at the floor, 115 F at the ceiling, and 107.5 F mean.

More effective heat removal can be provided by installing an exhaust fan to take the hot air out of the room and an intake to permit the entrance of the relatively cooler air from outside. Dust eliminating filters and a fan at the intake are advisable to avoid aggravating housekeeping problems. Two curves on the right-hand side of Fig. 6 indicate the results to be expected from forced air circulation the lower where the air flow is such that the air in the room is completely replaced every 3 minutes, the other where it is replaced once a minute.

Recently, an office with seventy operating terminals was equipped with intake fans to draw in the air through filters, and distribute it by means of ducts at floor level along the sides of the room, and an exhaust fan to draw air from the ceiling level and discharge it outside the building through a plenum chamber treated to reduce noise. Thermostatic control regulates the proportion of outside air circulated to room air recirculated. Temperatures were measured from June to September in this office at floor level, at a level of 6 feet above the floor, and at the top-of-bay level, approximately 12 feet above the floor, with an estimated 50 changes of air per hour. From these data, the curves of Fig. 8 were plotted. In this room with approximately 7,000 cubic foot volume, 70 terminals were in operation, dissipating 24.5 kw or 3.5 watts per cubic foot. The observed data check the theory about as well as could be expected in view of the difficulty of distributing the air efficiently at this high rate and of obtaining temperature measurements that

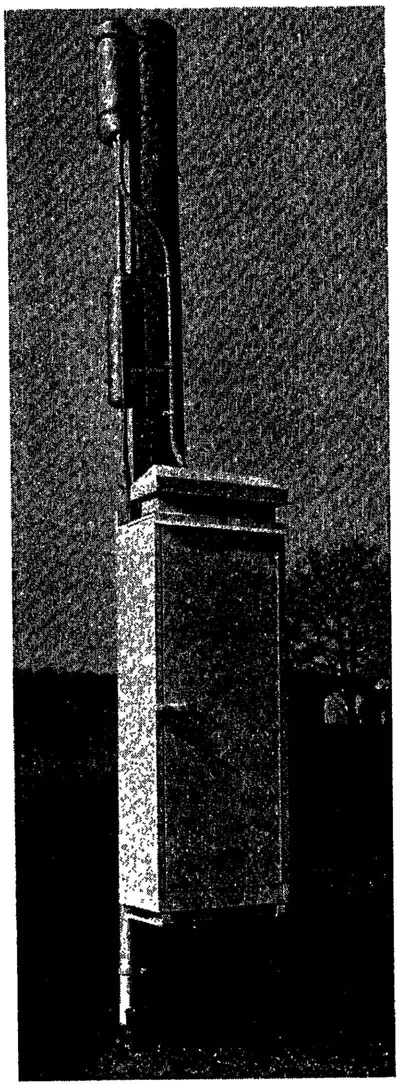

Fig. 9. Pole-mounted N1 repeater cabinet

represent average conditions. Probably the most interesting result is the lack of any discomfort with such a high rate of air circulation. The reason for this, no doubt, is that the circulated air is so near body-surface temperature. Careful engineering is needed in the introduction and distribution of air at these high rates so as to obtain as uniform conditions as are practicable throughout the room.

As compared with a ventilating system having a high rate of air change with consequent heavy dirt infiltration, the economies of refrigerative air conditioning may well be considered. The consideration of such a system will include temperature and humidity control. The air is filtered, cooled, and dehumidified to the required degree in a common equipment, from which it is circulated through the areas to be conditioned and returned for recirculation. A proportion of outdoor air is introduced for freshening. Installations of this type are generally engineered to provide a fairly uniform distribution of air over the entire space to be conditioned. The balance is seriously upset when a large concentration of heat is introduced in a small part of the area. It is then generally preferable, where this can be done, to partition off high-heat-producing equipment from the remainder of the office or to locate it in a room by itself. Where general air conditioning is available, this can be drawn upon for part of the cooling required and supplemented as needed by packaged-type unit air conditioners within the partitioned space. Where general air-conditioning is not available, packaged-type air conditioners can be used for the full duty and located in the room with the heat-producing equipment. Where the primary objective is the removal of heat generated by the equipment, the unit conditioners can be operated with only thermostatic control, since in this case humidity control is not necessary.

If it is assumed as a first approximation that just enough refrigerating capacity is provided to care for the heat generated in the equipment, then the refrigerative capacity for 120 terminals, for example, located where the heat conditions are as represented in Fig. 6, will be approximately 12 tons, 1 ton of refrigerating capacity being defined as the heat required to freeze 1 ton of water at 32 F per 24 hours, or 12,000 British thermal unit per hour. The cost of such refrigerative equipment may amount to a little more than the cost of the building space to house the equipment or, in the case of *N* carrier terminals, to perhaps 2 per cent of the cost of the equipment itself. It may actually be cheaper than high-rate outside air circulation where this requires extensive duct work.

New Equipment Arrangements

It has frequently been stated as an axion that heat generated in equipment should be removed at its source and not released into the room to be taken care of by space air conditioning. Examination of specific methods, however, does not prove that this is necessarily axiomatic. Too often in considering relative methods the objective can be inadvertently changed so that one method is considered only so far as equipment safety is affected, while another is made to include employee comfort.

Various methods have been suggested, such as, for example, turning a pair of back-to-back equipment bays inside out so that the vacuum tubes, instead of being in the aisles, project into a duct space between the two bays. A refrigerant could then be run through a finned pipe in the base of the bays and cold air circulated up the chimneylike central space by a small exhaust blower at the top. Other possible arrangements involve the circulation of a refrigerant directly through the equipment to be cooled.

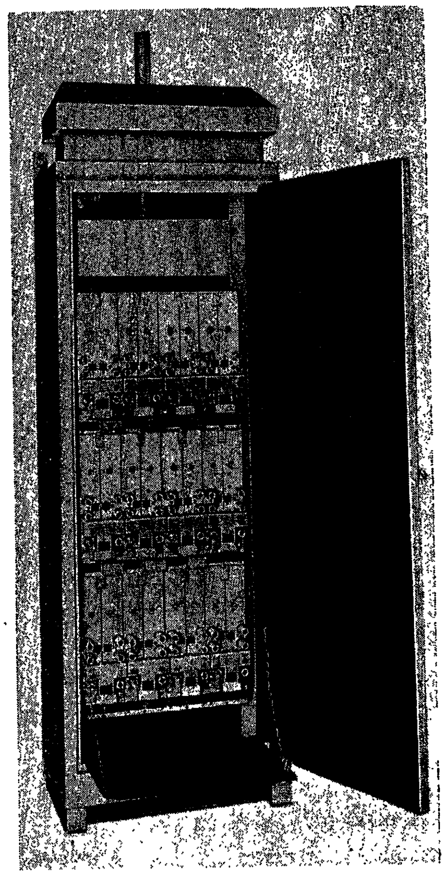

Fig. 10. Arrangement of 12 N1 repeaters in a pole-mounted cabinet

While such arrangements are obviously practicable, they generally involve relatively expensive means for the circulation of the refrigerant and the air, the presence of refrigerants may increase the hazard to service, and the component apparatus may be made less accessible for operation and maintenance. Fitting them into existing offices, existing methods of manufacture, and (perhaps even more) into the engineering consciousness of those who are responsible for equipment design and office layouts, would constitute a major undertaking which does not seem to be justified by the advantages, except in unusual situations where the heat generated cannot readily be taken care of otherwise.

Pole-Mounted Repeater Cabinets

At many of the repeater points in *N* carrier systems the repeaters are located in cabinets mounted in the open on line poles as in Fig. 9, or on a cross arm between the line pole and a stub. Each cabinet contains 12 2-way repeaters arranged as shown in Fig. 10. Power is fed to these repeaters from the next adjacent office over the same cable pairs used for transmission. No commercial power supply is needed therefore at these pole-cabinet locations. As a result, no power is readily available for the operation of ventilating blowers. A full complement of 12 repeaters dissipates approximately 300 watts. The requirement set up when the development was initiated, was for operation over a climatic temperature range of −40 F to +120 F.

The cabinet is lined with 1-inch-thick Cellotex for insulation against winter cold. A ventilator is provided at the top and an opening in the bottom for summer cooling by natural convection. The top opening is controlled by a thermostatically operated shutter. With this shutter closed the heat dissipation from the insulated cabinet in still air is calculated to be $1^1/_2$ watts per degree of temperature difference between the interior and exterior. If the cabinet is only partially equipped, say with 5 repeaters, the 125 watts of energy dissipated would, under ideal conditions, raise the temperature 80 F. Even with liberal allowance for air leakage, effect of wind, and other variable conditions, the rise should be at least half the theoretical value, keeping the inside temperature above zero degrees F. The repeaters will operate satisfactorily at this temperature or even lower. More repeaters in the cabinet will of course, raise the temperature higher. An initial installation of fewer than five repeaters is unlikely for any considerable period.

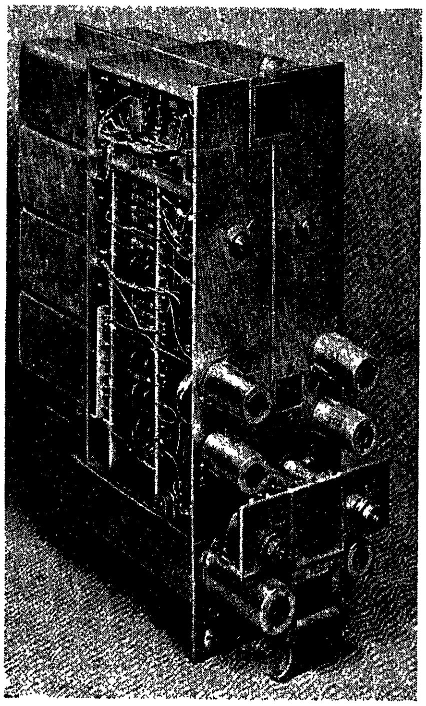

Fig. 11. N1 carrier repeater

As the temperature in the cabinet is raised the thermostat will begin to open the shutter in the top ventilator at about 60 F and will insure full opening at some temperature below 100 F. As shown in Fig. 11, the repeaters are arranged as are the terminal units, in that the vacuum tubes and power adjusting resistors are placed on the face of the units, and apparatus components not producing heat, inside. They are placed in the cabinet so that the heat-producing elements are located in a chimneylike compartment in the front of the box, Fig. 12. The main air flow is up this front space, while a secondary flow takes place between the rear of the repeater units and the back of the box. Measurements made in the laboratory indicated that the temperature rise of apparatus inside the repeater units in the top row would be about 35 F. Measurements made on working installations outdoors under various summer conditions gave results more variable than had been expected, as indicated in Fig. 13. The difference probably is largely because of the effect of wind, particularly of variable light breezes, in damping out the natural chimney effect. The apparatus temperature rise, as might be expected, varies almost directly with the temperature of the air issuing from the ventilator. Fig. 13 indicates that the usual temperature rise to be expected will be about 50 F. The apparatus will sustain no permanent damage below about 160 F, and up to this limit the operation of the repeaters will not be affected. This would indicate that safe operation may be expected in ambient temperatures up to 110 F and, because of the time lag between outside temperature rise and apparatus temperature rise, this limit could be exceeded for short periods. While the ideal of +120 F atmospheric temperature operation has not been met, it has been approached so closely that only a few very bad locations will need special attention. Weather bureau records indicate that temperatures above 110 F are seldom reached in

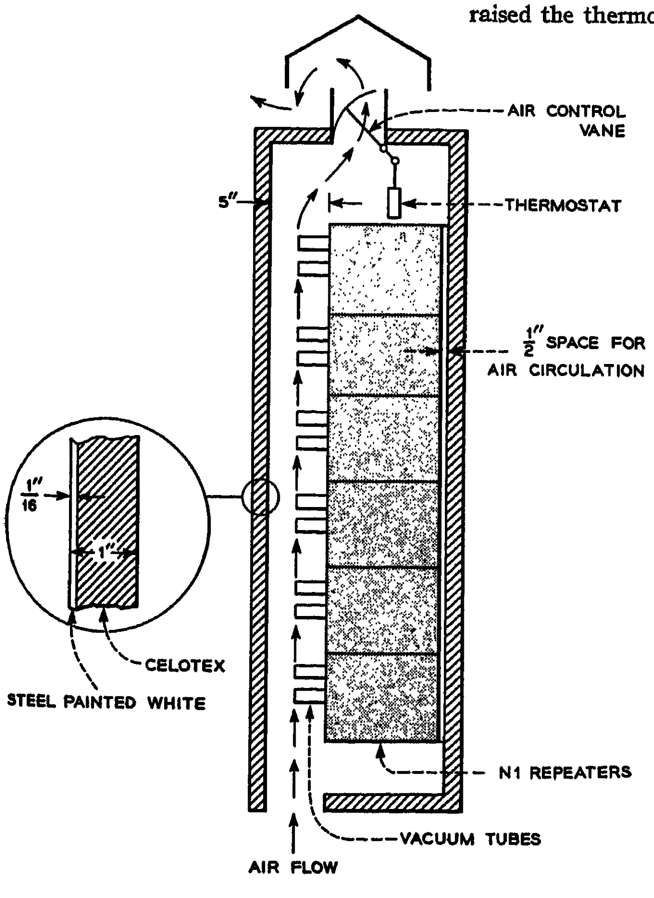

Fig. 12 (left). Temperature control in pole-mounted cabinet

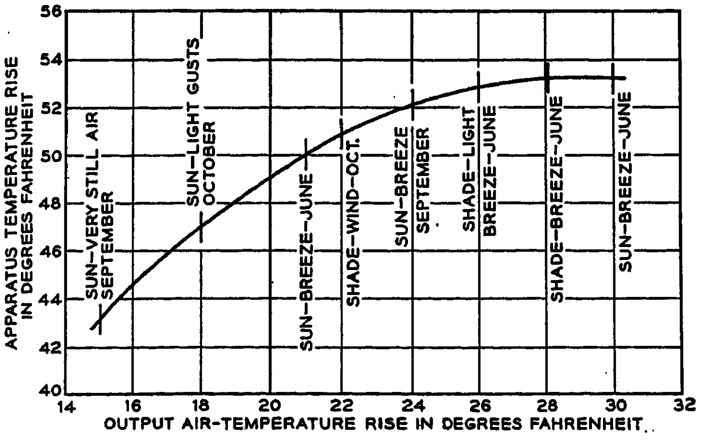
Fig. 13 (below). Observed apparatus temperature rise in a pole-mounted cabinet



this country except in the southwestern deserts.

Conclusion

The disposition of heat from present-day miniaturized equipment requires attention from the design engineer. Hot-spot temperatures in the units need to be kept below the limit where components will be damaged or operation impaired. Basically this requires simply that the heat be removed rapidly enough from the immediate vicinity where it is generated. The problem of accomplishing this, however, usually is resolved into two parts, first removing the heat from each unit and, second, disposing of it outside the office. The second problem is of a type readily soluble by ordinary heating and air-conditioning methods. Apparatus arrangement, air circulation, and, where necessary, refrigerative cooling are the means available. The introduction of transistors in place of vacuum tubes will require new methods of solving the first phase and will reduce the total heat to be disposed of in the second. Continued growth of demand for facilities, however, will enlarge the over-all problem.

Temperature Fields in Electrical Coils: Numerical Solutions

P. J. SCHNEIDER
NONMEMBER AIEE

Synopsis: This paper illustrates the computation of steady temperature fields in electrical coils by the numerical-relaxation method of Emmons and Southwell. The general numerical method is briefly reviewed, and several examples serve to exemplify the simplicity of the technique and to verify that numerical temperatures are in substantial agreement with both experimental data and exact analytical values.

A PLANE cutting normal to the curved longitudinal axis of a typical electrical coil of toroidal form reveals a profile (cross section) of insulated metallic wires. For analytical purposes one replaces this actual coil by a mathematical model whose longitudinal axis has a large radius of curvature, and whose profile is a homogeneous area of uniform thermal conductivity k. Higgins[1] gives a comprehensive outline of the physical basis for this mathematical model. If the coil carries constant electric current i and is of electrical resistivity ρ, then the Joulean heat generated within the coil is $Q=i^2\rho$ at a profile temperature t, and the heat developed at a reference temperature $t=0$ is correspondingly $Q_0=i^2\rho_0$. In the temperature range of normal coil operation, ρ varies linearly with local profile temperature as $\rho_t=\rho_0(1+\alpha_0 t)$ wherein α_0 is identified as the temperature coefficient of electrical resistivity for the particular coil material in question. Then if $\alpha_0\neq 0$, one extends this nonuniformity to the Joulean heat generation as $Q_t=Q_0(1+\alpha_0 t)$.

The mathematical model of the electrical coil effectively focuses attention on the steady-state 2-dimensional temperature distribution in a region generating nonuniform heat and having the same boundaries as the profile of the prototype coil. All heat conducted to the profile boundary is assumed to be dissipated to an ambient medium of uniform temperature t_a, where the unit thermal conductance on this boundary is to be specified by a uniform coefficient h_s.

Having identified the shape and dimensions of the profile and the parameters Q_0, α_0, k, t_a, and h_s, the problem that remains is to find $t(x,y)$ by the most expeditious method. Such information is needed to predict the maximum permissible electrical loading limit for the coil as based on this general temperature field, and the location and magnitude of hot spots in the profile. Now, it is well known that exact analytical solutions for $t(x,y)$ are available if the profile of the coil is of simple geometric form. It is also common experience that exact solutions for the more realistic cases frequently require the excessive interpretive and computational labor attendant to infinite trigonometric series, ordinary and modified Bessel functions, and the like. The designer of electrical coils should therefore have available some simple alternate operational technique for computing $t(x,y)$, and such is offered here by the approximate numerical-relaxation method of Emmons and Southwell.[2] The numerical method is not only accurate enough to be competitive with exact solutions (if available), but flexible enough to encompass a number of practical cases for which exact solutions are intractable. One of several possible experimental approaches to this problem is contained in the literature.[3,4]

The Numerical Method

For purposes of illustration, consider a general region of uniform thermal conductivity and developing distributed linear heat as in Fig. 1(A). The first step in a numerical solution for $t(x,y)$ is to subdivide this system into a number of small regular subvolumes. The subdivision (square in this case) is then replaced by a network of fictitious heat-conducting rods between central nodal points 1, 2, 3, 4, and 5, as indicated in Fig. 1(B). Now if an appropriate thermal conductance K is assigned to a particular rod, then the steady and linear heat flow q in this rod will serve to approximate the steady heat flow by conduction between the nodal points of the two subvolumes for which the rod was substituted. The scheme is essentially the same as used in familiar forms of approximate integration, and so in analogy as the subdivision is made finer (the network denser), the results become increasingly more exact.

The heat flux in each rod is now expressed by Fourier's 1-dimensional conduction equation in finite differences as $\Delta q=K\Delta t=k(a/L)\Delta t$, wherein a is the conducting area normal to the heat flow path and L is the linear length of this path. If boundary temperatures are

P. J. Schneider is with the State University of Iowa, Iowa City, Iowa.

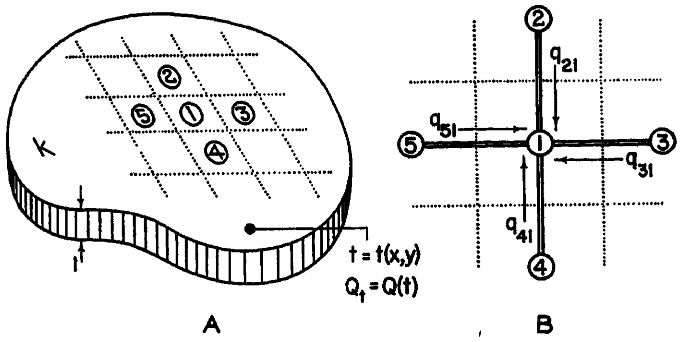

Fig. 1 (left). Subdivision and network of heat-conducting rods for numerical solution

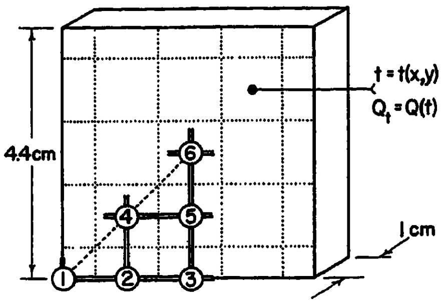
Fig. 2 (right). Numerical network for coil of solid square profile



unknown, then one also places conducting rods in the boundary and this heat loss is expressed by Newton's equation as $\Delta q = h_s A \Delta t$ in which A is the boundary area associated with each boundary nodal point. Now, the steady heat flow by conduction into a typical nodal point 1 of volume v_1 feet³ from all four adjacent nodal points 2, 3, 4, and 5, together with the heat generation at 1 in amount Q_t Btu per hour-feet³, is given by $\bar{q}_1 = Q_{t_1} v_1 + q_{21} + q_{31} + q_{41} + q_{51}$ as

$$\bar{q}_1 = Q_{t_1} v_1 + K_{21}\Delta t_{21} + K_{31}\Delta t_{31} + K_{41}\Delta t_{41} + K_{51}\Delta t_{51}$$

or

$$\bar{q}_1' = \frac{Q_{0_1} v_1}{k} + \frac{Q_{0_1} v_1 \alpha_0}{k} t_1 + (a/L)_{21}(t_2 - t_1) + (a/L)_{31}(t_3 - t_1) + (a/L)_{41}(t_4 - t_1) + (a/L)_{51}(t_5 - t_1)$$

where for the special case of uniform square subdivision the a/L's $=1$.

Then, in general, for a subdivided region of n nodal points, one writes the set of n simultaneous algebraic residual equations

$$\left.\begin{aligned}
\bar{q}_1' &= \frac{Q_{0_1} v_1}{k} + \frac{Q_{0_1} v_1 \alpha_0}{k} t_1 + \sum_{\alpha} (a/L)_{\alpha 1}(t_\alpha - t_1) \\
\bar{q}_2' &= \frac{Q_{0_2} v_2}{k} + \frac{Q_{0_2} v_2 \alpha_0}{k} t_2 + \sum_{\beta} (a/L)_{\beta 2}(t_\beta - t_2) \\
&\cdot \\
&\cdot \\
&\cdot \\
\bar{q}_n' &= \frac{Q_{0_n} v_n}{k} + \frac{Q_{0_n} v_n \alpha_0}{k} t_n + \sum_{\lambda} (a/L)_{\lambda n}(t_\lambda - t_n)
\end{aligned}\right\} \tag{1}$$

In the steady state all residuals $\bar{q}_i'$ must be zero above the datum $Q_{0_i} v_i / k$, and this is in simple analogy to the Kirchhoff electrical circuit law which states that the algebraic sum of all steady currents at a junction must vanish. The remainder of the solution is concerned with finding all t_i that satisfy equations 1, and this can be accomplished by any one of the available methods of solving a system of n simultaneous algebraic equations in n unknowns. However, when n is large, such methods as solution by determinants become somewhat tedious, and this is particularly so in cases where the residual equations have nonintegral coefficients. Southwell[5] has developed an alternate relaxation method for this portion of the work, and rather than explain his method here we can go on to a number of examples in which the purely formal procedure of a relaxation solution will become evident.

An Example Checked by Experiment

Higgins[1] gives data from electrical-coil experiments by Rogowski and Vieweg[6] in which the isothermal boundary of a toroidal coil of square profile, 4.4 by 4.4 centimeters (cm) was maintained at 76.1 degrees centigrade (C), and the maximum profile temperature t_m recorded as 122.4 C. Higgins takes the Joulean heat generation in the coil as the linear function $Q_t = Q_0(1 + \alpha_0 t)$ and then computes the unit-volume heat development at $t=0$ as $Q_0 = 0.1207$ watt per cm³, and selects the temperature coefficient as $\alpha_0 = 0.00423$ per C. Jacob[7] computes an equivalent uniform thermal conductivity for this particular coil as $k = 0.00531$ watt per cm, C. With these data one can easily effect a numerical solution and then compare the two t_m's.

Let the 4.4-cm² profile be subdivided as in Fig. 2 with half subvolumes at the boundaries. With the same uniform boundary temperature on all four edges, the temperature field has one-eighth symmetry so that only one-eighth of the profile need be considered as long as one remembers to double the effect of, say, rod 5–4 on the nodal point 4, and so on. Moreover, with isothermal boundaries the surface rods 1–2 and 2–3 are inactive. Then, for a typical internal nodal point such as 4

$$\bar{q}_4 = Q_{t_4} v_4 + 2K_{24}(t_2 - t_4) + 2K_{54}(t_5 - t_4)$$

But for all rods in a square network $K_{ij} = k(4.4/4)/(4.4/4) = k$, and for all 4.4/4 cm³ subvolumes of unit depth $Q_{0_i} v_i = 0.1207 \times (1.1)^2 = 0.146$, so that

$$Q_{t_i} v_i = 0.146(1 + 0.00423 t_i), \text{ and}$$

$$\bar{q}_4' = 2t_2 + 2t_5 + 0.146/0.00531 - (4 - 0.146 \times 0.00423/0.00531) t_4$$

In like manner the three required residuals corresponding to equations 1 appear as

$$\left.\begin{aligned}
\bar{q}_4' &= 2t_2 + 2t_5 + 27.5 - 3.884 t_4 \\
\bar{q}_5' &= t_3 + 2t_4 + t_6 + 27.5 - 3.884 t_5 \\
\bar{q}_6' &\quad 4t_5 + 27.5 - 3.884 t_6
\end{aligned}\right\} \tag{2}$$

The most elementary approach to finding the t_4, t_5, and t_6 that satisfy equations 2 is to venture a guess at these unknown temperatures and then compute the $\bar{q}_4'$, $\bar{q}_5'$, and $\bar{q}_6'$. In all probability these $\bar{q}'$'s will not be zero (above 27.5) as required, and consequently the t's would have to be successively changed until this condition was fulfilled. The Southwell relaxation procedure is a convenient tabular means of carrying out these successive guesses and cumulative corrections.

The relaxation of equations 2 was carried out for this example in Table I. The procedure was begun by first assuming all $\bar{q}_i'$ and t_i as zero on line 1. All $\bar{q}_i'$ were then corrected for the generated heat at each subvolume and according to what change would occur in each residual with changing the boundary temperature from zero to its correct value of 76.1 C. Thus in changing t_2 by 76.1, a change in $\bar{q}_4'$ in amount 2(76.1) = 152.2 is realized. Adding 27.5 to this value gives 179.7 as the corrected $\bar{q}_4'$, and this result together with similar corrections for $\bar{q}_5'$ and $\bar{q}_6'$ are entered on line 2 of Table I.

Table I. Relaxation of Residual Equations 2

	$\bar{q}_4'$	t_4	$\bar{q}_5'$	t_5	$\bar{q}_6'$	t_6
1	0.0	0.0	0.0	0.0	0.0	0.0
2	179.7	0.0	103.6	0.0	27.5	0.0
3	−388.4	100.0	200.0			
4	−208.7	100.0	303.6			
5	220.0		−427.0	110.0	440.0	
6	11.3		−123.4	110.0	467.5	
7			120.0		−466.0	120.0
8			−3.4		1.5	120.0
9	−13.6	3.5	7.0			
10	−2.3	103.5	3.6			
11	3.0		−5.8	1.5	−6.0	
12	0.7		−2.2	111.5	7.5	
13			2.0		−7.8	2.0
14			−0.2		−0.3	122.0

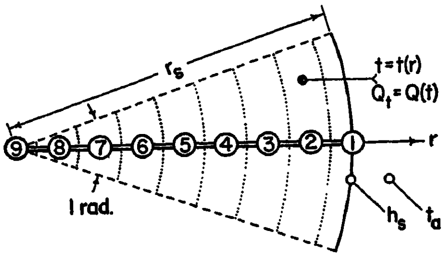


Fig. 3. Numerical network for coil of solid circular profile

One now advances the guess that, say, $t_4=100$, which effectively changes $\bar{q}_4'$ by $-3.884(100)=-388.4$. A change in t_4 in amount 100 also changes $\bar{q}_5'$ by $2(100)=200$. These changes are entered in Table I on line 3 and their algebraic sums are on line 4. The tabulation of guesses and corrections is carried on in this manner until all residuals in the network are reduced as nearly to zero as accuracy requires. In Table I the algebraic sum of the remaining residuals over the entire field is only 0.2, and to improve this further would require temperature changes of less than 0.5 C. If the end temperatures in Table I are correct, then the heat generated in the internal subregions should just balance the heat transferred to all four edges:

$$\Sigma q_0(1+\alpha_0 t)=\Sigma k\Delta t$$

$$4\times 0.146(1+0.00423\times 103.5)+4\times 0.146(1+0.00423\times 111.5)+1\times 0.146(1+0.00423\times 122.0)\ 8\times 0.00531(103.5-76.1)+4\times 0.00531(111.5-76.1)$$

$$1.920 \text{ watt} \doteq 1.917 \text{ watt}$$

The maximum temperature in this coil computed by the numerical method is thus $t_m=122.0$ C to the nearest 1/2 degree. Despite the choice of a relatively crude numerical subdivision, this result is in close agreement with the experimentally measured value of $t_m=122.4$ C.

An Example Checked by Theory

To compare numerical results with an exact analytical solution for $t(x,y)$, consider the coil of solid circular profile dissipating heat to an ambient medium of uniform temperature $t_a=0$ degrees Fahrenheit (F). In particular, let $r_s=2$ inches, $k=1$ Btu per hour-feet-F, $Q_0=10^4$ Btu per hour-feet³, $\alpha_0=0.001$ per F, and $h_s=15$ Btu per hour-feet²-F.

Table II. Conductances and Volumes

$K_1=2.5$	$v_1=0.3347/144$
$K_2=7.5$	$v_2=0.4375/144$
$K_3=6.5$	$v_3=0.3750/144$
$K_{43}=5.5$	$v_4=0.3125/144$
$K_{54}=4.5$	$v_5=0.2500/144$
$K_{65}=3.5$	$v_6=0.1875/144$
$K_{76}=2.5$	$v_7=0.1250/144$
$K_{87}=1.5$	$v_8=0.0625/144$
$K_{98}=0.5$	$v_9=0.0781/144$

This is an elementary case of radial conduction in which t_s as well as the $t(r)$ are unknown. The radial subdivision of any segment of the profile is selected with the view of either simplifying the computation or increasing the density of the network in a region of expected maximum temperature gradient. Suppose that temperatures at equal intervals of radius are required and, accordingly, choose the uniform radial subdivision in Fig. 3, where the bounding radii are separated by one radian in order to eliminate π from the computations.

The conductances and volumes appropriate to this subdivision are contained in Table II. As examples in their computation: $K_{1a}=h_s(2/12)=2.5$; $K_{32}=k(a/L)_{32}$ where $a_{32}=1.625/12$ and $L_{32}=0.25/12$, whence $K_{32}=6.5$; and the volume of region 3, $v_3=[(\pi/4)(3.25/12)^2-(\pi/4)(2.75/12)^2]1/2\pi=0.3750/144$. From Table II the nine required residual equations follow directly as

$$\left.\begin{aligned}
\bar{q}_1' &= 2.5t_a+7.5t_2+16.819-9.983t_1\\
\bar{q}_2' &= 7.5t_1+6.5t_3+30.382-13.970t_2\\
\bar{q}_3' &= 6.5t_2+5.5t_4+26.042-11.974t_3\\
\bar{q}_4' &= 5.5t_3+4.5t_5+21.702-9.978t_4\\
\bar{q}_5' &= 4.5t_4+3.5t_6+17.361-7.983t_5\\
\bar{q}_6' &= 3.5t_5+2.5t_7+13.021-5.987t_6\\
\bar{q}_7' &= 2.5t_6+1.5t_8+8.681-3.991t_7\\
\bar{q}_8' &= 1.5t_7+0.5t_9+4.340-1.996t_8\\
\bar{q}_9' &= 0.5t_8+0.542-0.499t_9
\end{aligned}\right\} \quad (3)$$

Table III. Numerical and Exact Temperatures

Numerical	Exact
61	61.09
79	79.05
95	94.76
108	108.13
119	119.20
128	127.73
134	133.86
138	137.56
139	138.82

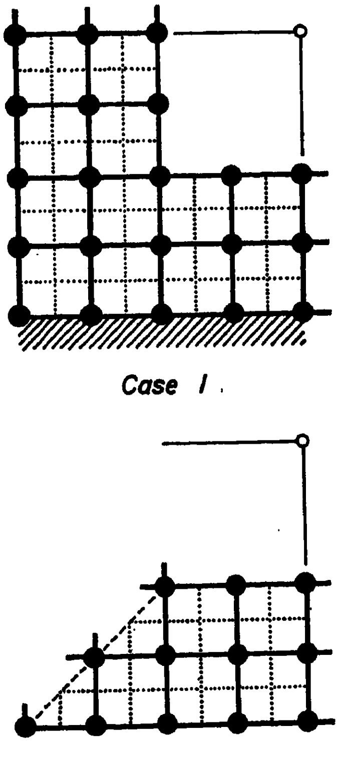
An exact solution for this case is given in the Appendix as

$$t=\frac{(1/\alpha_0+ta)}{J_0(\sigma_s)-\mu J_1(\sigma_s)}J_0(\sigma)-\frac{1}{\alpha_0}$$
$$=1138.819J_0(\sigma)-1{,}000 \quad (4)$$

wherein the J_n are first-kind Bessel functions of order n, $\mu^2=Q_0\alpha_0 k/h_s^2$, and $\sigma^2=(Q_0\alpha_0/k)r^2$. Table III lists the approximate numerical temperatures to the nearest degree obtained through relaxation of equations 3, and the corresponding exact temperatures computed by equation 4. It is apparent that the two solutions are nearly identical.

Internally Cooled Coil

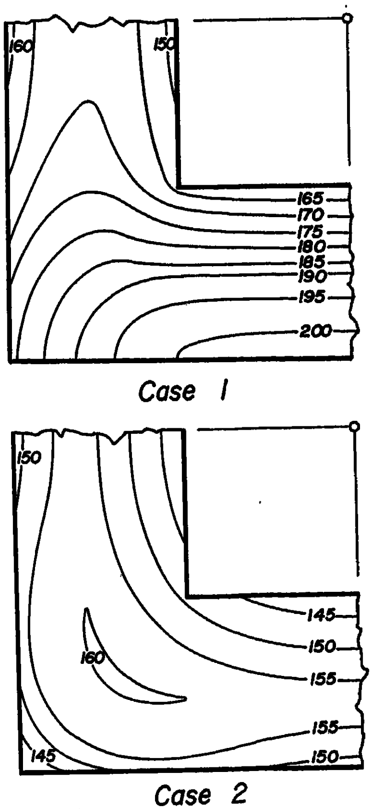
The hollow-profile internally cooled coil is a rather recent innovation for use in high-output generators. Consider the special case of a hollow-square profile (4 inches on a side and 1-inch thick walls) exposed to ambient air at 80 F and cooled



Case 1

Case 2

Fig. 4 (left). Numerical network for coil of hollow square profile



Case 1

Case 2

Fig. 5 (right). Temperature fields in internally cooled coils of hollow square profile

internally by a forced gas flow at a mean temperature of 120 F. Let $k=1$ Btu per hour-feet-F; $Q_0=86.4$ Btu per hour-feet^3; $\alpha_0=0.002$ per F, and select an outer unit surface conductance of 6 Btu per hour-feet^2-F, and an inner unit surface conductance of 24 Btu per hour-feet^2-F.

We consider two cases. In case 1 let a number of such coils be in contact with each other so that all contact surfaces can be regarded as adiabatic. In case 2 let the individual coils be separated so that all outer surfaces are exposed to ambient air. Temperature symmetry can be observed in both cases, and a uniform square subdivision selected as in Fig. 4.

The final relaxation of these systems gives the two distinctly different temperature fields shown in Fig. 5. These are solutions to an otherwise intractable problem by a method whose simplicity rests rather uniquely on a little algebra, and the elementary operations of addition and multiplication.

Appendix. Derivation of Equation 4

The symmetrical temperature field $t(r)$ for the circular profile of uniform thermal conductivity and generating Joulean heat as a linear function of local profile temperature is that which satisfies the ordinary differential equation

$$\frac{d^2t}{dr^2}+\frac{1}{r}\frac{dt}{dr}+\frac{Q_0}{k}(1+\alpha_0 t)=0 \tag{5}$$

and the particular boundary conditions for this case

$$\left(\frac{dt}{dr}\right)_s=-\frac{hs}{k}(t_s-t_a) \tag{6}$$

Defining a new dependent variable T as

$$T=\frac{Q_0}{k}(1+\alpha_0 t)=\zeta+\xi t$$

forces equation 5 to reappear as the familiar Bessel equation of zero order

$$r^2\frac{d^2T}{dr^2}+r\frac{dT}{dr}+\xi r^2T=0$$

whose general solution reads

$$T=C_1J_0(\sqrt{\xi}r)+C_2Y_0(\sqrt{\xi}r)$$

The second arbitrary integration constant C_2 is evaluated by noting that the Neumann second solution Y_0 cannot be retained for this case since T must remain finite as $r\to 0$. Thus with $\sigma=\sqrt{\xi}r$

$$t=\frac{C}{\xi}J_0(\sigma)-\frac{\zeta}{\xi} \tag{7}$$

The remaining integration constant is evaluated by the boundary condition of equation 6, according to

$$\left(\frac{dt}{dr}\right)_s=-\frac{C}{\sqrt{\xi}}J_1(\sigma_s)=-\frac{hs}{k}\left[\frac{C}{\xi}J_0(\sigma_s)-\frac{\zeta}{\xi}-t_a\right]$$

as

$$C=\xi\left(\frac{\zeta}{\xi}+t_a\right)/[J_0(\sigma_s)-\mu J_1(\sigma_s)]$$

wherein $\mu=\sqrt{\xi}k/h_s$. This serves to complete the solution for $t(r)$ which finally reads

$$t=\frac{(1/\alpha_0+t_a)}{J_0(\sigma_s)-\mu J_1(\sigma_s)}J_0(\sigma)-\frac{1}{\alpha_0} \tag{8}$$

Production of Unipolar Air with Radium Isotopes

THOMAS L. MARTIN, JR.
ASSOCIATE MEMBER AIEE

Synopsis: This article is a general survey of recent development work on sources of unipolar air using alpha-emitting radioactive materials. Specific reference is made to a new device, operating at relatively high air speeds of about 450 feet per minute, which will provide an air output containing only positive or only negative ions. The method of controlling the density of this unipolar output is also treated.

UNIPOLAR air is air that contains ions of only a single polarity. There are many industrial applications in which it is necessary or desirable to have facilities for discharging electrified particles that adhere to materials or machines. It has also been suggested that atmospheric ionization can be used to cleanse rooms of contaminations such as smoke, dust, certain pollens, and some viruses. Such an action, in conjunction with air-conditioning systems, would prove extremely beneficial to sufferers of various allergies. With such an apparently diversified group of applications awaiting the availability of appropriate sources of unipolar air, it is not surprising that the development program has received considerable impetus.

Unipolar air may be produced in a number of different ways, but, for reasons discussed elsewhere, thermionic and alpha-particle radiation methods appear most suitable. It has been shown that thermionic methods lack the necessary degree of control, uniformity of output, and predictability desirable in ion sources.[1] Thus, it is concluded that ion production through alpha-particle radiation offers the greatest immediate area for potential development. This paper is concerned with recent efforts to produce unipolar air with alpha-emitting radioactive materials.

Choosing the Radioactive Emitter

In selecting the radioactive material for use in an ion generator, there are two main factors of importance to be considered:

Paper 53-351, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B. C., September 1–4, 1953. Manuscript submitted May 13, 1953; made available for printing July 2, 1953.

Thomas L. Martin, Jr., is with the University of Arizona, Tucson, Ariz.

1. The half life of the emitter should be quite long. From the commercial viewpoint, a desirable half life would fall in the 3- to 5-year region, since this assures a reasonable shelf life for the manufactured ion sources. Moreover, this would be long enough to maintain a relatively constant ion output over the duration of most biological tests and would not require frequent replacement of units in commercial applications.
2. The emission of alpha particles should not be accompanied by strong beta or gamma radiation, nor should disintegration produce an isotope that will subsequently produce strong beta or gamma radiation.

With the foregoing factors in mind and with all cost considerations temporarily set aside, it was concluded that there are no satisfactory isotopes in the thorium or actinium series.

There are a number of alpha-emitting isotopes of radium that disintegrate with long half-life periods. However, radon is an ultimate product of the disintegrations of the heavier isotopes. Since it is a gas and radioactive, it is very dangerous to work with and should be avoided. Thus, all isotopes above radon in the series are ruled out.

Radium *G* is the nonradioactive end product of the radium series. Radium *F*, otherwise known as polonium, emits alpha particles only, reducing to radium *G* with a half life of about 140 days. It would be an ideal alpha-particle source if it had a longer half life. It is relatively inexpensive in comparison to other isotopes.

Radium *D* disintegrates to radium *E* and thence to polonium. In doing so, it radiates both beta and gamma rays of appreciable, but relatively low, energy. The transformation occurs with about a 22.2-year half life. An equilibrium mixture of radium *D* and polonium is thereby an effective alpha-particle source, having a half life of about 22 years.

The main disadvantage involved in the use of radium *D* is the presence of beta and gamma radiations. Fortunately the energy levels are comparatively low. Careful attention to shielding is required, but this is primarily a detail and not at all impossible to handle. Radium *D* is considerably more expensive than polonium. Nevertheless, in view of the 22-year half life, it could well prove to be more economical than polonium.

One more factor should be noted in connection with the use of polonium and radium *D*. It has been shown in the case of some types of polonium foils, that free polonium atoms are produced when alpha particles are emitted. In such cases, free polonium would be circulated into the air and would constitute a serious physiological problem. It appears that this problem has been overstated in some instances, and the advanced methods of foil preparation described in the next section have ended the problem.

Preparation of the Alpha Emitter

The alpha emitter used in all of the devices described in this paper was polonium foil. The method of preparing this foil is briefly summarized here.*

"The polonium is precipitated as a hydroxide mixed with silver powder. The intimately mixed powders are then introduced into a die and formed into a solid compact by heat and pressure. The radioactive component is then rolled to predetermined dimensions and is then ready for incorporation into a foil sandwich. The sandwich is composed of a base, consisting of a 1/8 inch silver block. A thin layer of inactive gold is laid over this base. A section cut from the radioactive compact is laid over this and another sheet of inactive gold is then placed over this. The entire unit is then compressed by heat and pressure into a solid fused block. The block is then rolled into ribbon form to an overall thickness of 0.005 to 0.006 inches. In this form, most of the foil thickness is due to the silver backing. Accordingly, alpha particles can be emitted only from the side without the silver backing.

"To add a harder and abrasion resistant surface, the rolled foil is given a final coating of about 0.4 micron thickness of rhodium or palladium. This improved foil is definitely *not* causing any of the old migration contamination troubles that are associated with polonium sources."

Important Aspects of Air Ionization with Alpha Particles

The main constituents of air are oxygen and nitrogen. These gases are diatomic, so that the discussion is mainly concerned with molecular rather than atomic effects. When alpha particles are emitted into this mixture, they collide with molecules, of both gases, producing free electrons and positive molecular ions of oxygen and nitrogen.

Oxygen readily forms negative molecular ions. Thus, except for a small number of electrons lost through recombination, the free electrons become attached to oxygen molecules. None of the electrons become attached to nitrogen molecules because it has been shown[2] that molecular nitrogen does not form negative ions. Thus, the ultimate result of the passage of alpha particles through air is the production of negative molecular ions of oxygen and positive molecular ions of nitrogen and oxygen, with the former predominating.

The mobility of an ion is its velocity in a unit electric field. If an absolutely pure gas could be obtained, at a constant pressure there would be a unique value for the mobility of an ion in that gas, starting about 1 microsecond after ion-formation.[3] However, such a gas does not exist and ion mobilities are found to vary over a wide range as a result of gas contamination and age of the ion.

As a result of the large variations in measured ion mobilities, there is no one value applicable for a given ion in a given gas. Thus, designers of ionizers should be wary of basing their design upon a special value for ion mobility taken from tables.

Losses

The number of ions that can be produced in air by an alpha emitter of known activity is easily computed. The number of ions obtained in the output from the ion tube can be determined experimentally. The ratio of the actual ion output to the theoretical maximum ion formation rate can be used as an index of the efficiency of the tube in utilizing the available ionizing capabilities of the alpha emitter.

This efficiency will always be less than 100 per cent. The reasons for this might be listed as follows:

1. Recombination losses;
2. Alpha-emission losses in the emitter;
3. Alpha absorption in the collimator;
4. Ionization losses in the separation process.

Each of these factors is discussed briefly in the following paragraphs.

Loeb[4] lists four types of ion recombination of potential importance here:

1. Preferential recombination;
2. Initial recombination;
3. Columnar recombination;
4. Volume recombination.

Regardless of the type of recombination, the rate of recombination can be computed from the general equation

$$\frac{dN(+)}{dt}=\frac{dN(-)}{dt}=-\alpha N(+)N(-)$$

where

α = recombination coefficient

---

* Permitted quotation from C. W. Wallhausen, United States Radium Corporation, New York, N. Y.

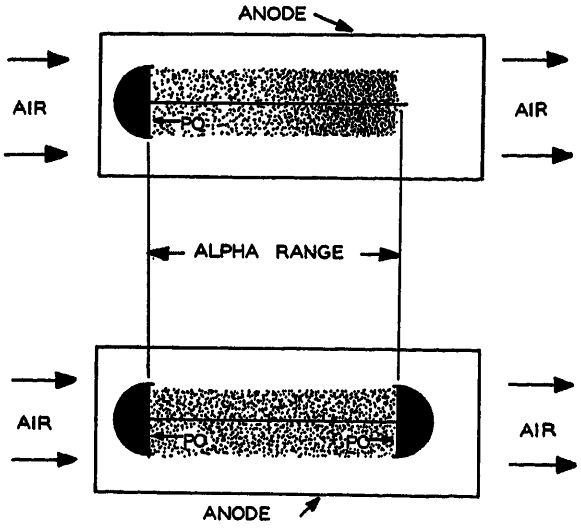

Fig. 1 (left). Two-electrode ion tubes

Desired ion pattern shown

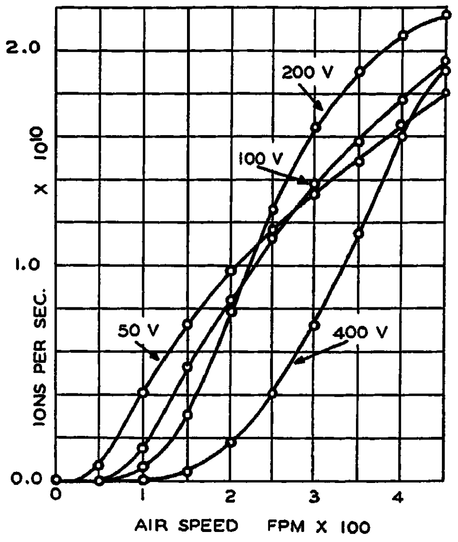

Fig. 3 (right). Characteristics of a 2-electrode ion tube; desired ion output versus air speed

$N(+)$ = density of positive ions

$N(-)$ = density of negative ions

However, the calculation is possible only if the recombination coefficient is known and, according to Loeb[5] "tables of values for α are more or less meaningless." Thus, recombination losses do occur, and the extent is probably appreciable, but it cannot be calculated with any degree of certainty.

Alpha losses in the emitter are largely caused by the construction of the polonium foil. From the foil preparation process described earlier, it is clear that on the average only half of the disintegrations will eject alpha particles into the air, because half of them will be absorbed in the silver backing. Alpha radiation parallel (or close to parallel) to the foil surface is weak because of the retardation of the rhodium or palladium coating. Also, because of this coating, all alpha particles will experience some retardation and loss of ionizing capability. Consequently, the effective alpha radiation from the foil is considerably less than the theoretical maximum of the polonium imbedded in the foil.

The alpha particles are emitted from the forward surface of the polonium foil in a fan shaped pattern.[6] This pattern is undesirable in some instances and collimating devices are used to confine the alpha radiation to a more beam-like pattern. This is accomplished by absorbing that radiation occurring at oblique angles from the foil surface. This absorption further reduces the effective activity of the emitter in producing ions.

To produce unipolar air from an original bipolar sample, some sort of ion separation mechanism must be used. It is inevitable that some of the desired ions will be lost in the process.

Ideally, these four losses could be separated and individually determined so that efficiency improvements could be made on an exact basis. Unfortunately, the author has not been able to do this and is not sure that it can be done.

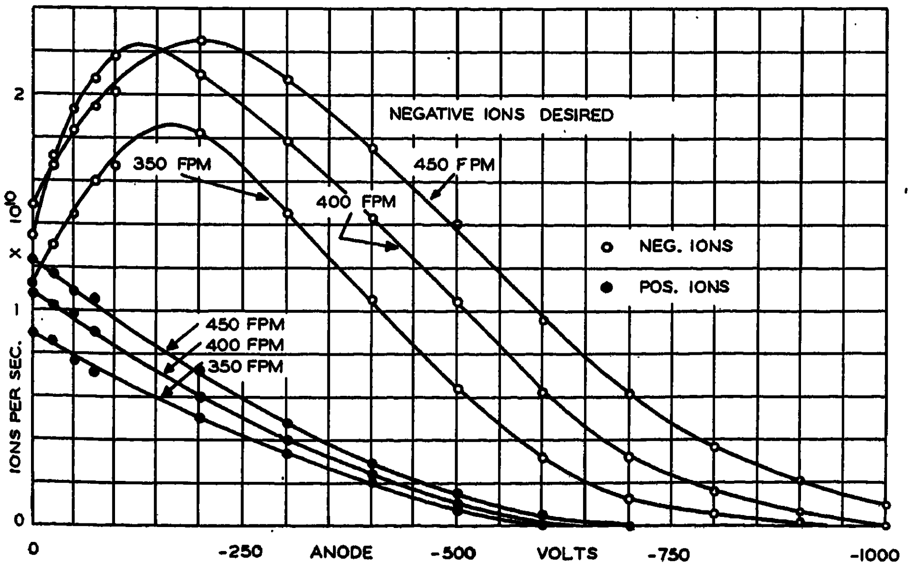

Fig. 2. Characteristics of a 2-electrode ion tube; ion output versus electrode voltage

Single Electrode Ion Tube

One of the first radioactive ion tubes produced in any volume to serve as a source of unipolar air was developed by J. C. Beckett. (The tube was described in detail in an unpublished paper by Mr. Beckett and H. H. Skilling.) It has proven to be a very useful tool in preliminary experimentation, and may represent the best solution to certain commercial requirements.

The tube consists of a single tubular electrode with a strip of polonium foil mounted on one side of this electrode. A rectified alternating voltage is applied between this electrode and ground. The dimensions of the tube, the location of the polonium, and the applied potential are all critically related to one another. The electrostatic flux lines go between the tubular electrode and nearby grounded objects such as the floor, walls, and ceiling of a room, or possibly even nearby people. The flux distribution in the tube opening is altered only slightly when the locations of these grounded objects are changed.

The operation of the tube is rather simply explained in principle. Alpha particles emitted by the polonium ionize the air inside the tube. If negative ions are desired in the output, the tubular electrode is made negative with respect to ground. The field configuration is such that negative ions drift out of the tube into the air while the positive ions are attracted to the electrode and are discharged. In principle, the tube provides a unipolar output.[7] It is a simple tube, easy to fabricate, and does not require the use of a blower fan to remove

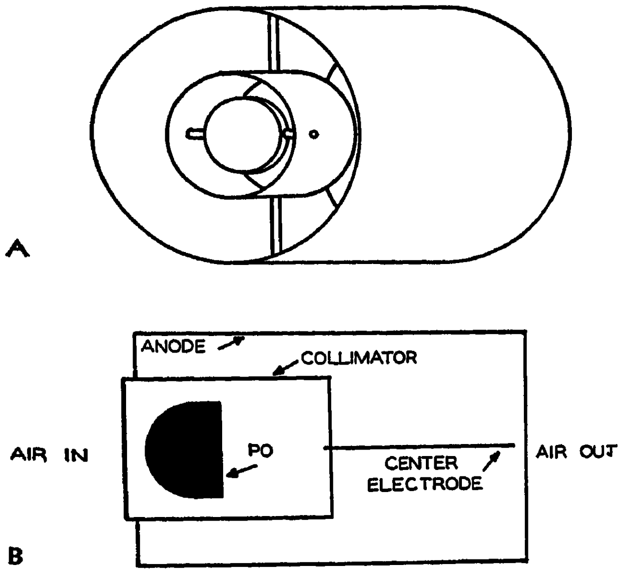

Fig. 4 (left). Triode ion tube

A. Assembly sketch
B. Cross-sectional schematic view

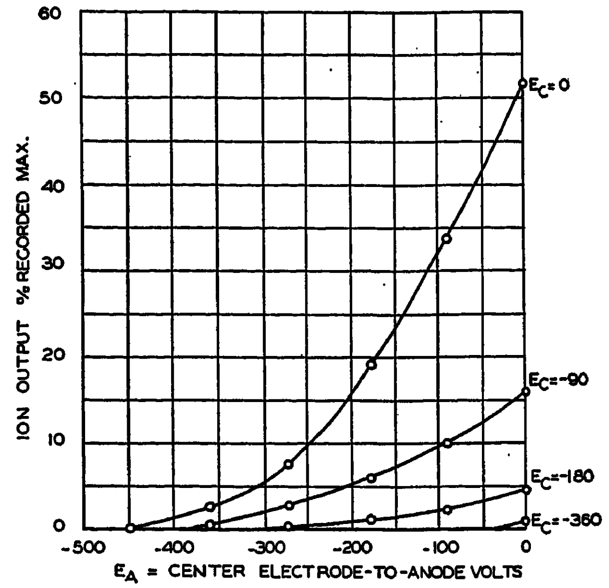

Fig. 6. Average characteristics of a triode ion tube; undesired positive ion output versus electrode voltages

the ions from the tube. This factor is of considerable importance in some areas of expected application. The main disadvantage of the tube is that it is not adapted to use at high air speeds, and would not be suitable in air-conditioning systems. A higher and controllable ion output would be advantageous in the same application.

Two-Electrode Ion Tubes

Two-electrode ion tubes were the first step taken in an effort to develop an ion source capable of operating at high air speeds. A cross-sectional schematic view of two early experimental models is shown in Fig. 1. There are two coaxial electrodes with the alpha emitting polonium facing axially down the tube. The ionization produced by the alpha particles would, desirably, be confined to a column about the innner electrode as shown in Fig. 1.

In operation, an electric field is established between the two electrodes and a relatively strong blast of air (450 feet per minute) is directed axially down the tube. The electric field strength varies inversely with the distance from the center electrode. Thus, the ions nearest this electrode are subjected to the strongest electrostatic forces. The ions of unwanted polarity are attracted toward the inner electrode into an ever increasing field intensity and are rapidly removed from the interelectrode space. The ions of desired polarity are forced toward the outer electrode into a field that becomes progressively weaker. These ions are thereby forced into the moving air stream and blown out of the tube before reaching the electrode.

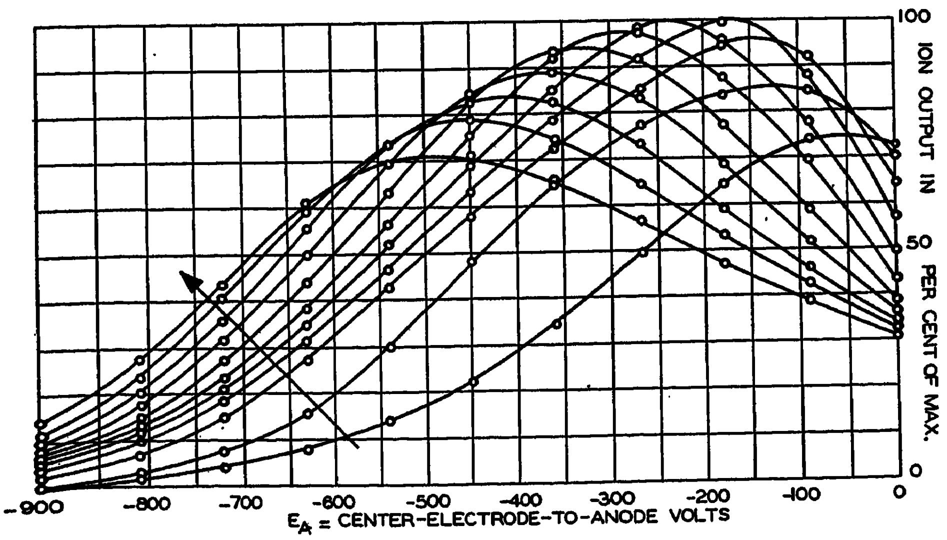

Fig. 5. Average characteristics of a triode ion tube; desired negative ion output versus electrode voltages

E_G is the parameter, changing in 90-volt steps commencing with 0 and ending with 900 volts. Direction of increase is shown by arrow. Air speed in Figs. 5–8 ≅450 feet per minute

Hypothetically, this tube could be made to operate as a true source of unipolar air. It can be shown that complete suppression of unwanted ions and complete removal of desired ions can be achieved for any combination of voltage and air speed if:

1. There is no fringing of the electric field;
2. The ions are confined to a cylindrical column, as shown.

Neither of these conditions exists, and this optimum kind of operation does not result.

Several of these tubes were constructed and tested. Some representative results are given in Figs. 2 and 3. Examination of these curves reveals the following points of interest:

1. The desired ion output is controllable through variations in electrode voltage.
2. The ions of unwanted polarity can be completely suppressed, but the voltage required is so high that the loss of desired ions is excessive and the output is low.
3. For any given electrode voltage, greater ion output is achieved by using higher air velocities.

Since these results did not agree at all well with earlier theoretical predictions, it was concluded that one or both of the assumptions made in the theoretical analysis were in error. Ultimately, it was concluded that the greatest error arose in the assumption that the ions were confined to a column about the inner electrode. As mentioned before, the emis-

sion pattern from polonium foil is fan shaped and the ions are more or less uniformly distributed throughout the interelectrode space. It was concluded that improved operation would be obtained if the ion column could be confined more nearly to the assumed form. This required the introduction of a collimating device and led to the triode ion tube discussed in the remainder of this paper.

Triode Ion Tubes

Several different methods of collimating the alpha-particle radiation are being studied. However, only one type is covered here. The essential geometric configuration of the tube is shown in Fig. 4. The collimator is made of aluminum, and serves as the third electrode of the tube.

In taking data, the anode is used as the reference, or grounded, electrode. The tube voltages are then specified as follows:

E_A = center electrode-to-anode volts

E_C = collimator-to-anode volts

All tests reported here were conducted with an average indicated air speed of 450 feet per minute. Preliminary tests with other air speeds indicate higher ion outputs can be obtained at higher air speeds. This suggests that the separation losses are still appreciable.

The operating characteristics of the tube at an air speed of 450 feet per minute are shown in Figs. 5 and 6. Although these only show the case where negative ions are desired, essentially the same results are obtained when positive ions are desired. These are average characteristics in the sense that they are the average of several sets of data taken under varying degrees of air temperature and pollution. These two factors have some effect upon the results, but there were no variations in excess of 5 per cent, under the conditions tested.

The method of data presentation requires some explanation. Each point is expressed as a percentage of the maximum obtainable desired ion output under all electrode voltage possibilities. It was necessary to use some sort of normalizing procedure like this, since the continually diminishing activity of the polonium made the use of absolute values impractical. From these curves it is apparent that a wide latitude of control over ion output is possible through variations in electrode potentials.

In every case, the positive ions appeared to be more plentiful than negative ions. The average ratio of maximum values is approximately

$$\gamma = [N(+)\max]/[N(-)\max] = 1.15$$

This has been characteristic of all ion sources within the author's experience. The reason is not understood.

From a comparison of Figs. 5 and 6, it should be clear that the tube can be made to operate as a true source of unipolar air. Moreover, there are many electrode voltage combinations that allow unipolar operation. Thus, the triode ion tube fulfills the same function as the single electrode tube, but with the added advantages of easy control of ion density and the ability to operate at high air speeds. The 2-electrode ion tube was not even a satisfactory unipolar source under any conditions.

The maximum ion outputs obtained (the 100-per-cent points on the curves) varied with the radioactivity of the polonium. Although facilities were not available to measure the activity of the polonium, it appears that the maximum ion output with about 200 microcuries of polonium is about 1.2×10^{10} ions per second. This amount of radioactivity will produce a theoretical maximum of about 118×10^{10} ion pairs per second. Thus, the output is only about 1 per cent of the theoretical maximum. This is not a bad figure when corrected for alpha losses in the emitter. However, it could undoubtedly be increased somewhat through improved tube design and the use of higher air speeds.

Controlling the Ion Output

The method of controlling the density of ions in the unipolar output from the triode ion tube can be deduced from the average control characteristics given in Figs. 7 and 8.

In both of these figures, a potential plane has been constructed with the collimator voltage E_C plotted vertically and the center electrode voltage E_A plotted horizontally. Contours of constant ion output are drawn on that plane. That is, the 70-per-cent contour shows all of the possible electrode voltage combinations that will produce 70 per cent of the maximum obtainable ion output. Similar contours are drawn for all percentages from 10 to 100 per cent in 10 per cent increments.

The contour for zero undesired ion output is also shown on each of these figures. If the operating point of the tube falls within this contour the tube no longer operates as a source of unipolar air. It is particularly interesting to note that a more precise adjustment of electrode voltages is required for optimum operation of the tube as a source of negative air than when positive air is desired.

These two figures show how the ion output is best controlled by variations in electrode potentials. Clearly, the desired ion output should be controlled by causing the operating point to shift approximately parallel to the zero-per-cent contour of undesired ions. This will maintain a unipolar output under all conditions.

The two figures also show that it is possible to select some combination of electrode potentials so that the tube could provide positive or negative air just by reversing the applied potentials. Indeed, careful adjustment of these voltages will result in almost equal ion outputs in either case, since more positive ions are obtainable and the tube could be operated at less than 100-per-cent output.

Conclusions

It appears to the writer that the feasibility of controllable sources of unipolar air operating at relatively high air speeds has been conclusively demonstrated. The triode ion tube needs engineering development to reduce its separation losses, but this should preferably be done in the light of some specific application. Thus, further development should probably await the specification of operating requirements by biologists, air-conditioning engineers, decontamination experts, and so on, for no one tube is likely to meet the demands of all users.

The present development program will continue. Other designs are under consideration. Work projected in the immediate future will be concerned with tubes using radium *D*, and some thought is being given the possibility of using beta emitters in unusual geometric configurations.

NONMEMBER AIEE

THE OBJECT of this paper is to evaluate quantitatively the termination of inert gas-filled power tubes by contact pins and sockets and by flexible leads with pressure-type terminals.

Background

At first glance, the equipment designer who plans to incorporate a modern temperature-free gaseous thyratron or rectifier tube in a unit, should not expect any problem in providing adequate termination facility for such tubes. Unfortunately, such a seemingly simple design consideration may be the cause of much grief during the life of the equipment, if the tube is of the socket-base type. When gaseous thyratron and rectifier-type tubes were first introduced approximately 25 years ago, it was thought that sockets should be used in order to allow quick replacement. In making this decision, it was not realized at that time, that the use of a base and socket would jeopardize the reliability of the tube in service. Analysis of end of life tubes returned from the field over the past several years shows that over 9.0 per cent of such failures have been directly caused by inadequate socket conditions. Since tubes of this type are now one of the most important components in the power systems of modern industry, military aircraft, fire control equipment, and many other types of critical mechanisms, the importance of high tube reliability cannot be overemphasized.

Field reports indicate that a typical sequence of events in a socket failure is somewhat as follows: A new tube is placed in a socket and performs normally. After a short time oxidation or corrosion, aided by heat flow from the filament down into the base pin, increases the resistance at the filament pin contact. The temperature rises, accelerating the process until finally the increased contact resistance lowers the filament voltage enough to bring on a cathode failure after a relatively short life. Unsuspectingly a new tube is placed in the socket, and the process repeated but this time faster because of the initial oxidation of the socket clip and because the additional heat generated has caused the socket clip to relax some of its mechanical spring pressure. On some sockets, the variations in pin size and spacing within Radio and Television Manufacturers' Association (RTMA) tolerances are such that after a tube near the limits in one direction is used in the socket, the spring force will be seriously relaxed for a tube at the other limit.

3	2	30
4	2 1/2	50
5	2 1/2	50

Contact Requirements

The contact requirements for thyratron sockets are probably among the most severe to be found anywhere in industry, namely:

1. Fairly heavy currents must be handled: up to 26 amperes for the filament alone, plus load current as high as 77 amperes peak.
2. A fairly heavy wire must carry this current a short distance to a cathode running at 875 degrees centigrade; hence a substantial amount of heat is conducted to the contact.
3. The maximum total variation in filament voltage at the tube, for any substantial period without affecting tube life, is ±5 per cent. A change of contact resistance at each filament prong of 0.6 milliohms, generating a drop of 30 millivolts, would use up half of the allowable tolerance for low line voltage. In other words, it would affect tube life on many applications.
4. The contact must be maintained for several years, usually without any motion.

About 8 years ago, a 16-ampere tube was brought out on which the contact requirement was even more rigid: 34-ampere filament, and as high as 160 amperes continuously recurring peak load current. Realizing the pin-type limitations, this type was designed for bracket mounting with flexible leads ending in Hydent-type solderless-lug connections. The experience gained with this tube type was so gratifying that other types have followed, and the design has been adapted to many of the smaller 6-ampere diodes and thyratrons. Special thyratrons developed for military aircraft applications have incorporated the flexible lead connections with Hylugs for utmost dependability. Failures due to circuit connections on returned tubes of these types have dropped to an insignificant percentage. Out of many thousands of tubes now in service of this type only three instances of tube failure have come to light due to contact resistance in the filament lead. In each of these cases, it was evident that on installation one of the filament-lead nuts had only been set up with the fingers. Failure was prompt and obvious. The results have been sufficiently striking to warrant a more quantitative evaluation of the two terminating techniques.

Method

Spring Force

A base pin was arranged in a series circuit, Fig. 1, between two silver-plated phosphor-bronze spring clips from a typical tube socket. Contact forces were measured by looping a flexible cord around the top spring as near as possible to the pin. The mounting screws were adjusted to the desired force required to open the contact. This force was measured on a spring scale. Thirty amperes of alternating current were passed through the test setup at contact forces of 1/2, 1, and 2 pounds. Several sets of pins and springs were run simultaneously. Tem-

peratures were measured by use of thermocouples welded to the end of the springs as shown. The results are shown on Fig. 2, curves 1, 2, and 3.

This test was repeated using the test setup shown in Fig. 3, except at 50 amperes, of alternating current (at a contact force of $2^1/_2$ pounds). The conductor attached to the base pin was used as part of the test circuit. The mounting screw in Fig. 3 was adjusted until the desired spring tension was achieved. The results are shown on Fig. 2, curves 4 and 5.

Tube Tests

Two 6-ampere xenon-filled half-wave rectifiers were set up in a test circuit, Fig. 4, and mounted as shown in Figs. 5 and 6, on 3/16-inch aluminum sheet, back and bottom. The only difference between the two tubes was the method of terminating them. The pin-type tube (standard RTMA *A4-81* base) was terminated in a standard molded plastic socket with silver-plated phosphor-bronze contact springs. The flexible-lead type tube was mounted on 1/4-inch studs to the 3/16-inch aluminum backing sheet and terminated with 7 by 6 by 0.01-inch copper-core nickel-clad conductor, using standard no. 10 closed-back pressure-type solderless Hydent terminals, installed as shown in Fig. 19. The terminals were joined to a small plastic terminal block with no. 10-32 brass studs. The leads from the terminal block to the filament transformer were no. 10 insulated flexible copper conductor (*AN10*). The leads from the socket of the pin type tube to the filament transformer were also no. 10 insulated flexible copper conductor (*AN10*).

The mounting method shown was decided upon in order to simulate as much as possible the way these tubes would actually be used in equipment. The pin-type tube is normally mounted in a molded plastic base which, in turn, is firmly mounted to a metal surface. On the other hand, the bracket type tube is usually mounted against a sheet-metal backing and the flexible leads are then brought out to the required connection points. The two tubes were mounted $7^3/_4$ inches apart on centers. The entire assembly was placed in a draft-free room, specifically used for tests of this nature. Tests were performed under continuous, Fig. 4, and on-off loads, Fig. 7.

Temperature rise and millivolt drop were used to evaluate the performance of the tubes. The temperature rise above ambient of all external tube parts from the anode cap to the filament connections

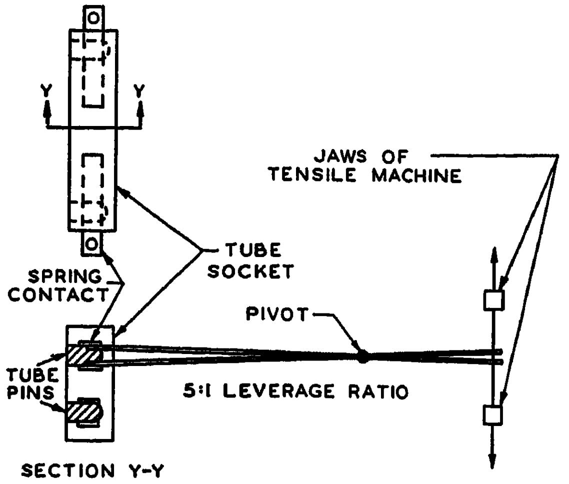

Fig. 10. Schematic showing measurement of socket spring contact forces

Spring contacts separated until 0.002 shim could be inserted between contact and tube pin. Force reading on 100-pound indicator at this point is divided by 5 to get actual value of force required at contact

was measured by thermocouples. The location of the various thermocouples are shown in Fig. 8. Thermocouples 4 and 5 were located the same vertical distance from the bottom of the tube base as thermocouples 11 and 12 on the pin-type tube. Thermocouples were also placed on the pressure terminals. Voltage drops were measured across the filament connections of both types of tubes, Fig. 8.

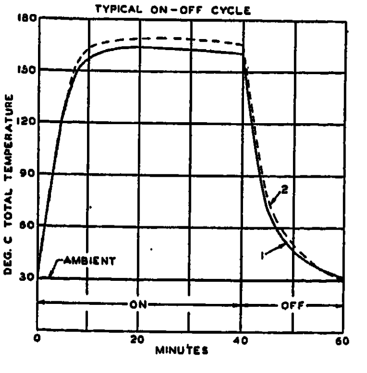

Fig. 9. Typical on-off cycle of 40 minutes on, 20 minutes off. Curve 1 is the anode cap of the flexible lead and Hylug tube. Curve 2 is the anode cap of the pin-type tube. There is sufficient off time for the hottest portion of the tube to return to ambient before the next cycle starts

Temperature and millivolt drop readings were taken on both tubes under continuous and on-off load conditions. The on-off cycle consisted of 40 minutes on and 20 minutes off. This was found to bring the parts of both tubes back to ambient temperature. Fig. 9 shows a typical heating cycle.

The force in the phosphor bronze spring contacts of the molded socket was measured by using a scissors-type device, Figs. 10 and 11. With the tube in the socket the prongs of the long arm were inserted just between the springs while the short lever arm was pulled in the jaws of a tensile machine. A reading was taken on the tensile machine when the spring contacts separated enough for a 0.002 shim to be inserted between the contact and tube pin. Readings were taken at the beginning and end of the continuous and on-off load tests. The filament transformer leads on the pin-type tube were soldered to the socket. The pressure terminals were screwed down to the no. 10-32 terminal strip studs with a torque of approximately 25 inch-pounds.

Results

Temperature Rise for Different Contact Forces

Fig. 2 indicates that low contact forces, in the order of 1/2 to 2 pounds for a phosphor-bronze silver-plated socket spring, will not result in a stable joint. At slightly higher forces, in the order of $2^1/_2$ pounds, the results are more or less stable, but stabilization occurs at relatively high temperature rises, in the order of 80 to 120 degrees centigrade.

Contact Force with Tube in Socket

Table I gives the results of measuring the contact force of the springs in the sockets with the tubes in place—before and after each test.

Terminal Force

Korn[1] gives the axial load in pounds per inch pound of applied torque for a no. 10 nut as 26 pounds. On the basis of an applied torque of approximately 25 inch-pounds, the total axial load on the pad of the terminal will be 25×26=650 pounds. This initial force is maintained because the small, constant, difference between

Table I. Contact Force

Load	At Beginning, Pounds	At End, Pounds
Continuous	7.3 to 7.8	3.86 to 3.85
On-Off	7.62 to 8.7	4.1 to 5.2

Fig. 11. Spring force measurement (shown schematically in Fig. 10)

millivolt drop *B* and *D* and between *A* and *C*, Figs. 12 and 13, indicates no change in the terminal connections. If either *A* or *B* had appreciably diverged from *C* or *D* during the progress of the test, it would have indicated a loss of contact force and an unstable contact condition.

Continuous Load-Millivolt Drop

The millivolt-drop readings of the continuous load test are shown in Fig. 12. One lead of the filament carries not only the filament current but also the additional plate load. The erratic behavior of the millivolt drop of the contact pins is the important thing to observe in Fig. 12. The voltage across both contact pins showed rising values, one more than the other. The drop across one pin increased by more than 100 per cent during the test.

Readings were taken from a point just below the tube base to the leads' own terminal, and to the filament transformer terminals. It should also be noted that the millivolt-drop reading for the flexible-lead tube was taken over a $5^1/_8$-inch dis-

tance, as compared to a distance of 1 inch on the socket-type tube. While the measuring distance was approximately 5 times greater on the flexible-lead type tube, the millivolt-drop reading was stable and lower compared to the contact-pin design.

Continuous Load—Temperature Rise

The temperature rise of the external tube parts are shown on Fig. 14. The anode caps and bulbs of both types of tubes stabilized at an approximately 140 degree-centigrade rise and remained there until the completion of the test at 360 hours. All the temperatures stabilized after approximately 50 hours. Continuing the test to 360 hours did not reveal anything which the first 50 hours had not already shown up. The outside of the phosphor-bronze springs in the molded socket had a 60-degree-centigrade rise, as compared to locations 4 and 5 on the flexible-lead tube, which stabilized at an approximately 55 degree-centigrade rise. The temperature rise of Hylugs 6 and 7 were considerably below the flexible-lead points at 4 and 5. The most marked temperature difference was between the tube base of the pin type which had a rise of 50 degrees centigrade, while the base of the flexible lead tube had a 25-degree-centigrade rise.

ON-OFF LOAD—MILLIVOLT DROP

The millivolt-drop readings of the on-off load test are shown in Fig. 13. As with the continuous load test, one contact pin of the pin type tube showed an erratic rising trend. It had millivolt drops over seven times higher than the drop across the other contact pin, which remained approximately stable. The drops across the flexible leads stabilized at approximately 40 millivolts, varying about this value during the course of the test.

ON-OFF LOAD—TEMPERATURE RISE

The temperature rises of the external tube parts are shown in Fig. 15. The anode caps of both tubes and the bulb of the pin-type tube had temperature rises of 135 degrees centigrade. The bulb of the flexible lead type tube was consistently about 25 degrees centigrade cooler. Similarly, the base of the flexible-lead-type tube was consistently 25 degrees centigrade or more cooler than the base of the pin-type tube.

The temperature rises of the contact springs and Hylugs show a direct relationship with the millivolt drop across these parts. When the voltage drop increased, the temperature rise also increased. When the voltage drop decreased, the temperature rise similarly decreased.

Table VI. Millivolt Drop—On-Off Load

	Voltage Drop, Millivolts					
	Pin-Type Tube		Flexible-Lead and Hylug-Type Tube			
No. of 1-Hour Cycles	Contact Pin E	Contact Pin F	A	B	C	D

1005	54	33	43	44	42.5	42

Conclusions

The results of both the continuous and on-off load tests show the flexible lead and Hylug tube to be significantly cooler than the pin-type design. With both tests, the tube bases of the flexible-lead and Hylug design were 50-per-cent cooler than the bases of the pin-type designs. During the on-off test, the bulb of the flexible-lead and Hylug design was 20-per-cent cooler than the bulb of the pin-type design.

The flexible-lead and Hylug-type design provides a more dependable, longer-lived tube than the pin-type design. The high stable contact forces achieved

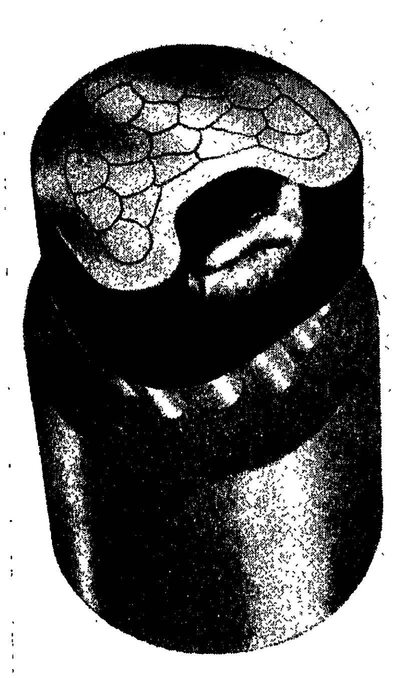

Fig. 20. Cross-section of a Hydent connection showing how the cup-shaped indentor cold-works the conductor. Each strand is compressed by the indentor into intimate contact with the Hylug barrel and the other strands, thus assuring a permanent stable joint

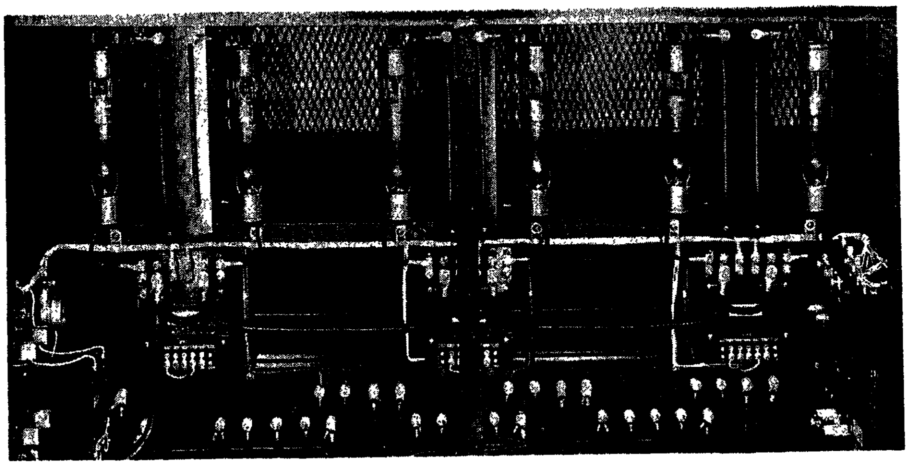

Fig. 21. Closeup of a heavy-duty power supply showing the use of six 16-ampere gas-filled rectifiers. The use of double-bracket mounted tubes and flexible leads with Hylugs gives the equipment designer great flexibility in mounting the tubes and provides better heat dissipation

by the flexible-lead-type tube results in greater voltage stability at the contacts. This means consistent operation within the tube's specifications, which results in more reliable and dependable tube operation. The allowable voltage tolerance of ±5 per cent is reserved for actual voltage fluctuations and is not used up almost immediately in the tube contacts. Instead of contact forces of seven pounds, which fall off to half that value in a few hundred hours of operation, contact forces of many hundreds of pounds are easily obtained and maintained.

The results indicate that the mounting bracket, flexible leads, and Hylugs drain away an appreciably greater amount of heat than the comparable tube of the pin and socket design. The importance of thermal engineering in the adequacy of electronic design[2] makes this a vital design consideration.

OTHER CONSIDERATIONS

Solder, with its attendant fluxes or acid, is completely eliminated with the flexible lead type tube. When the operating conditions of many tube applications are considered, this becomes extremely important. The high temperatures and corrosive conditions, coupled with the long life required, present a real quality-control problem to keep corrosion to a minimum.

Users at first were less sympathetic to the lug type than to the pin-and-socket type because of the longer time needed to change tubes, and because of the need of a tool to tighten the nut. Experience now indicates this should be considered as an advantage. Tests on tubes returned from service have traditionally disclosed a substantial percentage of tubes which pass all new tube tests. Investigating further, these tubes were usually replaced because the tube is the easiest thing to change. When any trouble occurs the first impulse is to replace all tubes and see if that fixes the trouble; if not, then a real search is initiated to run down the true cause. The Hylug seems to deter this philosophy, and results in a more careful analysis the first time.

There have been some disastrous epidemics of trouble with sockets. One was due to the substitution of another metal for silver-plated phosphor-bronze springs that had much better mechanical properties, but did not maintain good electrical contact. In another instance, spring-material quality control allowed a sizable percentage of certain sockets to relax their pressure with time. There have been socket designs that ultimately fill up with dirt, thus absorbing spring pressure and causing high resistance.

Design limitations make it difficult to provide a better factor of safety with a socket. For instance, if the contact pressure is increased, the tube cannot be inserted in the socket by hand unless longer travel and larger tube space is used. Since the required filament current for a given tube is fixed, unless a serious sacrifice in heating time can be tolerated, any higher filament voltage simply wastes heating watts in the tube and results in a larger tube. In view of these factors, a substantial improvement in contact method, such as flexible leads with Hylugs, is indicated.

In summary, experience and tests indicate that greatly improved unit reliability can be achieved with modern high-current temperature-free rectifiers and thyratrons, by eliminating base and socket construction through the use of bracket and pressure-lug construction.

Discussion

Robert N. Eck and Paul M. Fischer (Cutler-Hammer, Inc., Milwaukee, Wis.): We are glad to have some scientific study given to this matter, since we have found tube sockets to be a serious source of trouble in filament circuits, particularly with the larger power tubes. We have known for a long time that reliable tubes, which should have given exceedingly long life, would fail after several thousand hours of life due to poor contact connections in the socket. On one particular make of socket, we found the spring clips to be nickel plated, which very much aggravated the oxide resistance difficulty. Excessive heat developed at the clip in the socket soon resulted in loss of tension in the phosphor-bronze clips. Obviously, the deterioration is rapid once it starts. To eliminate this difficulty, we have gone to the bracket-mounted tube wherever possible, even though it meant a tube of special design. In this way we have obtained positive connections and eliminated the possibility of tubes loosening in their mountings.

We feel that a further weakness in industrial sockets for power tubes is the inadequacy of the terminals. In most cases, it is very nearly impossible to attach the large lead from the filament transformer, to say nothing of the additional connections that sometimes need to be made at this same terminal. The panel mounted tubes, with insulated studs for connections, are much better from this standpoint. Also, the terminals are more accessible for maintenance and trouble shooting.

Some effort has been made in the direction of providing set screws to tighten the pin of the tube into the socket. This could be rough on the tube and a hazard in some ways, but it is a possible means for insuring better contact.

The paper emphasized the advantage of the terminal connection over the socket connection, thinking only of the base of the tube. While it is true that practically all of our troubles due to poor contacts originated in the base socket, we feel there is also a need for a flexible-lead connection for the anode. We believe that the elimination of the anode cap would be a big improvement. We have had the experience of having the anode cap fit so tightly that on removal, the seal between the anode terminal on the tube and the glass envelope of the tube would break. Hence, we recommend that the tube manufacturer provide tubes complete with anode, filament, and grid leads, together with the mounting bracket. It is only in this way that the tube user can fully realize the good performance designed into present day power rectifiers and thyratrons.

Railroad Communications Using High-Power Carrier Technique

IN THE wilderness of the Quebec Labrador boundary a new Canadian industry is being established 360 miles from the nearest permanent settlement. This industry is the mining of iron ore and the location is Knob Lake, 360 miles almost due north of the small town of Seven Islands on the north shore of the Gulf of St. Lawrence.

It has been known for the past half century that large iron ore deposits existed in this area. Their location was so inaccessible, however, that the mining of it was commercially unattractive. The growth of air transportation during World War II made the project more feasible and the accelerated depletion of existing ore reserves made it desirable.

As a result of these factors the Iron Ore Company of Canada was formed in 1949. Two hundred million dollars capital was raised for establishing the necessary facilities to enable 70,000 tons of ore a day to be delivered to the docks at Seven Islands whence it can be transported by boat to steel mills throughout eastern North America and Europe.

A major part of the program is the construction of a railway over the 360 miles between Knob Lake and Seven Islands—a railroad that requires the heaviest rails rolled in Canada (132 pounds) and whose trains will carry the heaviest loads in North America (10,000 net long tons pulled by 4-unit diesel-electric locomotives, making a total of 14,000 trailing tons behind the locomotives).

Obviously such an extensive project must have excellent communications, not only for railway operation but in connection with the mining of iron ore and to provide public communications for the new town at Knob Lake. The responsibility of providing communications was assumed by the Quebec North Shore and Labrador Railway Company, a subsidiary of the Iron Ore Company of Canada. No major railroad has been built in North America in the last 50 years, so an exhaustive examination was necessary of the various communication facilities now available, whether conventional to railroad use or not.

Development of Specifications

Initial Considerations

The first thought was that space radio would be the ideal solution, as only three points required communications—Knob Lake and Seven Islands, and Oreway, the half-way point. The distance and traffic density, however, ruled out direct point-to-point radio on high frequencies since there are not enough high frequency channels available. Microwave or very high frequency (VHF) radio would be required with the necessity for a number of repeater stations located, on the average, not more than 30 miles apart.

Microwave began to look attractive with the addition of another requirement, that of signalling for the railroad operation. The railway line is single-track with passing tracks located, on the average, every 15 miles. It was decided to control all train movements from a central dispatch point using a centralized traffic control (CTC) system. In this system d-c signal pulses must be transmitted and received from each siding. It would therefore be necessary to place a radio station at each siding which could handle the CTC signals and which could also relay through traffic.

Two major requirements were necessary for such a radio system: a reliable source of power to operate the equipment, and over-all reliability. The great number of electronic tubes which would effectively be in series from end to end of the circuit (about 1,000) was of concern. First there is very little operating experience available on long unattended radio relay systems. With an average of 10,000 hours' tube life, two to three failures a day could be expected. Using duplicate equipment along with a preventive maintenance schedule and stand-by service personnel, it was expected that good continuity of service could be maintained during the time the railway was operating, but at high cost. During the winter, when the railway was closed down, the problem of maintenance would be more severe as many relay points would be accessible only by helicopter.

Paper 53-342, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B. C., Canada, September 1–4, 1953. Manuscript submitted June 8, 1953; made available for printing July 7, 1953.

A. K. Hansen is with the Quebec North Shore and Labrador Railway, Montreal, Quebec, Canada, W. W. H. Dean is with the Canadian Westinghouse Company, Ltd., Hamilton, Ontario, Canada, and F. G. Mullins, Jr., is with the Westinghouse Electric Corporation, Baltimore, Md.

The deciding point against radio, however, was the problem of supplying power. The cost of local generation and the problem of unattended operation at the many relay points was prohibitive. But power was also required at each siding to keep the batteries charged which are required for operation of the signal system. As a result of these considerations, it was decided to construct a power line along the right of way. Power for radio operation would then be available. But now the picture was altered. With a wire line available, radio was no longer required. Power line carrier could be employed eliminating the many repeaters and consequent cascading of tubes.

However, there was still the problem of reaching the sidings with CTC signals. A separate power line carrier channel could be run to each one from the control point, but the number of carrier channels is limited. It is also preferable to have direct connections in a CTC system wherever possible to ensure maximum reliability (although carrier equipment is used for this purpose). As the CTC operates on a direct current of less than 200 volts with shunt-keying across the line to provide signalling, it is essential that the line must have low series resistance and high shunt resistance.

The power line was to be constructed as a single-phase 23-kv balanced line using no. 4 steel-reinforced-aluminum-cable smooth-body 150-per-cent conductors. The same construction was suitable for a CTC line; thus a second line was strung on the same poles 13 feet below the first. As this lower line was isolated from the power line and was constructed with a barreling transposition every fifth pole, it should be possible to obtain a better signal-to-noise ratio by using it for the carrier. It could also be used for telephone signals from instruments located at each siding, and also from portable telephones used by train and work crews.

THE FINAL SPECIFICATION

Thus the pattern for communications developed, and final specifications were written for the system. They call for:

1. Nine trunk voice communication channels between Seven Islands and Knob Lake, four to be accessible at Oreway, the remainder to be direct.
2. One direct-voice channel for dispatch use connecting Seven Islands, Oreway, and Knob Lake.
3. One spare voice channel for dispatch operations.
4. Six teletype channels between Seven Islands and Knob Lake, four direct and two with party line taps at Oreway.
5. Voice communication, using the physical line, from each end of every siding to the dispatch center.
6. Portable telephones capable of being tapped on the line at any point for communication with the dispatcher.
7. Automatic dial telephone installation to serve the town of Knob Lake and Oreway.
8. A switchboard at Seven Islands to control all traffic over the trunk channels to Oreway and Knob Lake. All channels terminating on this switchboard must meet long-distance telephone standards, regarding frequency response and signal-to-noise ratio, as they will be connected into the nation-wide long-distance system through the local telephone company at Seven Islands.

All connections to the communications line must be designed so as to protect personnel and equipment from any accidental application of the power line voltage, and from lightning.

Meeting the Specifications

CHOICE OF CARRIER EQUIPMENT

To meet the performance specifications, consideration was first given to the trunk (or carrier) channels. While not actually on a power line, the line construction and its proximity to the power-carrying pair required that power line carrier techniques be employed.

All power line carrier in Canada is licensed by the same Department of Transport authority that controls space radio. They advised that under no circumstances could frequencies above 200 kc be used because of possible interference in the air navigational band. As the railway straddles the main transatlantic airway from Montreal via Goose Bay, the importance of avoiding interference is obvious.

Having had the upper limit of transmission thus fixed, and the lower limit fixed at about 40 kc by normal power line practice, there was available 160 kc of frequency spectrum to fit in the required channels. Remembering that each channel must be duplex, it was necessary to locate 22 single-voice carriers and 12 single-teletype carriers in this space.

By making use of single side-band techniques it is possible to space carriers 5 kc apart, using up 110 kc of spectrum for the voice channels. As only six teletype channels are required in each direction, frequency shift type carriers spaced 0.8 kc are supplied. This uses up another 10 kc, approximately, of spectrum, or no more than a duplex-voice channel incorporating voice frequency telegraph.

The total carrier requirements could be provided for in 120 kc of spectrum space.

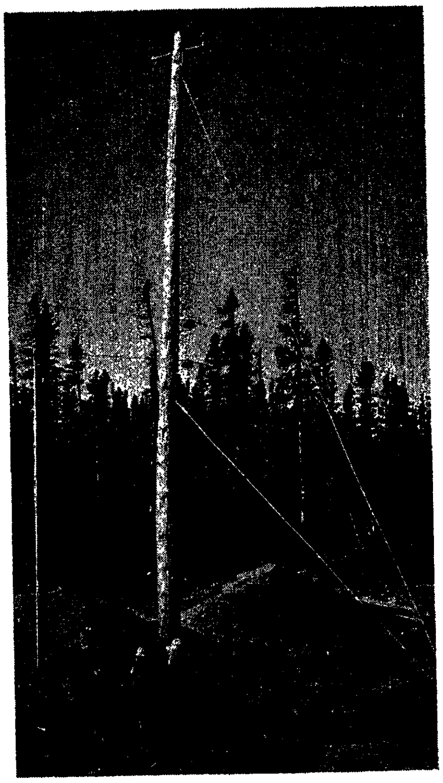

Fig. 1. Typical pole line construction

The remaining 40 kc is then left available for additional channels, guard bands and co-ordination with low-frequency radio services in case of mutual interference.

To meet the required transmission standards, it is not possible to transmit a carrier the entire 360 miles. Also, some channels must be accessible at Oreway, the halfway point in the line. All, therefore are repeated at this point. From the discussion on frequency requirements it may be seen that there are no frequencies available to allow a second set to be used beyond the relay point. All frequencies in the second section of the line are therefore duplicates of the first, but arranged so that each channel is received at or transmitted from Oreway on the same frequency in each direction. In this way the power level, either transmitting or receiving, is the same each side of Oreway on the duplicate frequencies. Good isolation of the equipment in the repeater installation by shielding, separate ground lead, etc., minimizes coupling between equipments. Also in one direction the physical line is replaced by a coaxial cable for 500 feet, to reduce mutual coupling between the two line sections. Detailed information on the carrier equipment and its application appears in the section "Equipment Application to the System."

TELEPHONE AND ASSOCIATED EQUIPMENT

Associated with the carrier equipment is terminal telephone and teletype equipment. At Knob Lake a 300-line, completely automatic dial-type exchange is being installed. It will serve the various offices connected with the mining operation as well as the town site, even providing pay phones. The telephone installation is made in such a way that it may be expanded in the future to match town growth.

A similar but smaller dial exchange will serve the dispatch center at Oreway. In addition to the regular telephone system, the dispatchers have their own private carrier channel with a loudspeaker monitor connected across it. They can thus hear all incoming calls, answering with a standard telephone handset, which cuts off the loudspeaker as soon as it is lifted off its cradle.

The Seven Islands installation consists of a switchboard on which all the carrier channels are terminated. Connections are made here to the company's private branch exchange telephones, to the local Seven Islands telephone system, and to long distance through the Seven Islands town operator.

The teletype instruments are all page-type printers and are connected to provide local copy. That is, all messages print on the local machine as well as the remote one. The teletypes are connected into the carrier system through the telephone cables, but have no other connection with the telephone equipment.

For communication from along the right-of-way, booth-type telephones are permanently installed at each siding. In addition, portable instruments are supplied and provided with hook sticks to enable temporary connections to be made to the line at any point by train and work crews.

System Operation

This system is designed to provide the most flexible possible operation while retaining control through the Seven Islands switchboard. The operator at this point can select carrier trunks connected to either Oreway or Knob Lake telephone equipment, and dial the desired local number. At the same time, subscribers at either of these points, by dialing "operator" will automatically pick up the first idle carrier circuit and signal the operator. For convenience, and as heavy traffic is not anticipated, it is possible to dial directly between Knob Lake and Midway by prefixing the desired number with "9."

Instead of leaving the spare dispatch channel idle except when required as a result of failure of the regular channel, it is connected to the switchboard and Knob Lake exchange. By making it the top level on the trunk selectors, it is the last channel to be used in regular telephone service, and consequently is the most likely one to be available. This spare is also connected to the dispatchers' locations in such a way that, by operating a switch, the dispatch equipment is connected to it and the exchange equipment disconnected, whether it is in use or not. The railway dispatchers are therefore, given complete priority.

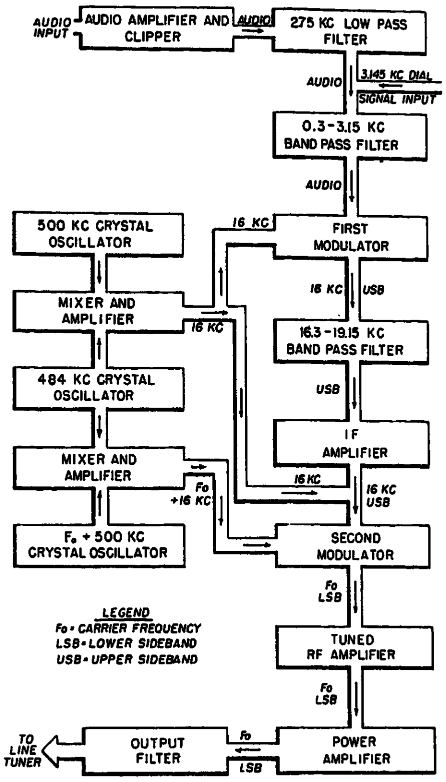

Fig. 2. Block diagram of single-side-band transmitter

Wayside Protectors

The terminal carrier equipment is connected to the communication line with conventional high-voltage capacitors just as if the line were energized. For the wayside and portable telephones, special protectors are required. A unit is available, known as the Osborne telephone protector, which is intended for coupling telephones to lines which are exposed to the application of high voltage.

This device consists of a high-voltage isolation transformer with the primary center tapped and grounded. There is also a double-coil relay series connected on the line side. Fault current, either between lines or to ground, causes the relay to close and ground both sides of the line. This relay has carbon contacts and is constructed so that quite heavy fault currents may be passed to ground without causing damage.

For this particular application two additional features are required. First, except under fault conditions, there must be no d-c path between lines or to ground. Second, and very important, a very small bridging loss must be caused at carrier frequencies, when the device is connected across the line. Direct current may be blocked by installing capacitors in series with each line just ahead of the center tapped transformer. Because of the practical limitation on capacity, however, these effectively prevent the flow of 60-cycle power current in case of a fault. This is overcome by placing a gas-type discharge tube from each line to ground. Finally a low-pass filter is added which will pass voice and direct current but which offers a very high impedance at carrier frequencies.

The final device, all housed in a cast aluminum enclosure, consists of the following components, starting at the line terminals:

1. Hook operated disconnect switch.
2. Grounding relay.
3. Discharge tubes, 400 to 600-volt rating.
4. Low-pass filter.
5. Blocking capacitors, 2 microfarads.
6. Isolation transformer.

CTC signal connections are tapped off ahead of the blocking capacitors and voice signals from the secondary of the transformer. (The CTC equipment contains filters to prevent it from interfering with voice signals.)

It will be noted that the discharge tubes have a 400 to 600-volt rating, with a nominal breakdown at 450 volts. This high voltage rating is necessary as the peak carrier voltage plus d-c CTC signals can theoretically exceed even 900 volts between lines. This peak would be reached at such infrequent intervals that any clipping caused by the tubes discharging is quite acceptable.

In this circuit the grounding relay and discharge tubes are placed ahead of the filter to obtain the maximum protection. The filter impedance at carrier frequencies is lowered by doing this; nevertheless, the loss introduced by connecting the protector across the line is less than 0.2 decibel at all carrier frequencies. The transmission loss through the device from the telephone instrument is about 2 decibels, while the d-c resistance for CTC signals is less than 2 ohms per leg.

Obviously, the portable telephones could not be supplied with such an elaborate device as the device is about three times the volume of the telephone unit itself. Since the portable units are connected only temporarily and for short periods, it was considered permissible to allow a slightly greater bridging loss. Also it has been observed that users very seldom ground portable units even when facilities are provided, and in the area where these sets are used, only elaborate and deep ground systems are effective because of soil conditions.

It was decided, therefore, to build as much insulation as possible into the portable telephones, to provide isolation for direct current, and to provide the highest impedance possible in the available space for carrier frequencies.

This was accomplished by using an isolation transformer similar to that in the fixed protector, but having a split primary winding with a blocking condenser in series to provide d-c isolation. This transformer is followed by a small, telephone-type carrier filter. An interesting feature of the isolating transformer is that, to save space and weight, yet provide good insulation, the transformer and its blocking capacitor are molded in a single unit. The thermosetting plastic used produces a unit which is capable of passing *MIL-T-27* specifications for class 1, grade A service.

Equipment Application to the System

Equipment Specifications

The preceding indicates in a general way the equipment chosen to meet the system requirements. A more detailed description of the carrier equipment will now be given. In particular, the voice carrier is described, as this equipment must operate through lines having an attenuation of 50 decibels, incorporate a repeater, and provide a signal to interference ratio and frequency response comparable to toll telephone service.

Teletypewriter Channels

Consideration was initially given to the use of a carrier channel, modulated by tones, to provide the teletypewriter service. In fact, it was contemplated that a 2-frequency duplex carrier could be modulated with six tones for the teletypewriter channels and ten tones for dial-signalling on the automatic telephone channels. This arrangement provides an economy in both equipment and frequency spectrum. Its disadvantage is, obviously, the fact that the entire communication system is dependent upon a single carrier channel.

This disadvantage could be offset to some degree by a spare carrier channel, manually or automatically switched into use if the primary channel should fail. However, in the final system, teletypewriter functions are each placed upon an independent frequency shift channel. Standard a-c/d-c frequency shift transmitters and receivers are suitable for this service. An adequate description of those used has been recently published.[1] Six transmitters are mounted upon an equipment rack with one rack located at each terminal and two racks located at the mid-point for repeater service. Similarly, six receivers per rack are provided at the terminals and at mid-point. An auxiliary rack at each station contains relay panels, where required, to establish teletypewriter loops and the necessary fuses and rectifiers for loop power. A total of 11 racks constitutes the teletypewriter communication system.

Voice Communication Channels

The gap in the communication transmission line at the mid-point alleviates the frequency spacing problem by allowing frequencies to be repeated in the northern and southern halves of the line. However, to place 22 voice signals, each with an audio response to 3,150 cycles, within the 40 to 200-kc range, in addition to the 12 previously described frequency shift signals, is thought to be a unique application in the power line carrier field. Single-side-band carrier operation makes this possible.

Use of single-side-band power line carrier transmission and reception in the United States and Canada is not new.[2,3] However, the use of selective filters for reduction of adjacent channel interference and spurious transmitter outputs[1,4] came into wide use in power line carrier practice after the development of the old, earlier type of single-side-band equipment.[3] Even with one side band eliminated, the closest usable spacing with this equipment was about 8 or 10 kc. To permit the closer channel spacing required for this job either modernization or complete redevelopment was necessary. The latter course was chosen, with 5-kc spacing between adjacent transmitters as the goal. New techniques, which were developed for frequency division multiplexing over microwave[5] were found to be readily adaptable to power line carrier.

Single-Side-Band Transmitter

A block diagram of the single-side-band transmitter applied to this system is shown in Fig. 2. Crystals are temperature-controlled to meet Canadian Department of Transport stability requirements. High-quality crystals of the frequencies used are readily obtainable. The 500-kc and 484-kc crystals are permanently installed. Outputs of the oscillators, controlled by these crystals, are mixed and amplified, the 16-kc frequency difference being used in the first modulator, regardless of the desired carrier frequency.

The output of the 484-kc oscillator is used again in the second mixer, where, in combination with the third crystal oscillator output, a frequency F_0 (the desired carrier frequency) plus 16 kc is derived, and amplified to a suitable level for use in the second modulator. To obtain single-side-band operation through the use of dual modulators permits the shaping of the passband by fixed filters, rather than units which must be changed with each change in output frequency.

A conventional audio amplifier contains two gain-controls to adjust input and clipping levels separately. A low-pass filter, flat within 2 decibels to 2,750 cycles and 40 decibels down at 3,145 cycles (the frequency of the dial-signalling tone) is used, together with a band-pass filter, flat within 2 decibels from 300 to 3,150 cycles, at least 30 decibels down at 120 cycles and 4,000.

A balanced ring modulator of conventional type, utilizing germanium diodes, combines audio output from the filters and the 16-kc output from the first mixer amplifier to produce side bands 16.3-kc to 19.15-kc and 15.7-kc to 12.85-kc. The 16-kc component is removed by the modulator.

A second band-pass filter, flat within 3 decibels from 16.3-kc to 19.15-kc, down 34 decibels at 15.7-kc and 30 decibels at 21-kc, passes the upper side band. An intermediate frequency amplifier compensates for filter losses and provides a convenient point for reinserting the 16-kc signal as a pilot carrier.

A second modulator, similar to the first, provides the means for deriving the output frequencies. The 16-kc carrier, together with the 16.3-kc to 19.15-kc side band are mixed with the F_0+16-kc output of the second crystal oscillator mixer. Difference signals produced are F_0 as pilot carrier and a lower side band, F_0-(0.3-kc to 3.15-kc). Sum signals produced, F_0+ 32-kc pilot carrier and a corresponding upper side band, are rejected by the triple-tuned radio frequency amplifier. Staggered tuning is used for the amplifier circuits to provide an adequate passband for the desired signals. An untuned class *A*, push-pull, parallel power amplifier, using eight *25L6* tubes, is capable of providing 16 watts output into the filter.

Two parallel-tuned traps in the output filter attenuate the second and third harmonic frequency outputs, and a series resonant circuit, of which these traps are a part, passes the output frequency to the coaxial cable connection to the line tuning device.

Table I. Transmitter Electrical Specifications

Supply voltage........	Nominal supply voltage, 129 volts d-c; heater voltage, 129 volts a-c or d-c
Supply variation.......	±10 per cent
Operating frequency...	40 to 200-kc
Frequency stability....	±8 cycles from 0 to 60 degrees centigrade
Output power.........	Ten-watt capability at filter output
Harmonic output......	60 decibels below transmitted output when terminated in 60-ohm resistive load
Audio input...........	Full modulation with −20 decibels referred to 1 milliwatt (dbm) input at 800 cycles

Specifications for the single-side-band transmitter are shown in Table I.

SINGLE-SIDE-BAND RECEIVER

Fig. 3 shows a block diagram of the single-side-band receiver.

The carrier input signal, F_0 pilot carrier and lower side band as produced by the transmitter, is applied to the receiver input filter. This filter is interchangeable at 5-kc intervals throughout the 40 to 200-kc frequency band. Characteristics of a typical filter may be illustrated for a frequency, F_0, of 100 kc. This filter is flat within 2 decibels from 96.85 kc to 99.7 kc. It is down 30 decibels at 94.7 kc and 101.85 kc, and is down 70 decibels at 91.55-kc and 105-kc.

This permits 2-frequency duplex operation with the receiver separated by 10 kc from the full power output of the transmitter. A radio frequency input control permits adjustment of input signal level.

The signal, after passing through the input filter is impressed on a clipper-cathode follower, the output of which is mixed in the first demodulator with the F_0+16-kc output of the crystal oscillator and amplifier. Any difficulty from frequency instability of the crystal oscillator is eliminated, since the error is applied in translation to the pilot carrier and side band equally.

Of the outputs produced in the first demodulator, only the difference frequencies are used, 16 kc for the pilot carrier, and 16.3 kc to 19.15 kc for an upper side band. Characteristics of the 16.3-kc to 19.15-kc band-pass filter are similar to those of the filter used in the transmitter. Three single-tuned intermediate frequency amplifier stages provide additional selectivity and the necessary gain for the receiver.

The 16-kc pilot carrier signal is extracted from the output of the intermediate frequency amplifier and is further amplified through 16-kc tuned circuits, rectified, and the resulting voltage applied back to the intermediate frequency amplifiers as conventional automatic gain control. This 16-kc output of the intermediate frequency amplifier is further used to synchronize a self-excited oscillator, which provides the final translating signal. The 16-kc pilot signal could be applied directly for translation, but the arrangement used allows for fades or other temporary loss of the pilot signal, the self-excited oscillator continuing to function near the desired frequency even in the absence of the synchronizing carrier.

The second demodulator, similar to the first, is a balanced ring type. It mixes the 16.3-kc to 19.15-kc side band with the 16-kc output of the synchronized oscillator to produce audio of 300 cycles to 3,150 cycles.

A low-pass filter for side-band separation, and a low-pass filter for signalling tone exclusion in the receiver, permit extraction of the 3,145-cycle dial signalling tone and allow elimination of spurious outputs above and below the desired 300 to 2,750 cycles at the output of the audio amplifier. Specifications for the single-side-band receiver are shown in Table II.

SINGLE-SIDE-BAND ASSEMBLIES

A single-side-band transmitter and receiver, together with the necessary rectifiers for a-c operation and other auxiliaries, constitute a voice communication assembly. Three different types are included. For the channel designated for the railroad dispatcher, 2-wire telephone termination and amplifiers, and speakers for voice calling are provided. For the equipments terminating in automatic telephone switchboards, 2-wire telephone and a 3,145-cycle frequency shift tone for dial signalling are provided. For the equipments used for repeaters at the mid-point, 4-wire audio termination is used, the receiver audio output from one direction being connected to the corresponding transmitter audio input in the opposite direction. Signalling equipment and hybrids are eliminated in the latter. Equalizer amplifiers are added on the automatic telephone channels to provide the desired flatness in the audio response. A total of 44 racks constitute the carrier voice communication equipment, 11 racks at the south and north terminals, and 22 racks at the mid-point.

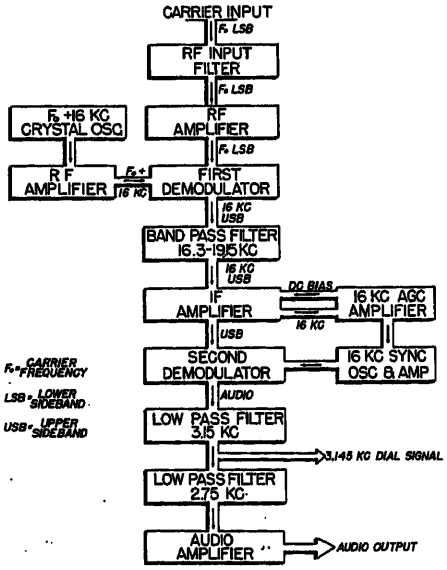

Fig. 3. Block diagram of single-side-band receiver

Table II. Receiver Electrical Specifications

Supply voltage........	Nominal supply voltage, 129 volts d-c; heater voltage 129 volts a-c or d-c
Supply variation.......	±10 per cent
Operating frequency...	40 to 200-kc
Temperature limits....	0 to 60 degrees centigrade
Sensitivity............	One-watt pilot carrier and 4.5-watt peak power side band produce ±8 dbm audio output through a 70-decibel (db) noiseless channel
Selectivity............	0.3-kc and 3.15-kc below carrier frequency, 3 db At ±3.575-kc from channel center frequency, 80 db
Automatic gain........	Less than 6-db increase in audio for 40-db increase in radio frequency

COUPLING PROBLEMS

Two problems were outstanding in this application, both relating to coupling. First, operating all transmitters in parallel, with the requirement that spurious signals be 30 decibels or more below desired signals in the receivers, required that intermodulation products in the receiver passbands be 80 or 90 decibels below the transmitted output levels. The second problem related to broad-band coupling to the line.

Transmitter output filters provide some isolation, although it is anticipated that transmitter outputs may have to be reduced to prevent the transmitters from overloading each other. All transmitters at one terminal are grouped, with 5-kc frequency spacing, into one end of the frequency band with a high-pass or low-pass filter as required to protect the receivers, which are grouped in the opposite end of the frequency band. All frequency shift channels are grouped near the center of the frequency band with a band-pass filter at the frequency shift transmitter outputs to prevent the generation of voice intermodulation products

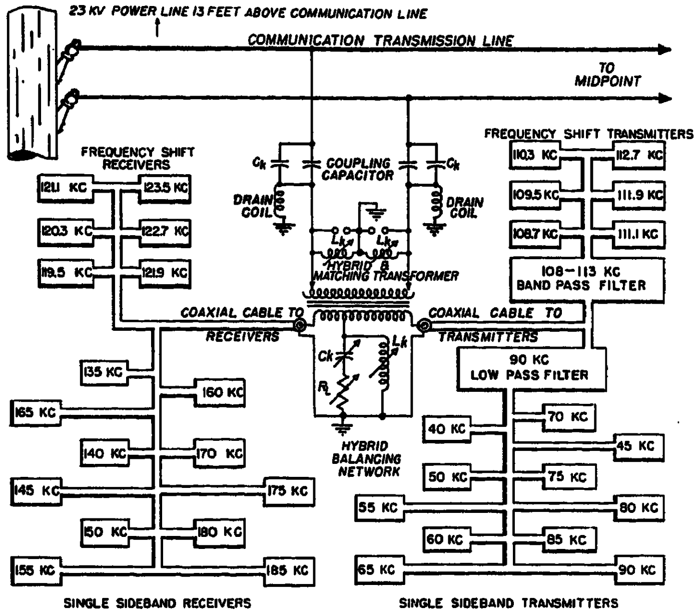

Fig. 4. Coupling method used for paralleling transmitters and isolating receivers at terminal stations

in the frequency shift transmitter outputs. One additional provision had been suggested, that of using a hybrid to separate transmitters from receivers.

A subsidiary problem was presented with the discovery that the available hybrid transformers produced intermodulation products beyond the tolerable limits. A special transformer was designed, utilizing a Hypernik toroidal core and a very low magnetizing current. To avoid the necessity of designing a separate matching transformer, the hybrid and matching functions were combined.

For true broad-band coupling, a constant-*k* high-pass filter is suitable, provided the cut-off frequency can be set sufficiently low to allow impedance matching at the lowest frequency used. A coupling capacitance of 0.005 microfarads, such as is available for higher voltages, results in a cut-off frequency of 98-kc for a 325-ohm termination. Fortunately, this application involves a low-voltage circuit of 11.5-kc, line-to-ground, and 0.02-microfarad capacitors having a cut-off frequency of 24.5-kc can be economically used.

Fig. 4 shows how the necessary coupling elements are combined. A combined hybrid and matching transformer is situated with constant-*k* filter elements in its primary and secondary. The constant-*k* element in the primary, together with the balancing resistor in the primary, constitutes the balancing element of the hybrid. The input to the coupler matches the 60-ohm impedance of the normal coaxial line, while the coupler output is adjusted to match the impedance of the communication line.

CONCLUSION

The elements discussed as constituting this system, that is, frequency-shift transmitters and receivers for the teletypewriter channels; single-side-band transmitters and receivers for voice communication with automatic dial telephone switchboards; and broad-band coupling to a communication line in joint use with direct current for centralized railway traffic control and audio for linkage of base railroad radio communication circuits, provide a unique communication system of great diversification, which involves several novel approaches to the railway communication problem.

Discussion

C. W. Boadway (The Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada). The technical presentation is an interesting engineering adventure. It would be of great interest and assistance to the communication field if, after completion of the over-all installation and field measurements as to line and equipment performance characteristics, the authors would prepare an additional presentation describing the practical difficulties and ultimate solutions involving the over-all application and installation.

The provision of communication and d-c signalling over 360 miles of virgin territory with numerous sidings, or tap points, is indeed a difficult problem. The text of this paper indicates that considerable thought and investigation were given to the problem before the choice of carrier on open-wire line was finally decided.

Because of the unusual length of the telephone line, and its exposure to a 23-kv single-phase power circuit, together with the numerous services and service taps required, it is expected that transmission and operating difficulties may be encountered before the system is finally accepted for service. There is a lack of power system information included in the technical presentation which prevents the reader from analyzing the inductive effects which may be expected from such a long power exposure with the telephone circuit.

In the section on "Initial Considerations" it was stated that the communication line was constructed with a transposition in the telephone circuit every fifth pole, or approximately 1,100 feet apart. It would be of great interest to know the magnitude of the induced voltage at various points along the line from the generating source, and whether or not additional remedial measures may be required for safe operation of the equipment and safety of operating personnel. In view of the fact that each siding has to use the physical line back to the dispatch center, it would be of interest if the authors were to elaborate on the magnitude of audio noise on the physical circuit, and the bridging loss at voice frequencies due to the numerous tap conditions; also, the effective transmission equivalent between the most distant siding and the dispatch center.

It is noted that the carrier equipment is to operate through a total line attenuation of approximately 50 decibels. We would assume from this estimated attenuation that it involves only the half-portion of line between repeater points, as our experience would indicate that the over-all installation would involve an average attenuation of 0.2 decibel per mile at approximately 100 kc not including equipment loss. On this basis, and including normal equipment losses (including line coupling apparatus, hybrids, and bridging filters), the over-all attenuation for the 360 miles would be of the order of 90 to 100 decibels. With this order of attenuation, it might be possible or necessary, due to noise over the carrier frequency spectrum, to consider additional repeater points.

The application deviates somewhat from our normal communication procedures as applied to telephone system facilities, and in view of the importance of the communication circuit requirements and the multiple services to be provided, I feel that the authors and those participating in the design and installation should be congratulated and encouraged in developing and applying a new communication technique.

A. K. Hansen, W. W. H. Dean, and F. G. Mullins, Jr.: Mr. Boadway suggests that further information be published when this installation is complete. This is contemplated, and will provide actual measured values of line noise, attenuation, and general operating characteristics. Starting in the fall of 1953, continuous noise and attenuation measurements will be made for a period of at least 1 year.

Calculations on the idealized line configuration give a very low interference figure in the communications line from the power line. Actual measurements with power on will be required to determine the effect of the unavoidable discontinuities introduced during construction. Drain circuits or other corrective steps can only be taken when the magnitude of the interference is known.

The effect of the many taps on the line is referred to. The coupling units at these taps are designed to introduce a bridging loss at carrier frequencies of less than 0.1 decibel and an insertion loss at voice frequencies of less than 2 decibels. In addition they present a low d-c series resistance to the railway signalling system.

The physical telephone circuit is presently in use over more than 100 miles of line with excellent performance. The effect of noise from the energized power line is yet to be determined, however.

Several calculated values are yet to be checked by actual measurement and undoubtedly unexpected problems will arise. We look forward to making a complete report on these when the project is completed.

Program Transmission Over Type-N Carrier Telephone

R. L. CASE
MEMBER AIEE

IDEN KERNEY
NONMEMBER AIEE

THE transmission of program material over a nation-wide system of wire-line networks interconnecting most of the country's broadcast and television stations has grown apace with the development of the radio and television arts. Today, program networks aggregating as much as 156,000 miles in length, including both radio broadcast circuits and television sound channels, may be employed during a single evening.

Initially, all program networks operated over voice frequency facilities, either open-wire or cable. The open-wire circuits were nonloaded, but the cable circuits, other than short runs in metropolitan areas used to connect studios and transmitters, were, in general, equipped with special loading, and the transmission variations with temperature were controlled by pilot-wire regulators. The voice frequency cable pairs assigned to program transmission were usually 16-gauge, so that the program levels in each repeater section might be maintained at adequate values, and the repeaters still spaced far enough apart to permit their being placed at the same locations as the message repeaters.

In 1945, program transmission on a commercial basis was first provided for each of the major networks over *K* carrier facilities between Los Angeles and Omaha, utilizing three message channels to provide a single program channel in each *K* system.[1] However, as only a few of the broadcasters requested facilities with a wider band than that provided by schedule *A* program (approximately 100–5,000 cycles) the program terminal was modified to permit one of the three channels to be returned to message service.

With the advent of the less expensive type-*N* carrier system[2] about 3 years ago, the possibility of both schedule *A* and schedule *C* (approximately 200–3,500 cycles) program transmission over one or two links of this facility became of great interest. This was partly because of the flexibility of the proposed arrangements and partly because of the economies envisioned. With the increased use of television facilities a high speed of propagation for the sound channel was required so as to synchronize properly with the video channel, a speed not possible with long voice frequency loaded pairs. In addition, in anticipation of the use of program over carrier, new cables, both quadded and nonquadded, were being fabricated without any 16-gauge pairs.

Schedule *A* and *B* (part time schedule *A*) program requires a band which is wider than the total frequency space allotted to a type-*N* channel. To obtain this band with existing type-*N* arrangements, it is necessary to give up three message channels. While schedule *C* and *D* (part-time schedule *C*) program requires the band space of only a single-message channel, it is necessary to widen the message band and to eliminate the 3,700-cycle built-in signaling system.

Engineering Considerations

Prototype program channel units providing schedules *A* and *C* transmissions were tried out on two Milwaukee-Madison experimental *N* systems in 1950. Exploratory work was also carried out to determine the feasibility of providing 8- and 15-kc facilities over these systems. As there were few commercial requirements at that time for program service with a band wider than that provided by schedule *A* facilities, it was decided to concentrate on the development of channel units for schedules *A* and *C* program transmission.

The Milwaukee field investigation indicated that while satisfactory program transmission was readily realized over type-*N* carrier systems in fair weather, excessive static interference resulted during severe electrical storms in the vicinity of the Milwaukee-Madison cable. Various remedial measures were tried on the *N* systems themselves, such as application of direct drainage on the *N* pairs; application of roof (low-pass) filters at the inputs of high-low repeaters and of cellar (high-pass) filters at the inputs of low-high repeaters, and substitution of a local battery supply for the individual repeaters in place of the power supply usually fed over the *N* pairs. These measures offered only minor reductions in the static disturbance, so it was concluded that most of the noise was introduced through the open-wire taps along the cable. However, because of the large number of taps involved it was not found practicable to apply suppression measures to them during the 1950 static season.

The following year, another series of tests was conducted, this time on an *N* system operating over the Harrisburg-Sunbury, Pa., toll cable, which, when the field study began, had only a single open-

Paper 53-335, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Pacific General Meeting, Vancouver, B. C., Canada, September 1–4, 1953. Manuscript submitted May 25, 1953; made available for printing July 13, 1953.

R. L. CASE and IDEN KERNEY are with the Bell Telephone Laboratories, Inc., New York, N. Y.

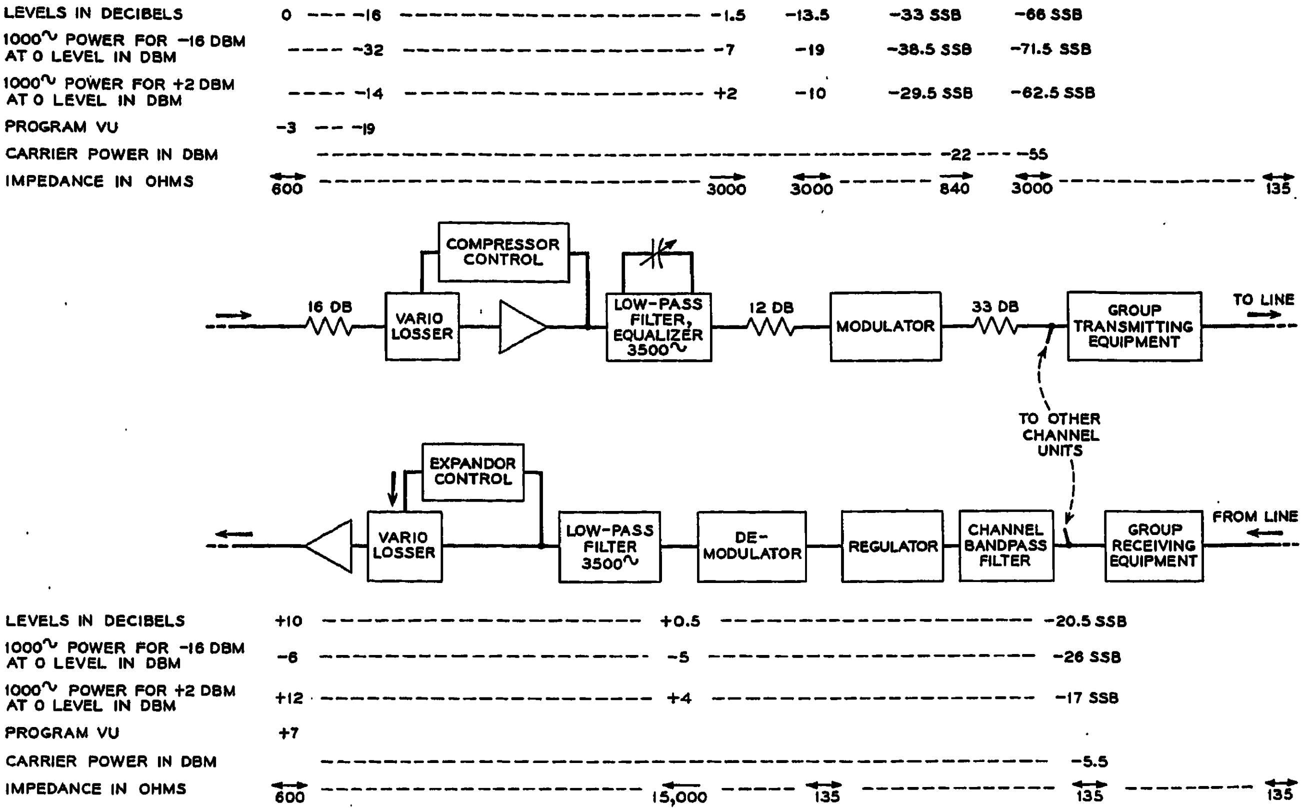

Fig. 1. Block schematic of schedule C compressor and expandor, level diagrams included

wire tap location with two open-wire pairs entering the cable at that location. Means were provided at this junction for switching suppression filters in or out of the circuit as desired, one filter being supplied for each of the two open-wire pairs.

The observed effectiveness of the suppression filters located at this tap was found to be about 20 decibels (db), a value great enough to permit satisfactory schedule *C* program transmission even under storm conditions. While no tests have been made on schedule *A* performance when a severe electrical storm was centered over one or more of the open-wire taps, it is expected that such suppression will also permit the use of these wider band program facilities during periods of high static noise. To obtain satisfactory year-round program service over *N* systems, it may be necessary to treat each and every open-wire pair at its junction with the cable carrying the *N* pairs.

Type-*N* carrier will provide more economical program circuits than can be obtained with voice frequency facilities, which, though meeting the technical requirements, are inflexible. For example, in planning for schedule *A* program service over such voice facilities, a sufficient number of program pairs must initially be fabricated in the cable, not only to take care of immediate requirements but also to provide for future growth during the life of the cable. In addition, the program pairs must be specially loaded (*B-22* or *B-44*), and, if the toll cable in which these pairs are located is aerial, pilot-wire regulation must be furnished for the associated program amplifiers along the circuit, as well as for the 2-wire and 4-wire message repeaters. This can be an expensive addition when only a small number of voice circuits is involved.

The design of the *N*-carrier-derived schedule *A* program system makes use of all of channel 6 and of a 1-kc band in channel 5 and in channel 7. If there is a paralleling *N* system operating in the same cable, crosstalk which might result from the 3,700-cycle signaling tones of that system, could show up at the receiving schedule *A* terminal as a 3,700-cycle tone effected by the channel 6 upper and lower side bands of 3,700 cycles; a 4,300-cycle tone effected by the channel 5 upper side band, and a 4,300-cycle tone effected by the channel 7 lower side band. The disturbing effect of these tones is of a different nature when several *N* systems are operating in the same cable, in that the 3,700-cycle signaling oscillators of the various *N* systems are not in synchronism and are random in frequency at about the 3,700-cycle point. To add to this randomness, the channel carrier frequencies and the repeater carrier frequencies in the various systems in the cable also differ from each other. If there is also an *ON* system[3] operating in the same cable, crosstalk from one of its carriers could be transmitted through the program terminal and could show up as a 4-kc tone. When more than one *ON* system is operating in the cable, the effect of the 4-kc tones may be somewhat like that of the interference from multiple *N* systems just described. The results of a recent field study of schedule *A* program transmission operating over *N* carrier in a nonquadded cable between Bangor and Presque Isle, Me., showed that there was a tendency for the disturbance from the 3,700-cycle signaling tones of other *N* systems in the same cable to approach resistance noise in character. The values of the total interference from these random tones were found to be acceptable even over such a long nonquadded cable. While there may be marginal cases of *ON* interference,

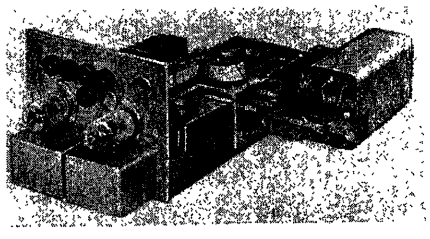

Fig. 2. Schedule C compressor subassembly

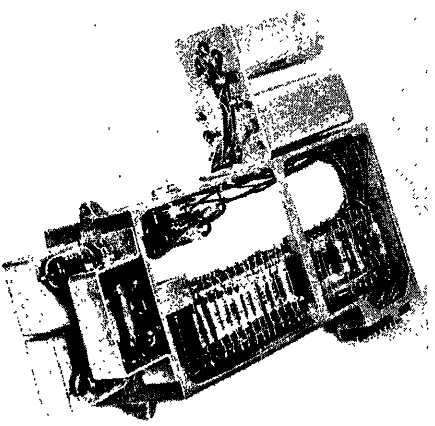

Fig. 3 (left). Schedule C expandor subassembly

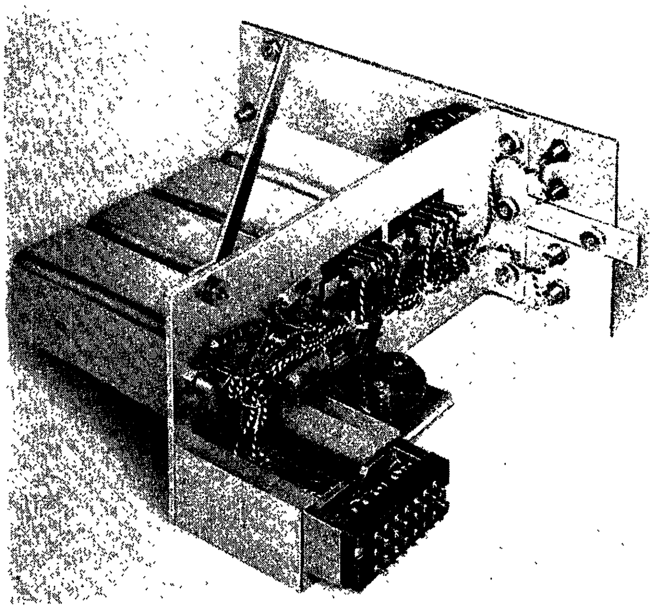

Fig. 5 (right). Schedule A low-frequency subassembly

it is believed that, in general, satisfactory crosstalk values may be realized by the selection of pairs or by a reduction in *ON* carrier level, or both, when a nonquadded cable is employed. The use of quadded toll grade cable should permit the operation of other *ON* or *N* systems in the same cable as schedule *A* program, without any special precautions, and with a reasonable assurance of low levels of disturbance present in the program channels.

Design of Program Channel Units—General

By making certain modifications in the type-*N* terminal channel unit, it is possible to replace any type-*N* message channel unit by a modified unit, and provide schedule *C* program service over that particular channel. One or more schedule *C* program channels may be used on a type *N* system.

To transmit the higher grade schedule *A* program over an *N* system, however, requires more elaborate changes. In the present design three specific message channels of the *N* system are relinquished and are replaced by one schedule *A* program channel. However, one message channel may be recovered by using the space of one of the channel units for the addition of a higher frequency channel unit now under development. Provision is made for the application of only one schedule *A* program circuit to an *N* system. External equalizers, predistorting and restoring networks, and compandor with a wider frequency band are required. All these items are presently available. No modifications of any kind are necessary in the type *N* group units or repeaters for either schedule *C* or *A* program.

Schedule *C* or *D* Program Channel Unit

Like the type-*N* message channel units, the schedule *C* program channel unit consists of a compressor subassembly, an expandor subassembly, and carrier subassemblies. The program compressor and expandor subassemblies are the same for any one of the 12-channel units. The carrier subassembly with its carrier frequency modulating oscillator and band filter is different for each channel unit but is the same for message and program units.

The compressor and expandor subassemblies, however, were considerably modified for program use. Since the program circuits are always operated on a 1-way basis, the 2- or 4-wire terminating equipment was removed and the transmitting low-pass filter and equalizer on the compressor subassembly were modified to extend the band down to 200 cycles and up to 3,500 cycles. An adjustable feature is provided in the high-frequency part of the equalizer to take care of variations that may be present in the over-all circuit. All signaling equipment was removed from the expandor subassembly and the receiving low-pass filter was modified to extend its band to 3,500 cycles.

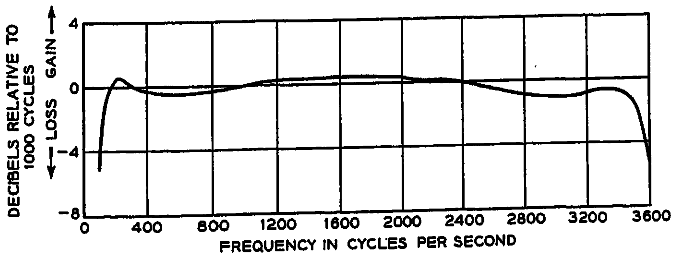

Fig. 4. Typical transmission frequency characteristic of schedule C type-N single link with ten intermediate repeaters

Additional filtering was provided in the plate circuit of the compressor and expandor so that different programs could be transmitted in both directions simultaneously over the same channel unit with negligible crosstalk between them.

A block schematic of the compressor and expandor subassemblies is shown in Fig. 1, and views of the equipment in Figs. 2 and 3. Minor alterations were made in the message unit die castings, and simple brackets were added to accommodate the additional circuit elements.

A typical over-all transmission frequency characteristic for a schedule *C* type-*N* link is shown in Fig. 4. It will be noted that the characteristic is flat within ±1.5 db over the 200- to 3,500-cycle band.

When the internal noise generator provided in the *N* system to mask crosstalk is adjusted to give +33 decibels adjusted of noise on message circuits at the +10 level point, the noise on the schedule *C* program channel at the +8 volume-unit point is well under a reasonable objective for this class of service. The crosstalk between message and program channels or from program-to-program channels is negligible.

The program unit mounts interchangeably with any message unit. To provide program service over a particular channel, it is only necessary to remove the message channel unit from its plug-in

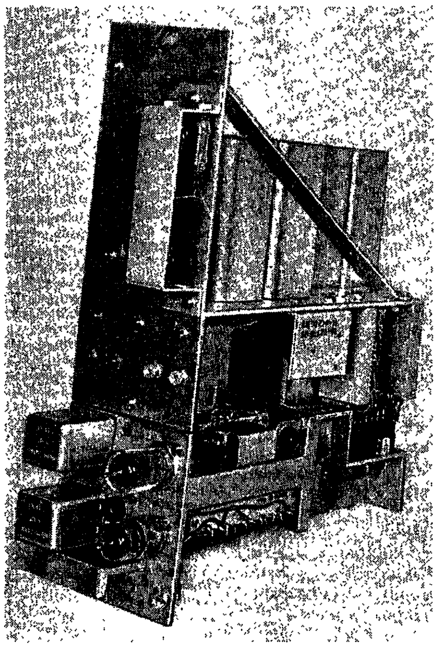

Fig. 6. Schedule A channel unit consisting of low-frequency and carrier subassemblies

socket and replace it by the program unit having the same channel number. If desired, the carrier subassembly may be removed from the message unit and reassembled with the program compressor and expandor subassemblies to form the new program channel unit.

The heater power required for the program channel unit is less than for the message unit but the program unit has a resistance load added so that the total heater battery drain for the program unit is the same as for the message unit. Thus no readjustment of the resistances in the heater battery supply circuit is necessary when changing from message to program units or vice versa.

Schedule *A* or *B* Program Unit

The transmission characteristics of the compressor and expandor of the type-*N* channel unit make them unsuitable for the wider band of the schedule *A* program. Likewise, the 4-kc wide-channel band-pass receiving filter is unsatisfactory for 5-kc transmission. Consequently, more elaborate changes are required to provide schedule *A* program transmission over type-*N* carrier than were required for schedule *C*.

Since the demand for schedule *A* service over type-*N*, initially at least, is expected to be considerably less than that for schedule *C*, arrangements have been made to provide only one 5-kc program channel over a type *N* system. This is obtained by removing message channel units 5, 6, and 7, and by replacing these three units with one program unit having a carrier subassembly similar to channel 6 but with a 5-kc wide-band receiving filter. The program band now occupies a 1-kc portion of both channels 5 and 7 but of course does not interfere with message transmission since those channels have been removed. For regulating purposes the transmitted carrier of channel 6 is increased 5 db in order to maintain the same total transmitted carrier power of the 12 channels as existed when channels 5, 6, and 7 were used for message service. With the channel 6 carrier increased 5 db, the program input to the modulator is increased a corresponding 5 db in order to gain signal-to-noise improvement.

The message compressor and expandor subassemblies are replaced by a single unit consisting of an equalizer and transformers so that the 600-ohm sending and receiving voice frequency program circuits may be properly coupled to the modulator and demodulator circuits on the carrier subassembly. These units are shown in Figs. 5 and 6.

The channel 6 unit is built out to take the same heater load as the corresponding message unit. To avoid the necessity for any readjustment of heater voltage, plates are provided, each of which is equipped with a resistance to take the same heater load as would be taken by a message channel unit 5 or 7. These plates may be plugged into the blank spaces caused by removing channel units 5 and 7. Fig. 7 shows a plate with heater load resistance.

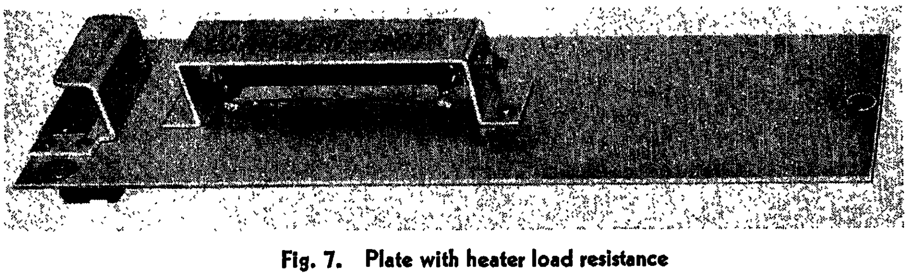

Fig. 7. Plate with heater load resistance

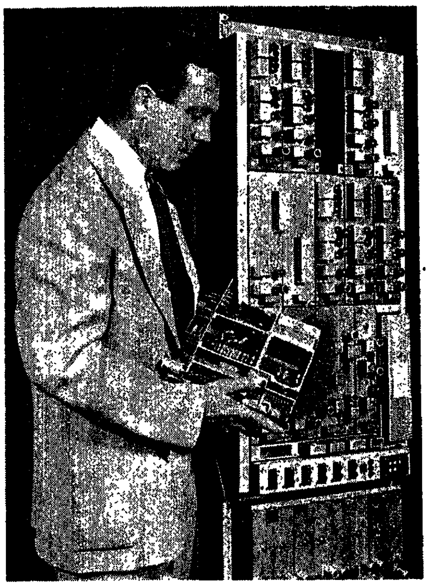

Fig. 8. Type-N terminal equipped with schedule A channel unit and plates. Engineer inspecting schedule C unit

The schedule *A* program unit can of course be readily plugged into the place of the channel 6 message unit. A view of a type-*N* terminal equipped with a schedule *A* channel unit is shown in Fig. 8. The engineer in the photograph is inspecting a schedule *C* channel unit.

The 1*A* compandor is used external to the *N* system to provide part of the improvement in noise and crosstalk performance desired for schedule *A* program. The 1*A* compandor has a range of compression and expansion similar to the type *N* compandor but has a bandwidth suitable for the schedule *A* program.

Further improvement in noise and crosstalk is obtained by the use of the 200-type predistorter and restorer, devices to partially equalize the power of the low and high frequencies at the sending end, and restore them to their normal relationship at the receiving end. A 5-kc low-pass filter is placed at the transmitting end to prevent extraneous frequencies above the program band from causing interference into the adjacent type *N* channels. Equalizers are furnished at the receiving end as required to meet the over-all transmission objective.

A block schematic of the over-all schedule *A* program system, together with a level diagram, is shown in Fig. 9. The circuit is arranged so that different programs can be transmitted simultaneously in the two directions. With the arrangement shown in Fig. 9 it is expected that the transmission will be flat within ±1 db over the band from 100 to 5,000 cycles, as shown in Fig. 10.

It will be noted that by using the channel 6 carrier frequency for the program-modulating frequency, any crosstalk from carriers of other *N* systems in the same cable either falls on the program carrier or

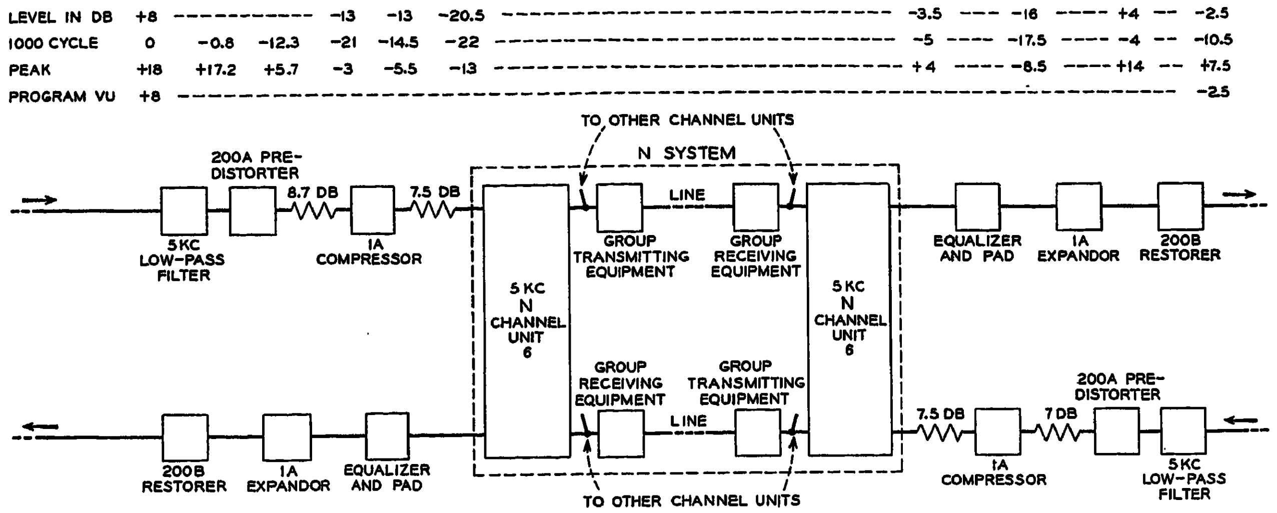

Fig. 9 (above). Block schematic of schedule A program system

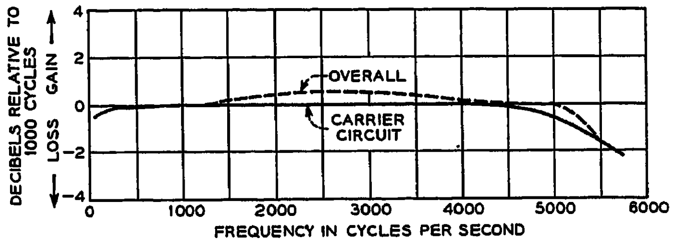
Fig. 10 (right). Typical transmission frequency characteristic of schedule A type-N single link. Over-all characteristic includes external equalizers, predistorting and restoring networks, compandor, and 5-kc low-pass filter



falls outside the program band. A rearrangement of the carrier modulator of the schedule *A* program system, so as to employ only two channels of band space instead of three in the *N* system, would have introduced more co-ordination problems with the carriers of the other *N* systems.

Reversal Arrangements for Schedule *A* Program

Although program over *N* carrier is usually limited to the last one or two links of a program network, provision for reversing must be considered, since all or part of the particular program may originate at the end of the network, for example, when the President of the United States on tour broadcasts from his train while it is held on a siding at some small locality. Circuit arrangements to provide for this reversing are now under development. With these arrangements, only one direction of transmission of the program at a time is used, the direction at any time being controlled by the customer or telephone company as required.

The relay-reversing arrangements for the voice frequency part of the circuit are similar to those used for other standard program circuits. To reverse the carrier part of the program circuit, a new unit is being designed to be used in place of channel 5. This unit will have a channel 5 carrier oscillator of somewhat lower amplitude than the normal message carrier so that the transmitted tone will not appreciably affect circuit regulation. This new channel 5 carrier oscillator will provide the transmitted reversal tone under control of the transmitting directional setup. Transmission of the channel 5 carrier oscillator tone over the circuit conditions the circuit for transmission in that direction. A crystal pick-off filter and receiving circuit are used to identify the tone sent by the distant end. The receiving channel regulator is eliminated to avoid large increases in receiving again with possible false indications when the reversing tone is removed at the sending end. The channel 5 reversing unit is built out to take the same heater load as the corresponding message unit and can readily be plugged into the channel 5 space.

Typical Bell System Application

A number of schedule *C* and *D* program systems are already in operation. It is expected that by the end of 1953 schedule *A* and *B* program transmission will be operating over *N* carrier systems between Joplin and Springfield, Mo.; Santa Ana and Los Angeles, Calif.; and Duluth and Minneapolis, Minn.

Use of Radio and Radar in the Petroleum Industry

W. M. RUST, JR.
NONMEMBER AIEE

THE Oil and Gas Division of the Department of the Interior requested the National Petroleum Council to appoint a committee to make a study and report on the radio and radar usage being made by the petroleum industry. This paper is based on the report prepared by the committee, under the chairmanship of F. W. Littell.

History of the Use of Radio in the Petroleum Industry

The first recorded use of radio in the petroleum industry was on board tank ships and was concerned primarily with safety of life at sea. In 1925, another use was found for radio in the petroleum industry by geophysical crews engaged in prospecting for petroleum deposits.

In 1928, needs for radio communication in the industry led to the submission of applications to the Federal Radio Commission (the predecessor to the Federal Communications Commission) for radio licenses by several oil companies. The Commission ruled at that time that radio channels could not be assigned for private use, but suggested that it would be in order for the companies interested to form a public service corporation to accomplish the desired result. Accordingly, in January 1929, the Petroleum Communications Corporation, later renamed the Western Radio Telegraph Company, was formed.

In 1932, a few oil companies began to use radio in the Special Emergency Radio Service on a very limited basis in the swamps of Louisiana for communications between drilling rigs and base offices. In 1938, a new class of station, "provisional," was established by the Federal Communications Commission under their rules governing "Miscellaneous Radio Services." A number of petroleum companies qualified for this service, because its primary use was for operations involving the safety of life and property. By 1941, considerable interest was being evidenced in the possibilities of radio usage throughout the industry, but World War II prevented any expansion of radio installations.

Because of the technical advances made in the radio art, under pressure of military necessity during the war, entire new portions of the frequency spectrum became usable, and the whole concept of radio usage changed.

In recognition of these new developments, the Federal Communications Commission, in keeping with obligations to study new uses of radio, decided to broaden the field of users to include several categories heretofore denied the use of radio.

In August 1946, the Commission established the Utility Radio Service, which included, among others, the petroleum-pipeline class of station. However, other petroleum industry radio operations, except geophysical, were still classed as "experimental."

Realizing the importance of radio as an operating tool for all branches of the industry, the Petroleum Industry Electrical Association petitioned the Commission in 1947 for the establishment of a "New Radio Service Governing Radio Stations Used in Petroleum Industry Production and Pipeline Operations and Promulgation of Rules and Regulations Therefor." Steps were taken to interest the American Petroleum Institute in the formation of a radio committee which could encompass all phases of the industry's varied operations in a recognized association which was truly representative of the industry as a whole. The newly created Central Committee on Radio Facilities of the American Petroleum Institute immediately concerned itself with the most pressing problem, that of finalizing the establishment of the Petroleum Radio Service.

Finally, on May 3, 1949, the Commission announced the adoption of its Industrial Radio Service Rules in final form, to become effective July 1, 1949. Subpart *G* of part 11, "Rules Governing Industrial Radio Services," covered "Petroleum Radio Service" and included all of the major target goals contained in the original petition for the service.

Upon establishment of this new service, another problem, that of co-ordination of frequencies assigned to the service, became of paramount importance. The result was the formation of the National Petroleum Radio Frequency Co-ordinating Association. In addition to co-ordinating radio problems among petroleum users, this association maintains close contact with the representatives of the other users in the Industrial Radio Services and co-operates with them on all matters of mutual interest.

Radio in Geophysics

The nation's supply of petroleum can be maintained only by a vigorous exploration program. A vital phase of this program is exploration geophysics. Radio facilities are essential auxiliaries in exploration geophysics, as they are in any operation where the transmission of information of any kind is of vital importance. While, in general, they are but one link in the rather diverse instrumentation that makes up a geophysical exploration unit, in certain cases they are a primary link.

Just as oil or gas might be collected in an inverted bowl held over water, so the oil and gas content of a permeable rock stratum will gravitationally segregate and be trapped at the top of a closed fold in the stratum, provided that the overlying rock is effectively impermeable. The location and delineation of such features is the ultimate goal of geophysical exploration.

It is self-evident that any geophysical technique must be based on distinguishable variations in the physical characteristics or properties of the subsurface rocks. They vary in:

1. Density;
2. Magnetic properties;
3. Elastic characteristics;
4. Electrical properties.

Electrical methods are of considerable importance in mineral exploration, but have very limited application to date in petroleum exploration.

The operational procedure based on density variations comprises nothing more than the transportation of a suitable gravity meter from point to point over the area to be investigated. As in the case of gravity measurements, the field procedure based on variations in magnetic properties comprises nothing more than the taking of precise magnetic measurements from point to point over the area under investigation. Airborne magnetometer operations are unique in geophysical oper-

Paper 53-381, recommended by the AIEE Radio Communications Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2-6, 1953. Manuscript submitted June 22, 1953; made available for printing July 29, 1953.

W. M. RUST, JR., is with the Humble Oil and Refining Company, Houston, Texas.

ations in that the necessary measurements are made in transit. Herein, of course, lies the particular advantage of this reconnaissance method, since the required magnetic data are collected at a speed determined only by the practical limitations on the speed of the aircraft, and with no limitations imposed by the nature of the terrain.

The seismic method makes use of differences in elastic properties of rocks. First of all, the seismic wave must be generated. This comprises the initiation of a shockwave at or near the surface of the ground by the use of a suitable explosive charge. An essential element in the method is the transmission of the shot instant so that it may be recorded on the same record as the seismic events.

The recording truck carries all of the instruments required for the recording of the seismic events picked up by suitable geophones or seismic detectors comprising the receiving array. Supplementing this equipment are, of course, the necessary communication facilities.

Communication equipment is necessary, especially for the transmission of the shot moment, since the useful information on any seismic record is the time interval between the shot and the arrival of reflected or refracted events. The desired timing accuracy is on the order of 0.001 second; hence, good recording reliability is essential. Voice communication is also necessary to co-ordinate operations between recorder and shooter which may involve distances of a few thousand feet up to ten or twelve miles, depending upon the seismic technique in use.

Radio facilities are required for geophysical operations primarily for three purposes. The first is the co-ordination of activities, including safety measures. The second is the transmission of special data. The third is the determination of position by radiolocation methods. The extent to which a specific geophysical crew utilizes radio varies widely with the nature of the geophysical technique employed and with the type of terrain covered. Radiolocation is the newest, but by no means the least important. It is fair to say that airborne and offshore operations are practical only when radiolocation techniques are employed.

Use of Radio in Production Operations

Petroleum is useful only when it has been drilled and produced. It has long been recognized that efficient communications are essential in drilling and production operations, because of the inherent hazards of such operations. Production is frequently found in remote regions, far removed from any existing communications facilities.

As an example, the last few years have seen substantial developments being conducted in the marshes of Louisiana, offshore in the Gulf of Mexico, and in remote sections of Montana, Wyoming, South Dakota, and elsewhere. Communication with drilling locations in these areas is possible only through the use of automobiles, boats, and radio. Obviously, the use of automobiles and boats as a means of communication in these areas is so slow as to be completely useless in emergencies.

In an emergency, it may take many hours for the toolpusher to drive to the nearest telephone and get a call through to his central office or to a point where help is available. During these lost hours untold damage may be done to the well and the drilling equipment on the well. If the rig is equipped with radio, immediate contact can be established and the loss prevented or lessened. The same conditions exist where drilling is being conducted offshore. In these offshore operations, the personnel on the rig can be kept advised at all times about weather conditions, and, in the event of severe storms or hurricanes, warnings can be sent to the drilling site in time to allow for proper precautions to be taken before the blow strikes. This is possible only where radio communication is available.

Radio contact with drilling rigs has also proved valuable from another angle. Very often data from the well make it essential to change the drilling procedure and, in many cases, because of communication difficulties, the instructions do not reach the rig until after it is too late to make the change. No doubt more than one well has been ruined because of the failure to get proper instructions to the rig in time. The use of radio greatly reduces this hazard.

Based on the actual experiences of many of the companies now using radio, it has been conclusively demonstrated that radio is the only practical solution to many of the communication problems of producing operations.

In addition to those companies actually engaged in drilling and production operations, there are many hundreds of companies engaged in supplying these companies with vital materials and services. For the most part, these companies serve the drilling companies and oil companies exclusively, and they are, therefore, considered part of the petroleum industry, even though they do not actually hold the leases or produce the oil.

These companies are engaged in a multitude of activities which are as vital to the production of petroleum as the work done by the individual oil companies. Because these service companies are so closely interwoven into the over-all petroleum operation, and because so many petroleum operations depend on the prompt supply of needed materials or services, they began using radio almost as soon as the production and drilling companies. Without minimizing the value of radio the drilling or production company, the service company often has an even greater need for radio communication.

Indicative of the size of the radio operations of such companies is the system operated by an oil-well cementing company. This 2-way radio system is one of the largest privately owned 2-way communication systems in the world. This system, consisting of dozens of base stations and several hundred mobile units, stretches from near the Canadian border to the Mexican border.

Pipeline Use of Radio

The pipeline industry is not a new one; therefore, the communications problems of the pipeline industry are not new, though they have changed greatly since the first short low-pressure crude-oil pipelines were built. Around the turn of the century, when pipelines were still new but useful adjuncts to the young oil industry, private communication systems for pipelines were necessary simply because public communications were not available to the remotely located pump stations. As the oil industry grew, and with the discovery of oil in Oklahoma, California, Louisiana, and Texas, pipelines reached out into even less densely settled areas, and in many of these, the communication facilities erected by the pipelines were the only facilities available to anyone. Generally, these conditions do not exist today. However, it is still the usual practice of the pipeline industry to own and operate its own communications facilities, since even today many of the pump stations are remote and because reliable full-time communication among all points is an operating necessity.

To understand the communications problems of pipelines, it is necessary to realize the magnitude of the shipping problem handled by a large line. A 250,000-barrel-per-day line 1,000 miles long moves approximately 37,500 tons per day through the line, for a total movement of product of 37,500,000 ton-miles per day. This is equivalent to a railroad keeping eighty 60-car trains in constant service.

On a tight line, with no intervening tankage anywhere on the line, any interruption to the flow at any point will be felt at every other point. If the flow is not reduced, the pressure in the line will continue to rise until the line is split, or pump units start breaking down. From this it can be seen that a tight line must have available a communication system as reliable as can be had and flexible enough to afford instant communication among the pump station engineers at all times. In addition to the constant interchange of operational information among pump stations, the dispatcher must be kept informed as to the passing of the head end and tail end of the various batches of oil in order that he can keep his dispatching orders corrected.

A communication requirement peculiar to pipelining is the keeping of the "line balance." The quantity being pumped into the line by the first station should equal the amount being delivered by the line at its terminus. When the balance shows "short" for two or three checks in succession, it is reasonable to suspect that the oil is being lost through leakage. Considering that a 22-inch line can deliver up to 10,000 gallons of crude oil per minute through a split, the essentiality of good communications is seen immediately.

Equally as important as the oil pipelines are the natural gas pipelines. Since gas is a fuel that is not readily adaptable to conventional storage methods, controlled stream flow must be utilized to accommodate varying demand. Pipeline pressure as well as pumping rate must be skillfully controlled to insure deliverability consistent with public requirements. The most important factor in controlled flow is a reliable communication system. Skilled dispatchers must watch demand along the system, varying gas intake from numerous well heads to accommodate these fluctuations, and in many instances, interrupting supply to less critical users in order to prevent hardships developing in areas where rapid temperature drops suddenly increase demands. Rapid order changes are necessary from the dispatching experts to handle these situations.

In some pipeline systems, the dispatching expert receives the pertinent telemetered information as to pressures, flow, and input quantities into the pipeline, delivered quantities from the pipeline to consumers, and other data, via microwave into headquarters. With this system of operation, the dispatcher continuously observes line conditions and, when system changes are required, either uses remote-control functions over the microwave facilities to effect the desired changes, or else utilizes voice channels to issue the required orders.

The far flung activities of a gas or oil pipeline result in very-high frequency (VHF) communications problems that can not be handled satisfactorily without supplementing the relatively short range of the VHF equipment with other auxiliary communications facilities without such range restrictions. It is not unusual to require that maintenance crews a hundred miles or so apart be co-ordinated for maximum efficiency and safety.

The petroleum industry has adopted microwave, one of the fastest growing communications mediums ever to be developed in this country, as a solution to this and other long-range communication problems. Many such systems are in operation and more are being installed.

Utilization of those frequency bands which the Federal Communications Commission has made available for microwave systems on a developmental basis has been great in the petroleum service and, in particular, in the long-haul natural-gas pipelines. At present, some 22 companies have approximately 15,000 miles in operation. Since these systems have from 8 to 24 circuits each, the total circuit miles are many times this figure.

In addition to the communications flexibility offered by microwaves, the simple addition of the microwave system's multichannel capabilities to the tools available to the pipeline industry is destined to change the industry more than anything since the introduction of the electric centrifugal pumping unit. Once a microwave system is installed, there are a very large number of signaling channels available for supervisory control and remote indicating applications which do not substantially affect the ability of the system to carry communications signals. This added capability of microwave systems, which is available at a very low cost after the system has been installed, is such as to make the completely remote operation of pump stations economically feasible for the first time.

Shipboard Use of Radio

While pipelines constitute the backbone of the petroleum transportation system, ships and barges also perform a vital service in moving petroleum economically. Marine operators moving petroleum products have been very progressive in taking advantage of the aids offered through radar and radio communication. The character of their cargo has made such help especially useful to them.

The petroleum tankers on the high seas use radio and radar in the same manner as other vessels, and are distinguished only by their greater utilization of these aids. They have proved to be an invaluable part of the tankers' equipment.

If possible, radar and radio are even more important to the operator on inland waters. The importance of the radiotelephone to the inland waterways transportation industry may be visualized by reference to an example of its practical use. The personnel of inland waterway vessels usually make soundings of all dangerous crossings and locations on the rivers, and these findings can be relayed to other vessels approaching such channels. Likewise, channel information furnished by the United States Corps of Engineers and the United States Coast Guard can be passed on by radiotelephone to vessels immediately upon its becoming available. This is a highly essential function when it is realized that river channels do not remain static because of the continuous shifting of sandbars and consequent channel changes. The importance of radar in this service is indicated by the existence of more than 300 radar-equipped vessels on inland waterways.

Petroleum Radio Relay Stations

The petroleum industry has many applications of radio where communications are needed over distances greater than can be covered directly from one fixed or base station to another fixed, base, or mobile station. In these cases, relay stations must be used to extend the range to accomplish the desired results. Very often mobile stations must communicate with each other, but they can not do so directly because of the terrain or the distance involved.

A pipeline approximately 185 miles long through rough mountainous country has been operated for several years with a VHF radio-relay system. This pipeline goes through territory where it would be practically impossible to maintain a wire-telephone line during the heavy snow season. The radio-relay system provides adequate communication with the mobile units not only along the pipeline but also traveling along the roads remote from the pipeline. Repair trucks and snow cats can keep in touch by means of radio when they are out in hazardous weather conditions, and they can call for material or help of any kind when needed. Maintenance foremen can reach pump stations promptly to restore the line to service after repairs have necessitated its being shut down. This greatly assists in maintaining the flow of oil essential to the industrial and governmental activities served by the pipeline. No other system of communication would have served this pipeline as well, and without it the hazards to life and property would be far greater than now exist.

Refinery Use of Radio

The use of radio communication within the refineries of the oil industry has grown with phenomenal speed in the last few years. At first thought, one might conclude that even the larger refineries would find point-to-point wire communications adequate for their needs. An average sized refinery of 100,000-barrel-per-day capacity will encompass an area of 1,000 acres, and be manned by 1,500 to 2,000 people. To carry out their duties most of these people must be in motion between unspecified locations. This presents a communication problem that is unique.

The largest section of manpower that benefits by mobile radio is that involved in maintenance and repair. The maintenance of plant equipment in safe and operable condition is the job of over half the manpower in a refinery. Every truck, every car, essentially every vehicle, is in constant 2-way communication with a central dispatcher.

A typical network for maintenance and construction in an average refinery with 100,000-barrel-per-day processing capacity would consist of a base station and approximately 100 mobile units. These mobile units would be located in supervisors' cars, craft foremen's pickup trucks, transportation department trucks, and straddle carriers. Actual statistics from existing systems show that on such a system the total number of messages handled in an 8-hour day will be between 800 and 900. During peak operating periods, the call density will reach one call every 30 seconds.

Regardless of how well planned a refinery may be, regardless of the intricate measures taken to avoid disaster, there comes the day when a serious emergency occurs. Point-to-point communications on what well may be a rapidly changing field are needed with instant dispatch. To meet such emergencies, the users of refinery radio have worked out systems and procedures in which the radio network is an essential part.

Use of Radio in Marketing Operations

Radio is being put to extensive and rapidly increasing use in the marketing and distribution of petroleum products. This use of radio in marketing operations has developed almost entirely since the establishment of the Highway Truck Radio Service on July 1, 1949. Prior to that date, radio for highway trucks was licensed on an experimental basis only and was in extremely limited use.

One of the largest users of radio in the Highway Truck Radio Service is the Liquified Petroleum Gas Communications Association. This association is comprised of 38 liquified petroleum fuel dealers in the state of Arkansas who have banded together for the sole purpose of providing a radio-communication service to the members. The association holds authorizations from the Federal Communications Commission for 38 base stations and 200 mobile units.

Petroleum Use of Radar and Other Radiolocation Methods

The petroleum industry adapted radar and shoran, which were developed by the military forces during World War II, to their own use immediately at the close of the war. They have provided modifications of both these two systems and have introduced a third system, the phase-comparison system, that is peculiarly suited to their specific needs.

The petroleum industry has made four diverse uses of radar in its operations. These are:

1. As a navigation device and as an anti-collision device on board the tankers of the petroleum industry's fleet;
2. As a location method for determining the position of the geophysical survey boats on the Continental Shelf off the coasts of the United States;
3. As a harbor surveillance device for guiding the boats for marine drilling operations into and out of coastal harbors during periods of low visibility resulting from fog;
4. As a device for detecting changes in weather, such as line squalls or hurricanes.

The second type of radiolocation device used in the petroleum industry has been Shoran. Shoran was developed for the guidance of aircraft engaged in precision bombing and is particularly applicable to aeronautical use. It has been used in the petroleum industry in connection with geophysical exploration, either the airborne magnetometer or the waterborne operations on the Continental Shelf. In many of the geophysical operations on the Continental Shelf, distances of 100 miles or more are involved. This precludes the possibility of using pulse type radiolocation methods for such surveying purposes, except for airborne operations, since all practical pulse systems operate in the frequency bands where propagation is restricted to line-of-sight distances. To overcome this limitation, the petroleum industry has employed a third type of radiolocation method, the phase comparison method. This method uses a continuous wave signal at a medium frequency which can be transmitted far beyond the horizon.

National Petroleum Radio Frequency Coordinating Association

The National Petroleum Radio Frequency Coordinating Association was organized in Washington, D. C., May 16, 1949. A tabulation of radio stations eligible for operation in the Petroleum Radio Service as of June, 1949, listed approximately 5,000 stations.

During the year June, 1949, to June, 1950, approximately 360 users requested frequency recommendations covering 10,450 transmitters. These were for all phases of petroleum operations, including the rapidly expanding products and natural-gas pipeline systems.

During the year 1950 to 1951, the number of users increased to a total of 438 and the number of recommendations to 15,603. This growth continued so that by June 30, 1952, there were 553 users with recommendations for 21,400 transmitters.

Forty-seven per cent of the petroleum radio stations are concentrated in Texas, Louisiana, Arkansas, and Mississippi. A belt approximately 75 miles deep along the Texas and Louisiana Gulf Coast contains the major portion of this concentration. The Petroleum Radio Service has reached the point of saturation in many sections of this area, with as many as 16 users operating co-channel, and with four of these within the same immediate area. This situation is not confined to any one band or group of frequencies. Technical improvements in equipment design have made practical adjacent channel installations within the same area; otherwise the limited number of frequencies in the Petroleum Radio Service would not have accommodated the large number of users.

At the annual meeting of the National Petroleum Radio Frequency Coordinating Association in Washington, D. C., June 7, 1951, a special committee on 20-kc equipment was appointed to conduct tests to determine whether the state of development of mobile radio communication equipment was such that operation on adjacent channels, with 20 kc center separation, is feasible in the bands from 25 to 50 megacycles.

It was concluded from these tests that

with proper adjustment of the center frequency and maximum deviation of the transmitters, it will be possible to operate adjacent channels with 20-kc separation with commercially available equipment, with practical geographical spacings between transmitters. At the present time, the petroleum industry has one system installed and working on a 20-kc basis. The equipment is working quite satisfactorily, and additional systems are in the process of being installed on frequencies between existing channels.

Continued expansion of petroleum systems, as well as installations of new systems, can be expected. In order to accommodate these, particularly in the oil-producing areas of the Gulf Coast, both channel-splitting and time-sharing must be utilized. Even so, only the fullest co-operation among users can prevent unbearable degradation of the service.

Radio has truly become one of the indispensable tools in the petroleum industry's never-ceasing struggle to supply the products that make possible our industrial civilization.

Microwave as Applied to Railroad Operation in the Gulf Coast Area

L. R. THOMAS
MEMBER AIEE

THE Santa Fe railroad has installed a microwave system between Galveston and Beaumont, Texas. The installation is being used to supplement existing wire-line communication and to obtain technical information regarding the operation and reliability of a microwave radio-relay system in this area. It was felt at the time the decision was made to install the system that, if microwave radio relay could be made to operate reliably in this area, it could be made to provide reliable service on other parts of the railroad where the terrain and atmospheric conditions would be more favorable to its use.

Fig. 1 shows a map of a part of the Santa Fe's facilities in the Gulf area, indicating that prior to the installation of the microwave system it was necessary for telephone and telegraph circuits to be routed from Galveston to Beaumont, Texas, via Somerville and Silsbee, a distance of 315 miles. From this point they extend on to Longview, Texas, and Oakdale, Louisiana.

The installation of the microwave-relay system on a direct route from Galveston to Beaumont, a distance of approximately 70 miles, makes it possible to pick up the circuits from Somerville east at Beaumont and thus release the physical pairs between Galveston and Somerville for other service. This type of installation also reduces the transmission losses experienced in long physical circuits and provides more satisfactory overall communication from Galveston to the field.

The microwave equipment was supplied by the Philco Company, and consists of their type *CLR-6* terminal and repeaters. There are two terminals and three repeaters in this installation, as shown by Fig. 2, which is an overall diagram of the system showing the antenna heights, distance between repeaters and terminals and the type of antennas used. The equipment operates in the 6,700-megacycle range with the transmitters providing a power output of approximately one watt and receivers adjusted to provide an operating sensitivity of −108 decibels referred to 1 watt.

The multiplexing equipment used with this installation was also supplied by the Philco Company and is pulse-amplitude-modulated equipment capable of providing a total of 24 telephone channels. In this particular installation, equipment to provide only eight telephone channels was used.

Fig. 3 shows the service which is operated over the telephone channels. The first of these is a service channel which is dropped out and inserted at each repeater point to provide communication with field-service personnel. This channel also carries the fault tone signals from the terminal at Beaumont and the three repeaters to the control terminal at Galveston. The second channel is used to pick up the dispatcher's telephone circuit which operates between Somerville, Longview, and Beaumont. The third channel is connected to a party-line telephone to Somerville. The fourth channel is connected to a party-line telephone to Longview. The fifth and sixth channels are used as trunk telephones between Galveston and Beaumont, the seventh is idle, and the eighth carries six channels of frequency-modulated telegraph carrier. This channel is capable of carrying up to 14 channels of telegraph carrier if needed.

The ringing on the trunk circuits is accomplished by means of Western Electric 1000/20-cycle ring oscillators. The

Paper 53-382, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2–6, 1953. Manuscript submitted May 14, 1953; made available for printing August 17, 1953.

L. R. THOMAS is with The Atchison, Topeka and Santa Fe Railway Company, Chicago, Ill.

The author wishes to acknowledge the assistance of R. B. Grantham and W. H. Veerman, assistant engineers, who performed the field work in connection with the Santa Fe microwave installation.

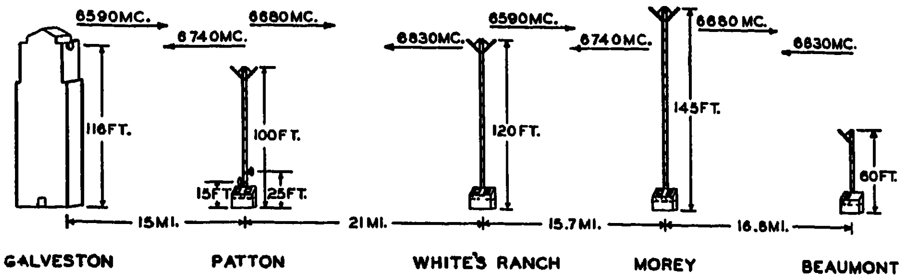

Fig. 2. Santa Fe microwave system, Galveston to Beaumont

ringing on the dispatcher's and party-line telephones is $3\frac{1}{2}$-cycle selector ringing from Beaumont, controlled from Galveston over telegraph-carrier channels. The ring keys at Galveston operate the send relay on a telegraph-carrier channel, and the receive relay on the telegraph-carrier channel in turn operates the relays of the ring case at Beaumont to provide battery to the physical circuits at that point.

The operators contact the dispatcher by means of his loud speaker in the normal manner. The party-line telephones on the other hand have 20-cycle ringing from the field by means of hand generators. These operate a 20-cycle relay at Beaumont which actuates the send relay of a telegraph carrier channel, and in turn the telegraph-carrier receive relay operates a telephone-type relay at Galveston which applies 20 cycles to the private branch exchange drop at that point. The other telegraph-carrier channels are used either for printer circuit or to pick up Morse wires for termination in the Galveston relay office.

The pulse-amplitude-modulated multiplexing equipment has presented a few problems which can be expected with a new type of equipment, but to date these problems have in most cases been eliminated. However, the signal-to-noise ratio which can be obtained from this type of equipment is not as good as that which can be obtained from land-line carrier circuits. This is to a large extent due to the signal-to-noise ratio of the microwave system itself and is a problem which no doubt will be taken care of in new equipment.

The trouble experienced with the *CLR-6* microwave equipment has reached the stage where it can be said to be of a more or less minor nature. However, it is only fair to point out that the degree of maintenance required to keep a system of this kind in first-class operating condition is rather high. The microwave equipment by its very nature is not a simple device. Therefore, it should be pointed out to those who are contemplating the installation of a microwave system that they should take into consideration the need for more highly trained personnel than is required to maintain a wire-line communication plant. Skilled personnel can be obtained or existing employees trained to satisfactorily maintain the equipment.

When this system was installed it was located in the area where the greatest difficulty could be expected from a standpoint of propagation. Problems were anticipated because of the large bodies of water to be crossed as well as the high moisture content of the air in the Gulf area. Referring to Fig. 4, the path from Beaumont to Morey, a distance of 16.8 miles, consists of relatively dry land with large areas covered with trees and buildings. Very little propagation trouble has been experienced in this area. The exception to this consists of the fades which are encountered when there are rapid changes in temperature or in the moisture content of the air. The fades are normally not of sufficient depth to interrupt service. However, outages do occur at infrequent intervals.

The tower at Beaumont is 60 feet high while the one at Morey is 145 feet. In both cases apparently the trees act as zonal screens which tend to reduce the intensity of fades caused by reflection from the surface of the land between these two points.

Referring to Fig. 5, the section between Morey and White's Ranch, a distance of 15.7 miles, is relatively dry land and there is little if anything in the path except a few trees and ranch buildings. There are also rice farms in this area which are flooded at certain times of the year. The tower at Morey is 145 feet and the tower at White's Ranch is 120 feet. Some rather severe fades have been experienced in this section. The fades are of the type caused by cancellations due to reflection as well as those caused by moisture fronts such as fog banks.

The section between White's Ranch and Patton, Fig. 6, a distance of 21 miles is over rice farms, salt water swamps, and a portion of Galveston Bay. The tower height at White's Ranch is 120 feet and at Patton 100 feet. However, the reflector on top of the tower at Patton is not being used due to severe fading conditions. The parabola employed in this section is located at a point 25 feet above the base of the tower. Comparative tests made with receivers on both the high and the low antenna at Patton indicated such severe fading conditions with the high antennas that satisfactcry service could not be obtained. This fading was apparently due to the changing moisture

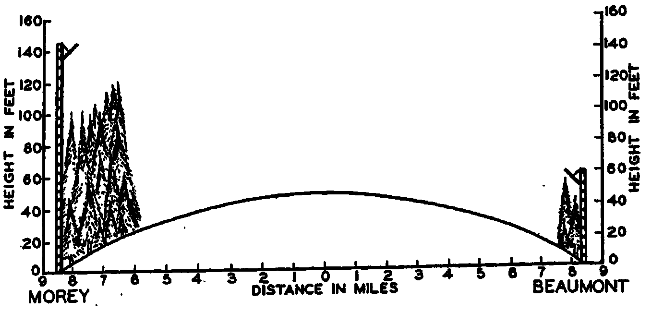

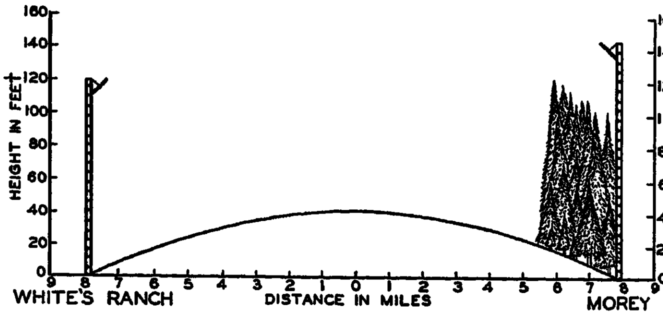

Fig. 5. Microwave link, White's Ranch to Morey

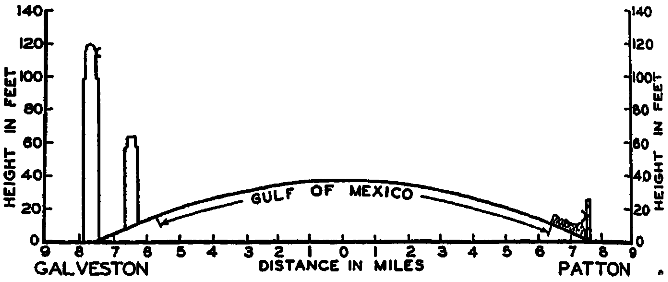

Fig. 7. Microwave link, Galveston to Patton

content of the air over the water and swampy land, as well as some instances of temperature inversion. The characteristics of the fades indicated surface reflection and multipath transmissions resulting in a slight increase in signal, followed by almost a complete cancellation. These fades repeated very rapidly and, in some cases, to the extent that they appeared on the recording voltmeter in a very broad pattern which might be termed "painting." With the low antenna, there was very little fading of this nature. However, there are conditions where the signal gradually decreases to a point of outage, staying out for a period of time dependent upon weather conditions, and then gradually returning to full strength.

The last section, Fig. 7, between Patton and Galveston, a distance of 15 miles over the Gulf of Mexico, has tower heights at Patton of 100 feet and at Galveston 116 feet. In the Patton-Galveston section, the same general condition exists as that between Patton and White's Ranch, and the reflector on top of the tower at Patton is likewise not being used. The parabola is located at a point 15 feet above the base of the tower.

At the time the original installation was made, it was decided to work from parabolas inside of the buildings to passive reflectors on top of towers at all locations, with the exception of Galveston, where the parabola was located on the side of the office building. When severe fading between Galveston and Patton became evident, some action had to be taken in order to obtain satisfactory operation. Several tests were made at Patton with the parabola located at different heights on the tower and recordings were made of the radio-frequency signal strength. Final decision was made to locate the parabola on the tower at a height of 15 feet from the ground, working toward Galveston. This establishes a high-low combination of antennas which changes the point of reflection from the surface of the water approximately midway between the two antennas to a point on the surface of the promontory almost at the base of the Patton tower. This arrangement of antennas practically eliminated the fading problems in this section.

When similar difficulty was experienced in the Patton to White's Ranch section, tests were made over long periods of time with different antenna heights in an effort to achieve the same results as were obtained between Galveston and Patton. To date, the most satisfactory performance has been achieved with the parabola at Patton mounted on the tower at a point approximately 25 feet above the ground. This location gives very satisfactory propagation results during practically all types of weather conditions except fog. During fog conditions, the signal is attenuated to a point where service is disrupted for long periods of time.

Propagation tests covering approximately 2 years indicate that on this system two basic types of fading conditions are generally encountered. One of these consists of a high-maximum low-minimum fade as shown in Fig. 8. This type of fading takes place during periods of temperature inversion or changes in humidity which tend to change the index of refraction, thus changing the path length over which the direct and reflected signals pass. Where the length of the direct signal path in relation to the reflected signal path changes by as much as 1/2 wave length, the receive signals present at the antenna may change from an in-phase to an out-of-phase condition, thereby increasing and decreasing the resultant signal strength. These conditions exist in the Gulf area when winds come down from the North blowing the moisture normally present out to sea, and dropping the temperature sometimes as much as 20 degrees or more in a matter of a few minutes. They also exist during periods where the ambient temperature and the dew-point temperature become the same. Under such conditions condensation takes place and the moisture content of the air increases. This occurs almost every night when there are no storm or fog conditions existing to bring about more violent changes.

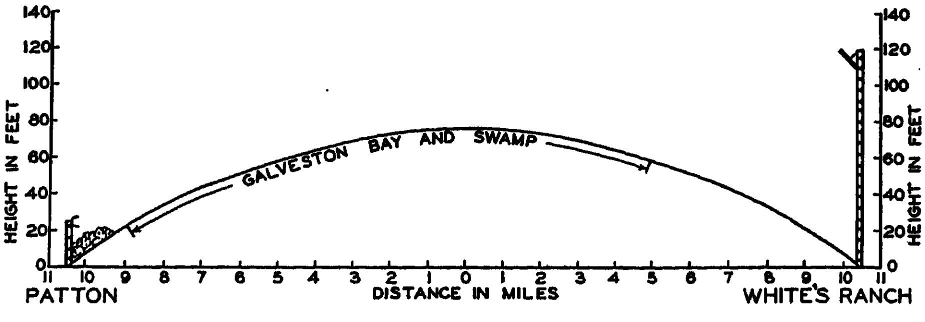

Fig. 6. Microwave link, Patton to White's Ranch

It was noted, with high antennas at both ends of the path, that the high-maximum low-minimum type of fades were more frequent and severe in the Patton to White's Ranch and Galveston to Patton hops than those experienced in other sections. As a result of these tests, it appears that the use of high antennas on paths over water is impractical. The use of the high-low antenna system, however, greatly reduced this type of difficulty, particularly over the 15-mile path between Galveston and Patton. Apparently this is due to the existing antenna height at Galveston being such that the point of reflection of the interfering signal is transferred from water to land and is very close to the base of the tower at Patton. When a high antenna is worked against a low antenna, and the combination of antenna heights and distance separating them is such that the point of reflection of the main beam is at the base of the tower of the low an-

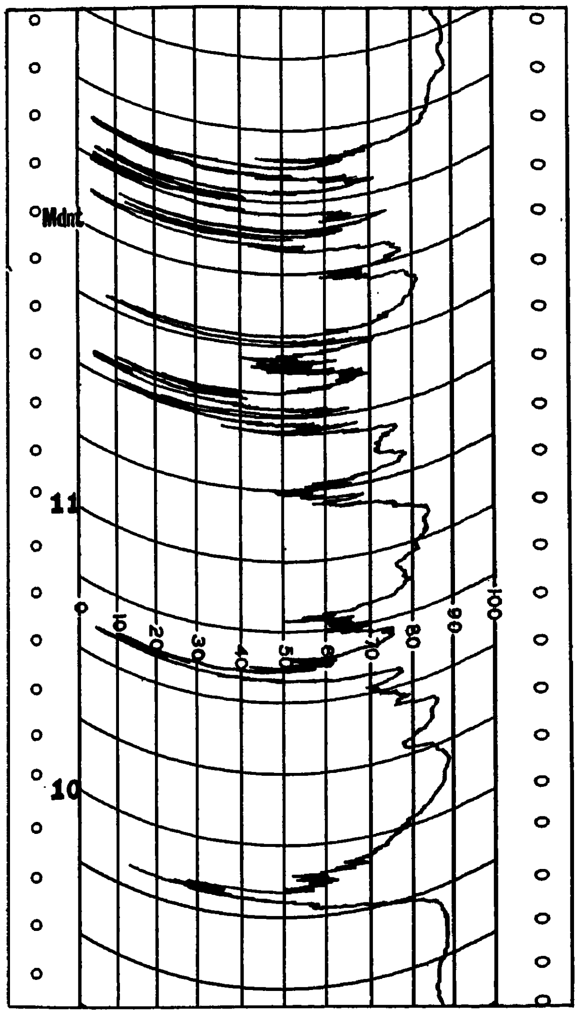

Fig. 8 (left). High-maximum low-minimum type fade

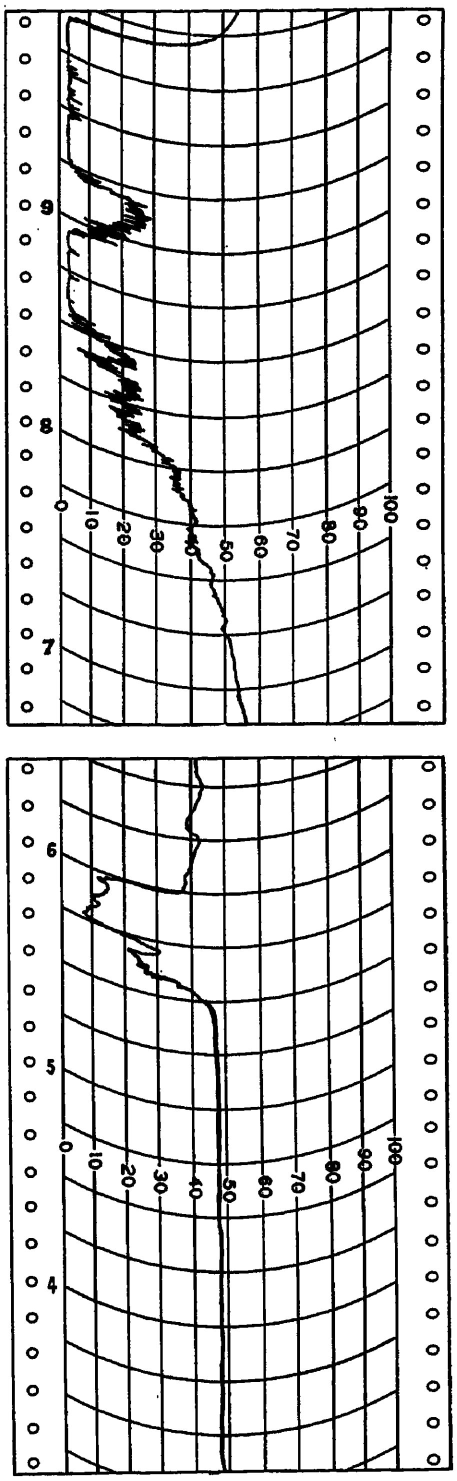

Fig. 9 (right). Fade due to high antenna above fog and low antenna in fog

tenna, the difference in path length is reduced to a value where it is evidently not so important a factor.

In the case of the Patton to White's Ranch hop, Fig. 6, a distance of 21 miles using high-low antennas, the point of reflection is some distance from the base of the tower at Patton, where the low antenna is located. However, due to the prevailing moisture content of the air in this area, the index of refraction is such that the point of reflection is shifted sufficiently to greatly improve the operation, insofar as high-maximum, low-minimum type of fade is concerned.

The second type of basic fade encountered was that brought about by fog. This condition was more prevalent in working a high antenna against a low antenna. During fog conditions, it is not unusual for the signals to be relatively stable and strong between two high antennas, while transmission between a high and low antenna would be attenuated to such an extent as to be unusable. Recent tests conducted revealed a very interesting situation which prevails to some extent in sections where the high-low antenna is used.

Observations were made during the time when fading conditions existed in the early morning hours and the following was determined: When a fog bank starts to move in from the Gulf, whether it is a heavy dense fog or a light ground fog, it is frequently at a low level and, at a later time, drifts upward. When this condition exists a fade occurs, as shown on Fig. 9. This is apparently due to the fact that the low antenna is in the fog layer and the high antenna is above this layer. The transmitted signal from the high antenna to the low antenna hits the surface of the fog layer and apparently a greater portion of the signal is reflected. The amount of reflected signal depends largely upon the density of the fog. This is one of the conditions which gives the greatest trouble between Patton an White's Ranch where the high-low antenna system is used.

During such fog conditions, the Galveston-Patton hop gave a much lesser degree of trouble, but nevertheless a definite reduction in signal level was noticed. Due to the shorter distance between Galveston and Patton and the fact that parabolas are used without reflectors, there is less attenuation in this hop. Therefore, a greater fading margin is available. Thus, it is possible to get a greater degree of signal through the fog in that section and less trouble is experienced.

On the Patton to White's Ranch hop, using a reflector on one end, and with a greater distance involved, the path length provides a lower fading margin. Therefore, on occasions this circuit is completely unusable for several hours at a time.

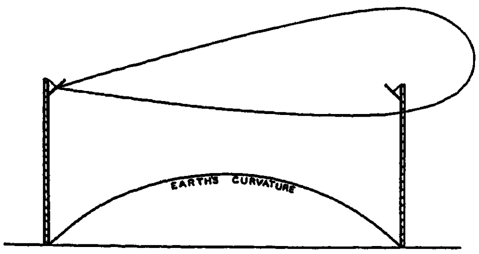

Fig. 10. Microwave transmitting beam adjustment

The Patton to White's Ranch hop, as well as the White's Ranch to Morey hop, also present unusual conditions in case of fog in that their transmission paths are located at an angle to the Gulf. Therefore, when a fog comes in from the Gulf, the front of the fog bank diagonally intersects the transmission path, creating a condition of refraction or reflection that is the same as that produced when one antenna is in the fog belt and the other above. It was noted in both cases that as soon as the fog completely enclosed the antenna on both towers, the signals returned to a relatively high level and stable communication was obtained.

In the same recent tests where it was determined what happened during the fog conditions it was also found that overall stability could be improved if the antennas, Fig. 10, were adjusted so that the half-power point on the bottom of the major lobe of the beam was set on the receiving antenna; that is, only the transmitting antennas were adjusted, and the receiving antennas were so placed in the beam by this adjustment that they were at a point approximately 2 decibels below the midpoint of the beam. Under conditions of normal weather, where the humidity increases slightly between night and day, recordings indicate that there will be a slight increase in level of the signal at night due to the change of index of refraction.

At the present time, arrangements are being made to replace the 4-foot parabolas and reflectors with 6-foot units in this system, thereby increasing the fading margin. This increase in fading margin should make it possible to obtain reliable communication in all hops of the system.

No Discussion

A Miniature Compandor for General Use in Wire and Radio Communication Systems

F. S. BOXALL
NONMEMBER AIEE

R. S. CARUTHERS
MEMBER AIEE

Synopsis: A miniaturized compandor has been developed for widespread application to open-wire, cable, and radio channels. Self-contained plug-in units can be inserted in telephone circuits at all commonly expected transmission levels. Two-wire operation is achieved with a plug-in resistance hybrid. Equipment simplification is achieved through use of only two miniature vacuum tubes. A conventional approach has been followed to obtain a compandor circuit with a two-to-one compression and expansion characteristic. Straightforward empirical methods are used to achieve the desired results. Reduction of noise and crosstalk, commonly stated as 22 decibels (db), actually varies considerably, depending on the type and magnitude of interference.

General

IN RECENT years, a rather remarkable increase has occurred in the use of compandors in the channelizing equipment of speech communication systems. Perhaps even more remarkable is the fact that from an over-all cost standpoint, new carrier installations in which the terminal equipment includes compandors are the least expensive. Compandors have been used for many years to reduce noise and crosstalk on open-wire systems. More recently, in carrier systems for cable and open wire, compandors have been integrated into the design of each channel.[1,2] This has been made possible by the development of a compact, inexpensive compandor which gives quality performance and only slight speech degradation, even when a number of these devices are connected in tandem.

Application

At the Lenkurt Electric Company, objectives in compandor application have included more widespread use on wire and radio systems than previously. Specifically, the aim has been to build a device that can either be used freely or omitted, depending on whether crosstalk or interference conditions warrant its use. This goal dictated a simple, self-contained plug-in unit.

In application to frequency modulation (FM) radio systems at Lenkurt, compandors increase permissible fade margins (thus allowing more freedom in site location, antenna sizes and heights). They also simplify the problem of maintaining an adequately low level of interchannel modulation, even when adding more channels. In another application, a large number of channels is planned for use on a single side-band basis on very high frequency (VHF) or microwave bands. Studies indicate that gains and power levels of the radio frequency amplifiers required are reduced so much by compandor use that a much wider selection of tube types is available.

Probably the most obvious use of a compandor is in the basic design of a carrier system where the use of a compandor in each channel eases all design requirements. The compandor results in more satisfactory modulator levels, lower amplifier gains, and smaller filter discriminations in the terminals. In repeaters and line facilities, at the same

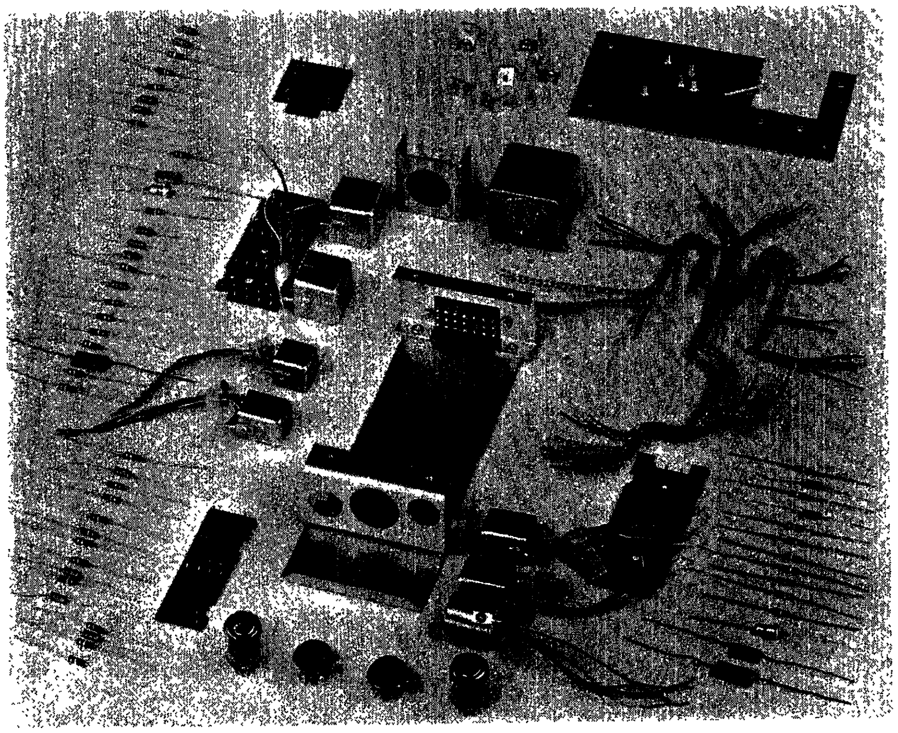

Fig. 2. Compandor frame and components unassembled

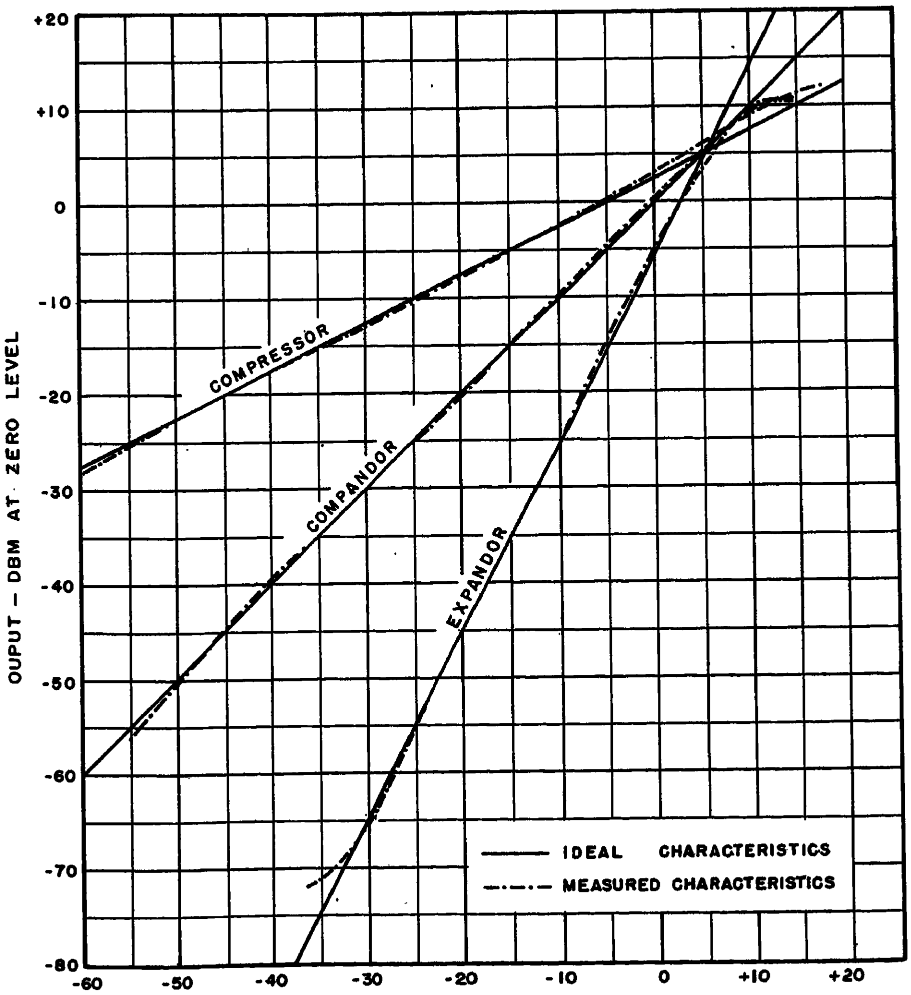

Fig. 3. Compandor load characteristics

time, interference from noise, intermodulation, and crosstalk are reduced.

Another important field of compandor use is in systems where the eventual field application finds some unexpected spurious interference, despite the best planning in the original design. Here, at spot locations in some channels, the use of compandors is warranted. In similar situations, systems designed for a broad geographic field of application sometimes are used in regions of high static and lightning interference. Compandors in such systems are needed only in the high interference areas.

Still another likely field of application is in systems and circuits which may have been installed for many years. Performance may have become increasingly poor through no basic fault of the equipment but through slow deterioration or lack of maintenance. In such cases, it may be difficult even to locate the exact point of system impairment, geographically or electrically. Compandors at the terminals of such circuits will restore operation to its original high-grade performance.

In the railroad and pipe-line field, compandors may be particularly useful in bringing substandard circuits up to high-quality toll performance, or in obtaining satisfactory operation under circumstances which would otherwise provide only intolerably poor circuits. Economies in obtaining circuits of any specified quality may also be effected by the use of compandors.

The compandor described in this paper is not particularly novel from an electrical standpoint, in that it follows closely the design procedures already described in technical literature. However, the actual compandor differs from any previously developed in being smaller, more compact, and in using fewer vacuum tubes. Despite this miniaturization and simplification of circuitry, excellent performance has been retained; and even a skilled observer can find little fault in speech passing through four to eight compandors in tandem.

No attempt has been made to employ other than an orthodox compandor with two-to-one compression and expansion ratios. A conventional syllabic type has been used without exploring the perhaps more intriguing aspects of an instantaneous device. The success achieved, however, indicates that further development might derive even greater noise benefits with higher compression ratios and with further simplification through some compromise between syllabic and instantaneous design. When transistors are

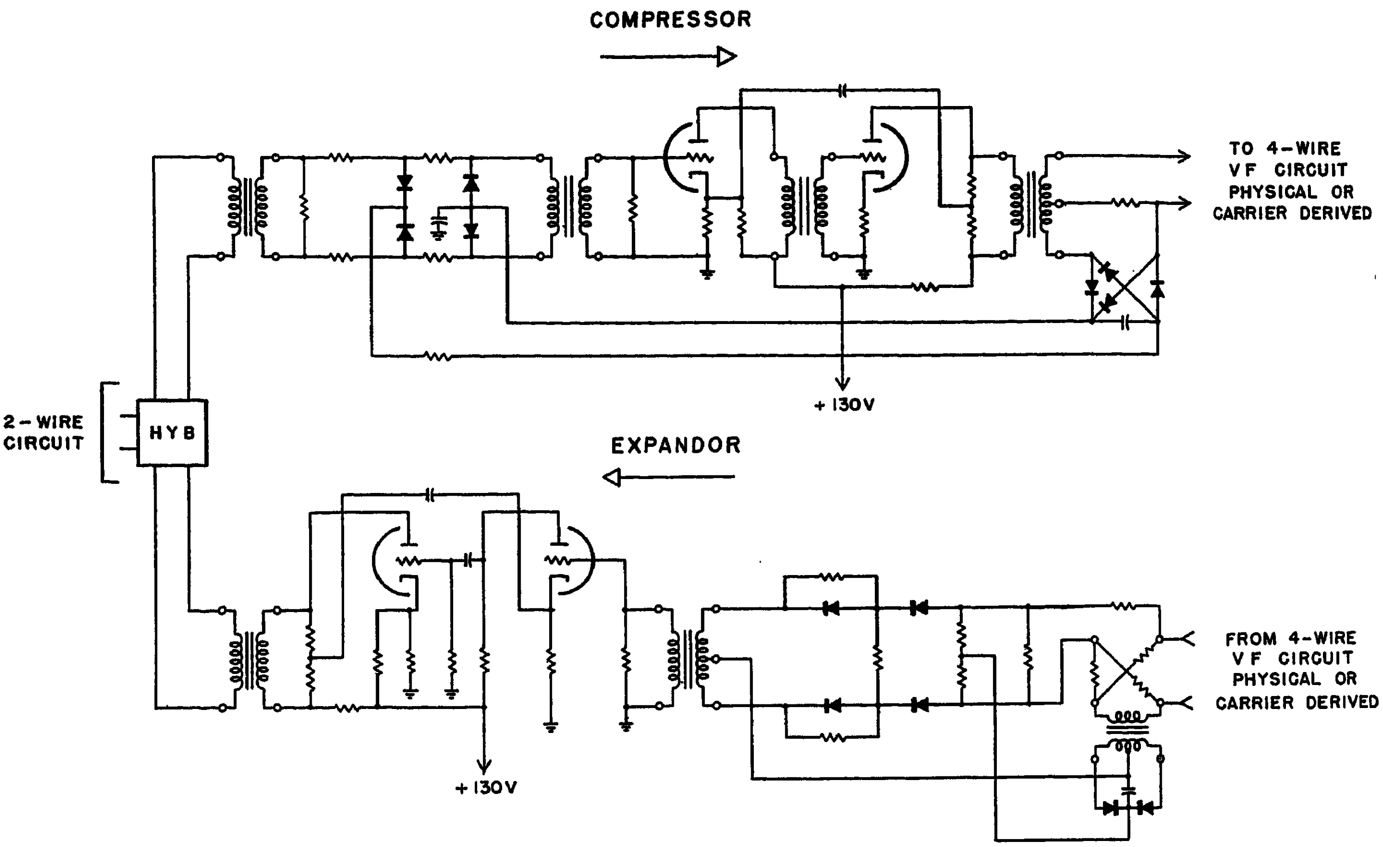

Fig. 4. Compandor simplified schematic diagram

added and cross-control included to permit lower over-all net loss operation, the use of compandors will be certain to expand greatly.

Equipment Arrangements

In Fig. 1, four compandors are shown in a shelf which is normally mounted in a standard 19-inch telephone type bay. One compandor is shown about to be plugged into the framework. Each compandor is approximately 2 inches high, $3^1/_4$ inches wide, and $8^1/_4$ inches deep. External connections are made through a 20-pin multicontact gold-plated plug at the rear of the unit. This plug is inserted in a jack mounted on the shelf. Equipment arrangements are provided for mounting either a single shelf of four units, or twelve units in three decks of four each.

In Fig. 2, an exploded view of one of the units shows the components. In the front are two vacuum tubes, a test socket and a removing handle. To the rear of the unit, an optional plug-in resistance hybrid is shown, permitting 2-wire termination when desired. Within the resistance hybrid is a screwdriver-adjustable potentiometer to set 2-wire net loss. Deposited carbon resistances are used throughout for precision and high stability. Miniature transformers in the amplifier circuits use epoxy resins for good moisture seal. Tantalum electrolytic condensers are used in the time constant circuits. Vacuum tubes in the compressor and expandor amplifier circuits are of the double-triode type. Preferred operation is with 20-volt and 40-volt heater arrangements utilizing Western Electric *407A* tubes, which give superior tube life. Where 6.3-volt operation is desired, the conventional *2C51* tubes may be used or, for better tube life, industrial equivalents.

Operating Levels

Most commonly expected operating levels are −16-db at the compressor input and output, and +7 at the expandor input and output. For older offices, however, where −13 and +4 levels are still standard, arrangements are provided for operating the compressor at −13 level and the expandor at +4 level. In either −16 or −13 office conditions, the compressor and expandor are made to operate with equal input and output levels. For use with some carrier equipment, operation of the compressor is desired at −4 level and of the expandor at +4 level. Where 4-wire operation is desired, the resistance hybrid is removed, and in its place a unit is used with 4-wire connections. Two types are provided to give either zero or 3-db 4-wire loss. Thus, either −16 or −13 level offices are easily accommodated by these optional plug-in units. Those special applications where −4 compressor level and +4 expandor level are desired are handled by internal strapping of the compandor unit.

Theory of Operation

The theory of compandor operation has been thoroughly described in technical literature, and will be reviewed only briefly in this article. It is sufficient to say that the compandor consists of a compressor unit at the input end of the circuit, and an expandor at the output end. Strong signals pass through the compressor and the expandor without gain or loss in either. On the other hand, weak signals receive a gain in the compressor and a compensating loss in the expandor. For example, a strong signal of +5 decibels above 1 milliwatt (dbm), at the zero level point entering the compressor, passes through the compressor with zero gain and also through the expandor with zero loss, and thus comes out at +5 dbm at the zero level point of the output terminal. In a two-to-one compandor, a signal 50 db below a +5 dbm signal receives a 25-db gain in the compressor and a corresponding 25-db loss in the expandor. The compandor noise advantage is derived from the gain given

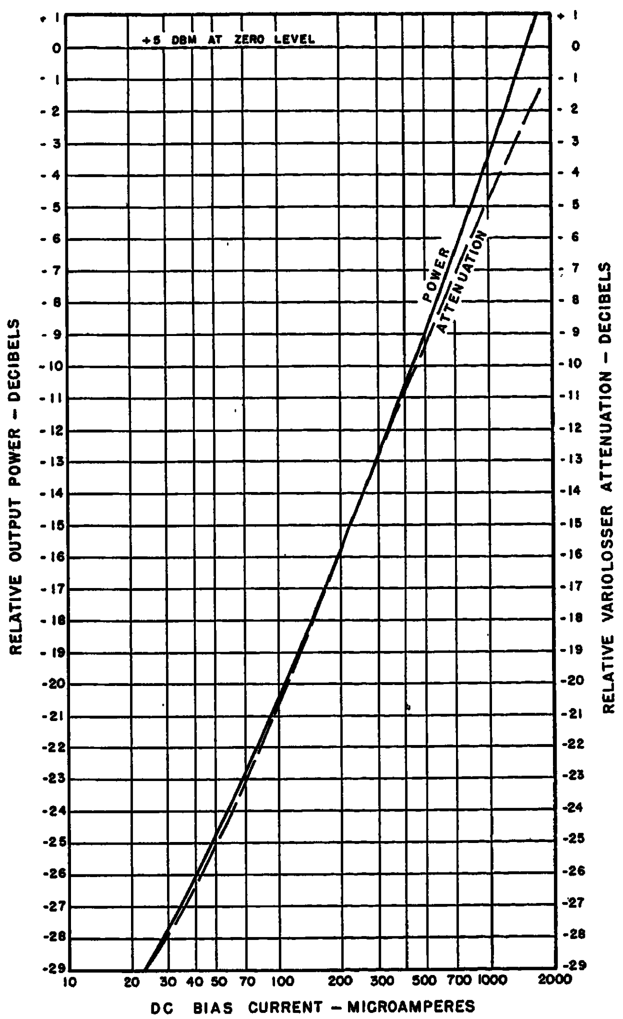

Fig. 5 (left). Compressor d-c operating characteristics

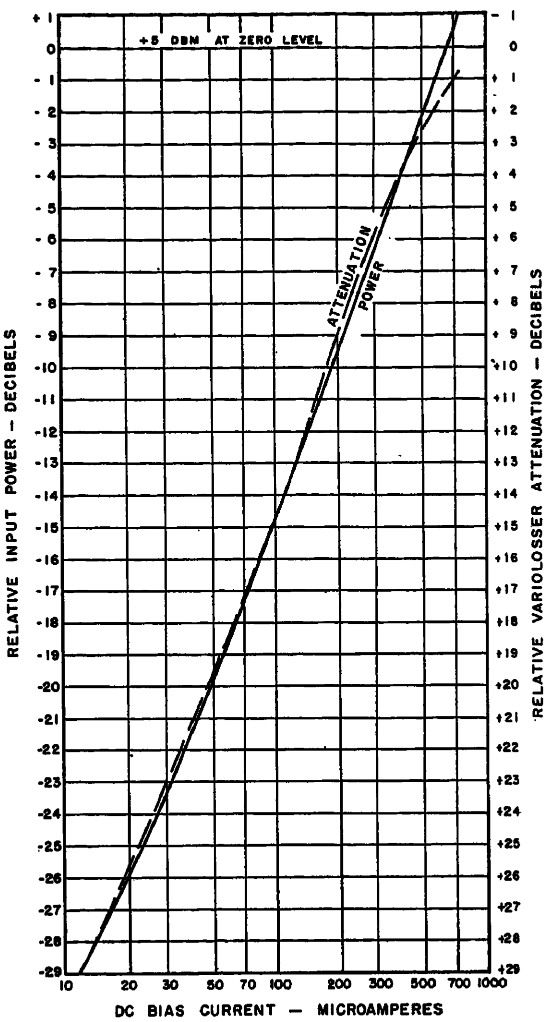

Fig. 6 (right). Expandor d-c operating characteristics

to weak signals so that they may override intervening circuit noise between the compressor and the expandor. Strong signals do not need such gain, and thus are passed over the circuits with zero gain in the compressor and compensating zero loss in the expandor. When the circuit is idle, the expandor retains the loss given to the weakest signal; and a corresponding gain exists in the compressor. This loss during the idle condition is the noise advantage of the compandor, and all interferences existing in the intervening medium between compressor and expandor are subjected to this expandor loss. As speech increases, the compressor gain and expandor loss decrease; while the expandor loss is removed by speech action, thus raising noise, speech masks the increasing noise that results. And thus, even though noise is much increased during the presence of speech, the masking advantage of the speech makes this still a satisfactory operating condition. Time constants of a syllabic length are used in the compressor and expandor circuits. It is important for the time constants to be so arranged that the compressor gain and expandor loss is reduced quickly upon a speech burst. At the end of a speech burst, it is likewise important that the compressor gain and expandor loss slowly recover to their idle values. No great precision is required in these time constant values. In fact, it is even difficult to state definitely what these time constant values are in a typical circuit, as they vary with the strength of the signal. It is sufficient that the compressor and expandor attain their final gain and loss values upon insertion of a strong speech burst within 1 to 5 milliseconds. Similarly, upon removal of the speech burst, restoration of the compressor and expandor gains to their original values within 20 to 100 milliseconds is probably adequate.

In Fig. 3, input-output curves are shown for compressor and expandor. Both ideal and measured curves are shown. Compressor and expandor curves are plotted as though each were operated at zero level at its input and output branches instead of the actual −16 and +7 levels respectively. An input of +5 dbm at zero level receives zero gain in both compressor and expandor. A 60-db weaker input to the compressor receives 30-db gain in the compressor and 30-db loss in the expandor. Failure of the compressor and expandor to introduce equal gain and loss introduces an over-all circuit error. With the compandor shown, this error is less than 1 db over a range of input signals of nearly 60 db.

Circuit Arrangement

In Fig. 4, the compressor and expandor circuit arrangements are shown. In the compressor circuit, a range of signals of approximately 60 db from the resistance hybrid or 4-wire input is compressed to half this amount by the variolosser circuit, and then fed through a 2-stage feedback amplifier to the output. At the output this compressed range of signals is fed through a rectifier circuit to control the loss of the variolosser at the input end of the circuit. At the output terminals, a coil hybrid arrangement isolates the output signal branch from the rectifier branch to prevent harmonic distortion of the rectifier from being fed into the output signal branch. The arrangement shown is known as a backward-acting device. The compressed output band acts backwardly to vary the loss at the input of the circuit.

In the expandor circuit, the compressed input range of signals is separated into two branches, one being fed through a rectifier circuit to control the loss of the variolosser; and in the other branch, the compressed range of signals is fed to the input of the variolosser. In this arrangement, an input range of 30 db of compressed signals is expanded to an output range of 60 db. Expanded signals are amplified through a 2-stage feedback amplifier and delivered to the output terminals of the expandor circuit. As in the compressor circuit, a hybrid bridge arrangement prevents modulation in the rectifier circuit from being introduced into the input signal branch to the variolosser. This is known as a forward-acting expandor circuit.

Development Approach

In the development of a compandor, the greatest problem is to obtain an adequate tracking characteristic. What this means is that over the whole operating range, the input-output characteristic of the compressor shall be exactly compensated for by the input-output characteristic of the expandor. It was formerly believed that perfect tracking could be obtained by using true inverse networks in compressor and expandor. In practice this does not work out, and the approach must be much more empirical. This is because of limitations imposed by circuit operating levels and limitations of varistor elements available. Experience shows that probably the best approach is to attempt to obtain a perfect two to one compressor over the entire range of operating input signals and, in turn, to obtain a perfect two-to-one expandor over its entire operating range.

It has been found that there is a very useful approach in obtaining directly a two-to-one characteristic in either compressor or expandor without any stress as to whether varistor characteristics are following square laws or exponential laws. It is merely a straightforward, empirical approach. This can be explained from Fig. 5. Here two curves are shown. One shows the rectified output speech currents plotted as a function of the output range of compressor signals. A second curve shows the d-c current from the rectifier plotted versus loss in the variolosser circuit. A simple examination will show that if these two curves fall one on top of the other, the compressor characteristic will follow exactly a two to one law. The experimental approach, then, is one of independently measuring these two characteristics in the circuit being developed, and attempting to move one curve or the other to fall on top of the second curve. By the simple expedient of using resistances in series or in parallel with the diodes, either the low-current end or the high-current end may be moved upward or downward, as desired. The curves in Fig. 5 show how closely this empirical approach was able to obtain a two-to-one characteristic over a 60 db range of input signals.

In Fig. 6, a similar method has been applied to the expandor. Again the circuit is split into two parts. The input range of signals to the expandor is plotted against the d-c current at the output of the speech rectifier. A second curve shows the variolosser loss as a function of the d-c current. Again, perfect two to one expansion requires that these two curves fall one on top of the other. It makes no difference how much these particular curves bow or twist as long as the superimposition is good. Despite these precautions, there is inevitably at either the lower or the top end of the characteristic some departure from the ideal two-to-one characteristic desired. Here as at other parts along the characteristics, there is a natural tendency for compressor and expandor errors to cancel because of the very nature of the inverse action going on in compressor and expandor. Though the method outlined is invaluable in obtaining a good two to one characteristic in either compressor or expandor, it is seldom possible to obtain the characteristic desired within 1 or 2 db of the ideal two to one characteristic. Not only are very highly selective methods required for diodes, but a great amount of empirical testing is needed to obtain this accuracy over a 60 db range of input signals. When the compressor and expandor characteristics are added, these deviations can be reduced to the order of magnitude of about ±0.5 db with good design.

In Fig. 7, deviation errors are plotted for compressor, expandor, and over all circuit. The tendency of compressor and expandor errors to compensate is seen.

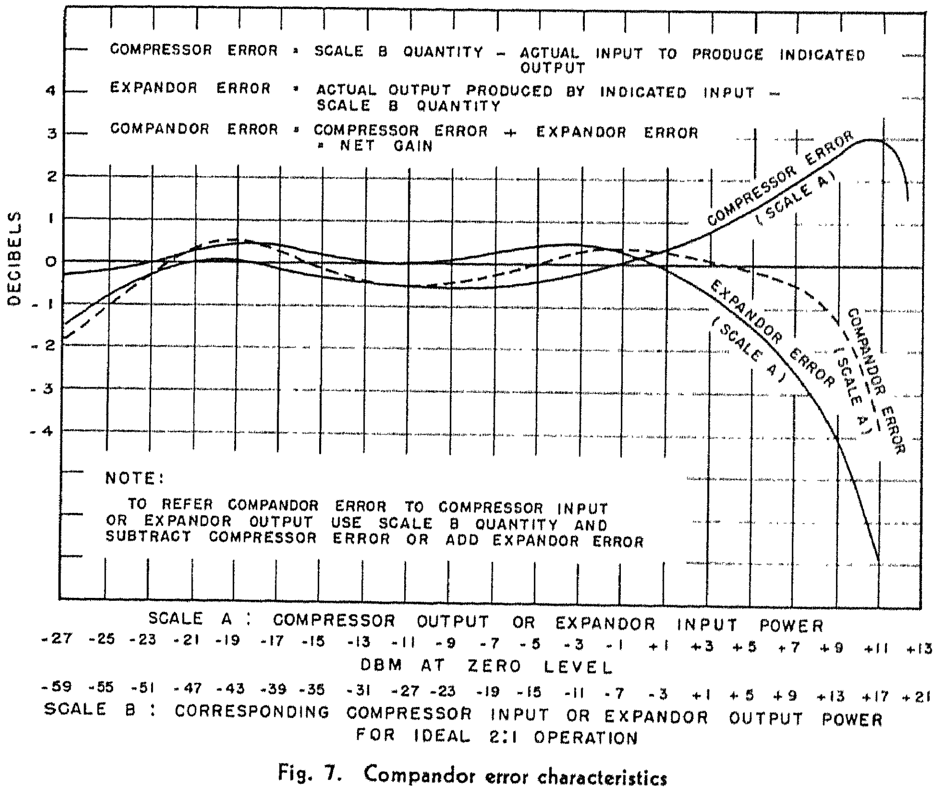

Fig. 7. Compandor error characteristics

Selection of Diodes

Obtaining a desired compressor or expandor characteristic is, of course, fully dependent on obtaining germanium diodes with the proper characteristics. In using the procedure just described to obtain good tracking, it was found that many sources of supply of suitable diodes were available. The procedure was to classify a large number of diodes from a particular manufacturer with generally suitable characteristics, find the highest concentration of diode characteristics in this lot, and then make the basic compandor circuit design suitable for the high concentration area of diodes. In exploring and classifying diodes, 2-point current measurements were used. Diodes were first grouped by resistance at about 500 microamperes (μa), and also at a current in the neighborhood of 12 μa, using a cir-

TWO-LETTER GROUP DESIGNATION "DF" INDICATES UNITS IN HIGH CURRENT GROUP D AND LOW CURRENT GROUP F.

TABLE SHOWS PERCENTAGE OF DIODES IN EACH CLASSIFICATION BASED ON SAMPLE OF 750 UNITS

Fig. 8. Diode selection

cuit shown in Fig. 8. Diodes were grouped at high current into five classes: *B*, *C*, *D*, *E* and *F*, using current steps of 20 μa from 420 to 520 μa. At low currents, diodes were grouped into 10 classes, ranging from 9 to 15 μa in steps of 0.6 μa. Particular diodes were given a 2-letter designation, thus, a *BA* diode had a current where *B* designated the high-current value and *A* designated the low-current value. A *BA* diode had a high-current value of between 420 and 440 μa, and a low-current value between 9 and 9.6 μa. A distribution of 750 diodes classified by this method is shown in Figure 8. The largest concentration occurred in the *DF* category, which included about 1/6 of the diodes tested. Consequently, the design of the compressor and expandor uses diodes only in this category. The 750 diodes studied were received from the manufacturer in three separate lots. In each instance, the *DF* category showed largest concentration, giving some indication that successive samples would not show wide departure from this type of distribution.

In Fig. 9, current-resistance plots are shown for the diodes just described. The ranges of resistance at high-current value are shown as well as those for low-current values. With such tight control limits specified for the *DF* units, the log-log current-resistance plot is practically certo be a straight line.

Frequency Characteristic

The frequency characteristics of the compandor are shown in Fig. 10. The over-all characteristic was made by the normal procedure of varying input frequencies to the compressor and measuring the levels of frequencies at the expandor output. In actual use, the frequency characteristic for speech is not determined quite in this manner. What happens is that the syllabic energy with its heavy concentration near the 1,000-cycle point sets the loss of the expandor and the compressor for the syllabic interval. During this period, nearly constant current flows in the compressor and expandor speech rectifier control circuit. The variolosser networks then act as fixed resistance pads, and there is no tendency for compressor or expandor variolosser circuits to double or halve errors that might ensue in the measurement with single frequency. Actually, in practice the frequency characteristics of control circuits have been carefully designed so that there is little difference between an actual over-all single-frequency measurement and the action with speech. The frequency characteristics shown were measured both with fixed bias simulating speech action, and with bias resulting from the input frequencies. There is little difference indicated in the test results.

In Fig. 11, harmonic distortion is plotted for the over-all compandor. In both the compressor and expandor, it was necessary to use special means to prevent harmonic distortion produced in the speech rectifiers from being reflected into the output signal branch. This separation was obtained by use of a hybrid bridge at the output of the compressor circuit. In the expandor, a similar hybrid used at the input where the speech was separated off for the power rectifier circuit and for the branch feeding to the variolosser, prevented reflection of harmonic distortion from the speech rectifier into the variolosser. It was assumed that in some cases there would be practically 100 per cent reflection from the input impedance feeding the expandor input

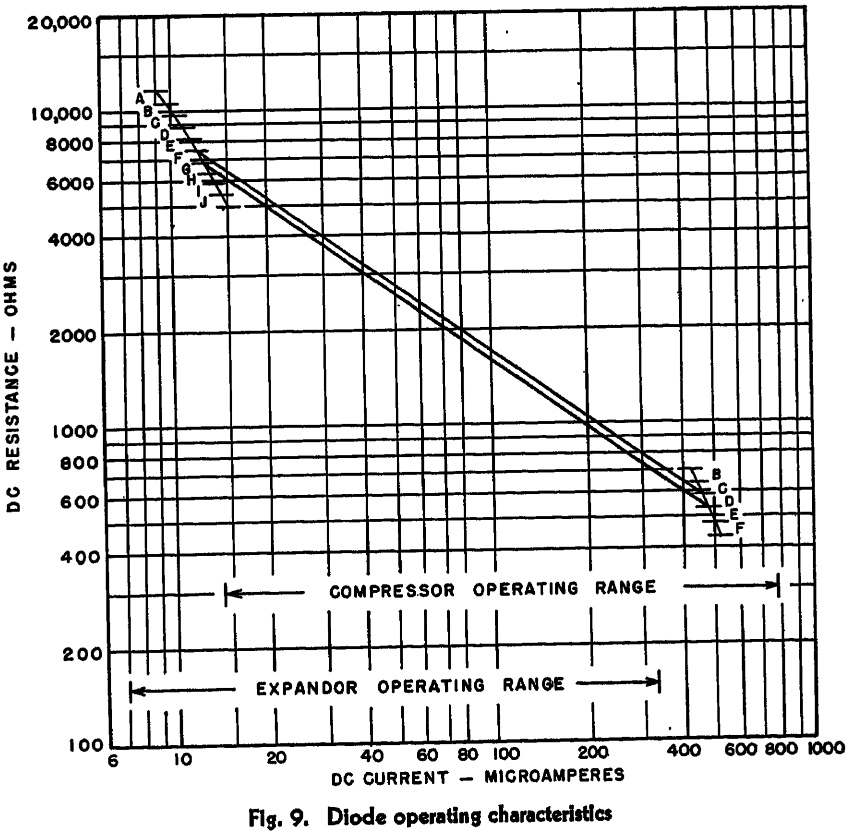

Fig. 9. Diode operating characteristics

terminal. This is most likely to occur above the passed band when expandors are put at the output of circuits containing low-pass filters.

Noise Advantage

The ability of a compandor to reduce interference in a speech channel depends on the nature of the interference and on its magnitude. A difference also exists in the reduction of interferences afforded by the compandor, whether speech is present or during idle speech periods. A listener waiting for answer or during speech pauses on a noncompandored circuit may hear intelligible crosstalk or tones. In these cases, the compandor advantage is equal to the magnitude of loss introduced by the expandor. At low noise levels, the noise advantage exceeds 30 db, becoming progressively less at high interference levels. Noise improvement for various interference levels, measured with a 3-kc band of thermal noise, is shown in Table I.

These measurements were made with a Western Electric Company *2B* noise meter. Subjective listening tests showed no differences from the noise meter readings.

The interference reduction in the expandor will depend on the magnitude of power in the interference, whether it be a 1,000-cycle tone, a 3-kc band of uniformly distributed thermal-type noise, or speech crosstalk. For equal input power of any of these three types of interference, about equal reduction of interference will take place.

The loudness of the interference to a listener at the expandor output will vary, however, due to the weighting afforded by the receiver ear characteristic. In a telephone circuit, speech and thermal noise will appear nearly equally loud, whereas 1,000-cycle tone will be approximately 8 db louder.

Table I. Noise Improvement for Various Interference Levels (No Speech Present)

Magnitude of Interference at 0 Level Input to Expandor, Db from 1 Milliwatt (Mw)	Interference Reduction in Expandor, Db	Magnitude of Interference at 0 Level Output from Expandor, Db from 1 Mw

−17	22	−39
−12	17.5	−29.5

In the case of intelligible crosstalk, with crosstalk intelligible only during absence of speech on the listener's channel, the expandor advantage appears in Table I. However, because of the compressor action in raising signal level, a crosstalk disadvantage will occur in the disturbing talker's compressor circuit. The magnitude of this disadvantage as a function of the talker volume is shown in Table II.

The talker volumes shown cover practically the entire range expected at the input to a toll telephone circuit. Since practical systems must be designed to tolerate crosstalk from the louder talkers, the compressor disadvantage is slight. A statistical study will show that a compressor disadvantage of about 5 db, corresponding closely to a −5-volume-unit (vu) volume talker, may be used for computing intelligible crosstalk. As an example, in a line with 25-db crosstalk coupling, a −5-vu talker would be raised

Table II. Crosstalk Disadvantage Resulting from Compressor Action

Talker Volume at 0 Level, Vu	Compressor Disadvantage, Db
−30	17.5
−16	10.5
− 5	5.0
0	2.5

Table III. Noise Improvement with Speech Present

Magnitude of 1,000-Cycle Interference	Compandor Noise Advantage Speech Volume at 0 Level		
Dbm at 0 Level	−26 Vu	−16 Vu	0 Vu
−30	27	25	24
−25	24	22	20
−20	22	19	18
−15	18	16.5	15
−10		14	11

to 0 vu at the compressor output. The interference would appear at −25 vu at the listener's expandor input and at −56 vu at the expandor output, a crosstalk coupling of 51 db (31-db expandor advantage; −5-db compressor disadvantage).

Compandor advantage in noise reduction during speech has been very loosely quoted as 22 db. Actually, the noise advantage varies considerably with the strength of the speech and the magnitude of the noise.

Extensive tests have been made using both 1,000-cycle tone and a 3-kc band of thermal noise as interference. Three typical expected talker volumes were used: 0 vu representing maximum, −16 vu as an average, and −26 vu near the minimum. Table III shows compandor advantage under these test conditions using 1,000-cycle tone as disturbance.

These test results are averages made by careful listeners whose judgment generally differed by less than 1 db. Most spread was observed at greatest compandor advantage and least interference level where tone from the compandor was near threshold of audibility for some listeners.

Observers had much more difficulty in evaluating compandor advantage when a 3-kc band of thermal noise was used in tests. However, by repeated tests it was evident that individual observers straddled the mean values obtained in 1,000-cycle measurements. It is probably a safe conclusion that no difference actually exists as far as the ear is concerned.

The Solution of Sturm-Liouville Problems by D-C Network Analyzer

GEORGE W. SWENSON, JR.
ASSOCIATE MEMBER AIEE

A GENERAL second-order ordinary differential equation occurring frequently in engineering analysis is

$$\frac{d}{dx}\left[f(x)\frac{d\phi}{dx}\right]+\lambda g(x)\phi=0 \tag{1}$$

in which λ is a constant and *f* and *g* are arbitrary functions such that a finite solution exists in the interval of interest. It is the purpose of this paper to show how solutions satisfying this equation and various boundary conditions can be obtained by means of a simple d-c network analyzer. For such an equation, there exist only certain values of the parameter λ, the eigenvalues, which permit the solution to satisfy the boundary conditions. The first problem, then, is to determine one or more of these eigenvalues, whereupon the corresponding solutions can be obtained. This procedure presents considerable difficulty, and analytical solutions are available only for a few special cases.

Numerical solutions can be obtained, at least in principle, with the aid of some results from the calculus of finite differences.[1] Consider Fig. 1, which represents an interval along the *x*-axis, divided into a number of equal segments of length *h*/2. If *h* is very small, the following expressions are approximately true:

$$\begin{aligned}
&\left(\frac{d\phi}{dx}\right)_0=\frac{\phi_b-\phi_a}{h}\\
&\left(\frac{d^2\phi}{dx^2}\right)_0=\frac{\phi_1+\phi_2-2\phi_0}{h^2}\\
&\left(\frac{df}{dx}\right)_0=\frac{f_b-f_a}{h}\\
&f_a=\frac{f_0+f_1}{2}\\
&f_b=\frac{f_0+f_2}{2}\\
&\left(\frac{df}{dx}\right)_0=\frac{f_2-f_1}{2h}\\
&\left(\frac{d\phi}{dx}\right)_0=\frac{\phi_2-\phi_1}{2h}
\end{aligned} \tag{2}$$

Equation 1 can be written

$$f\frac{d^2\phi}{dx^2}+\frac{df}{dx}\frac{d\phi}{dx}+\lambda g\phi=0 \tag{3}$$

Substitution into equation 3 from 2 yields a finite-difference expression, which holds at point 0

$$f_0\frac{\phi_1+\phi_2-2\phi_0}{h^2}+\frac{f_2-f_1}{2h}\frac{\phi_2-\phi_1}{2h}+\lambda g_0\phi_0=0$$

or

$$(4f_0-f_2+f_1)\phi_1+(4f_0+f_2-f_1)\phi_2-4(2f_0-\lambda g_0h^2)\phi_0=0 \tag{4}$$

A similar equation holds at each numbered point in the domain; therefore, given an appropriate value of λ, and values of *f* and *g* at each point, an approximate numerical solution of the problem can be obtained by solving the several difference equations simultaneously. As the set of equations is homogeneous, it is necessary that their determinant be zero in order that a nontrivial solution exist. By extracting the zeros of the determinant, therefore, eigenvalues of λ in number equal to the order of the determinant can be determined. However, if a large number of eigenvalues is needed, or if considerable accuracy is needed in the lowest few, it is necessary to use a large number of lattice-points and, thus, a determinant of high order. Because of the great labor involved in extracting the zeros of such a determinant, and in solving the set of homogeneous equations, it

The author wishes to express his appreciation to Professors H. A. Peterson, T. J. Higgins, and K. F. Wendt, of the University of Wisconsin, for the loan of equipment belonging to that institution.

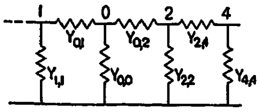

Fig. 2. The electric network

is usually necessary to use some numerical or experimental method to effect the solution.

The D-C Network Analyzer

A set of linear algebraic equations of the form of equation 4 can be used to describe the junction-point currents of a network of linear electric-circuit elements. The network takes the form of Fig. 2, in which the node-to-ground voltages correspond to the ϕ's of equation 4. The admittances $Y_{0,2}$ and $Y_{0,1}$ are equal to the coefficients of ϕ_2 and ϕ_1, respectively, and the admittance $Y_{0,0}$ is such that the sum of the admittances connected to point 0 equals the coefficient of ϕ_0.

It may occur that both positive and negative admittances are required. In this event, the use of inductors and capacitors and alternating currents suggests itself. However, substantial gains in economy and accuracy can be accomplished by the use of resistors and direct currents only, the required "negative resistors" being simulated by active networks containing resistors and voltage sources. The negative-resistor circuit is illustrated in Fig. 3, in which, when the voltmeter is made to read zero by manipulation of R_s, a current of magnitude V_n/R_n exists in the external circuit, of such polarity that the input resistance is negative and equal in magnitude to R_n.

If equation 1 is to be solved in its most general form, it is necessary so to construct the analyzer that both node-to node and node-to-ground admittance be adjustable through wide ranges of positive and negative values. This, in turn, requires that a separate battery be provided for each negative resistor. A considerable simplification is achieved if $f(x)$ in equation 1 is a constant. In this case, equation 1 becomes

$$\frac{d^2\phi}{dx^2}+\lambda p(x)\phi=0 \qquad (5)$$

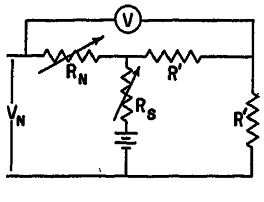

Fig. 3. The negative-resistor circuit

where $p=g/f$. The finite-difference equivalent applying at point 0 becomes, after multiplying by -1

$$-\phi_1-\phi_2+(2-\lambda p_0h^2)\phi_0=0 \qquad (6)$$

Similar equations can be written for the other points in the interval

Point 1: $-\phi_3-\phi_0+(2-\lambda p_1h^2)\phi_1=0$

Point 2: $-\phi_4-\phi_0+(2-\lambda p_2h^2)\phi_2=0$, etc.

The network for this simpler case is the same as that shown in Fig. 2, except that here the node-to-node resistances are all of the same positive value. It is clear, however, that the node-to-ground resistances may still be negative; in fact, if p is positive, any point n, whose neighboring ϕ's are nonzero, must have a node-to-ground resistance of $-R/(\lambda p_nh^2)$ ohms, where R is the common node-to-node resistance. All of these negative resistors have a common ground terminal; therefore, only one voltage source need be used for all of them. Such an analyzer[2] can be constructed with the node-to-node resistors, and the resistors R' of the negative-resistance circuits permanently wired with jacks provided for plugging in resistors R_s and R_n of the negative resistance circuits, or the positive node-to-ground resistors, whichever are needed. Jacks are also provided so that one voltmeter can be used in the adjustment of all circuits.

The setup and operation of such an analyzer, as well as methods of accommodating various boundary conditions, will be illustrated in connection with a torsional vibration problem. A second example will illustrate a more general problem.

Example 1. Torsional Vibration of a Uniform Shaft with a Flywheel

Consider a uniform shaft of length L, torsional rigidity C, and polar moment of inertia I per unit length, fixed at one end and free at the other, with a flywheel of moment of inertia $7IL/10$ fixed to the free end. Let it be desired to determine the natural frequency and eigenfunction corresponding to the lowest mode of torsional oscillation. The equation of motion, for sinusoidal oscillations, is

$$\frac{d^2\theta}{dx^2}+\frac{\omega^2h^2I}{C}\theta=0 \qquad (7)$$

where θ is the angle of twist of the shaft, and the boundary conditions are

$$\theta=0 \text{ at the fixed end} \qquad (8)$$

$$C\frac{d\theta}{dx}=7\omega^2IL/10 \text{ at the flywheel end} \qquad (9)$$

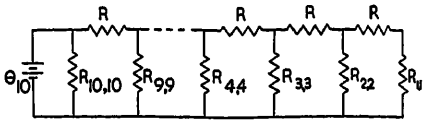

Fig. 4. Analyzer setup for a torsional vibration problem

If the interval L is divided into ten equal segments h, equation 7 can be represented approximately by nine difference equations, one for each interior lattice-point, numbered consecutively from the fixed end to the flywheel end. The boundary condition at the flywheel adds a tenth difference equation to the set, which is then

$$\theta_1(2-\omega^2h^2I/C)-\theta_2=0 \qquad (10.1)$$

$$-\theta_1+\theta_2(2-\omega^2h^2I/C)-\theta_3=0 \qquad (10.2)$$

$$\vdots$$

$$-\theta_8+\theta_9(2-\omega^2h^2I/C)-\theta_{10}=0 \qquad (10.3)$$

$$-\theta_9+\theta_{10}(1-7\omega^2h^2I/C)=0 \qquad (10.4)$$

Note that equation 10.1 contains only two terms, one of the neighboring points to point 1 having zero displacement. This is one boundary condition, the other being represented by equation 10.10. The analyzer setup is shown schematically in Fig. 4, in which $R_{1,1}=R/(1-\omega^2h^2I/C)$, $R_{2,2}=R_{3,3}=.\ \ .\ \ .=R_{0,9}=-R/(\omega^2h^2I/C)$, and $R_{10,10}=-R/(7\omega^2h^2I/C)$. The battery θ_{10} establishes the amplitude of vibration of the flywheel, and is necessary in order to obtain a nontrivial solution.

After the appropriate resistors have been plugged into the analyzer, the resistors R_s are adjusted in sequence to make all voltages V equal zero. This is an iterative adjustment, as each change affects all the other negative resistors; however, convergence is reasonably rapid in most cases. So far, nothing has been said about the determination of the natural frequencies. It is necessary to choose an arbitrary value of ω for the initial setting up of the analyzer, but the addition of the battery $\theta_{1,0}$ makes the system of nodal equations inhomogeneous, so that a solution is obtained for any ω. The battery current corresponds to a torque applied to the flywheel, and the lowest natural frequency can be found by trying different values of ω until the battery current is zero. This indicates that the system is oscillating without the application of any external torque; that is, oscillating in a normal mode. In this manner the lowest frequency of the system under discussion was determined, along with its eigenfunction, in about one hour's time, not including the time required for preliminary computations

The value obtained was $\omega = 0.976CI/L$, which is within 0.3 per cent of the analytically computed value. The analyzer components were calibrated on a Wheatstone bridge to within 1 per cent of their desired values, the forcing battery θ_{10} was $1^1/_2$ volts, and all voltages V were adjusted to less than 1 millivolt.

The iterative-adjustment process does not converge for higher modes; in fact, it does not converge for frequencies higher than the lowest at which the mechanical driving-point impedance becomes infinite. Another scheme must be used, therefore, for determining higher natural frequencies and eigenfunctions. For the second natural frequency, an estimate is made as to the position of the nodal point on the shaft. Then the lowest natural frequencies of the two portions of the shaft, as separated by the nodal point, are found and compared. If they are not equal, the nodal point is moved and the process repeated. Thus, by trial and error, the second frequency can be found. A similar, but considerably more tedious, process permits the determination of the third and higher modes.

Example 2. Torsional Vibration of a Nonuniform Shaft

Suppose that the shaft of example 1 were of two different diameters, the discontinuity occurring between points 4 and 5. Let the torsional rigidity be $2C$ between the fixed end and 4, and C for the rest of the shaft. Similarly, let the two polar moments be I_a and I_b, respectively. The nine difference equations corresponding to equation 4 can now be written, as well as a tenth equation expressing the boundary condition at the flywheel. The coefficient matrix is as follows

$$\begin{bmatrix} B_1 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ -2 & B_2 & -2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -2 & B_3 & -2 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & -9 & B_4 & -7 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -5 & B_5 & -3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & B_6 & -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & B_7 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & -1 & B_8 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & B_9 & -1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & B_{10} \end{bmatrix}$$

where

$$B_1 = B_2 = B_3 = (4C - \omega^2 h^2 I_a)/C$$
$$B_4 = 4(4C - \omega^2 h^2 I_a)/C$$
$$B_5 = 4(2C - \omega^2 h^2 I_b)/C$$
$$B_6 = B_7 = B_8 = B_9 = (2C - \omega^2 h^2 I_b)/C$$
$$B_{10} = (1 - 7\omega^2 h^2 I_b)/C$$

Note that the matrix is assymmetrical, and that the equations thus have no analogous network of bilateral resistors. This situation can be remedied by multiplying the fourth equation by 2/9, the fifth by 14/45, and each succeeding one by 14/15. The resulting system can be set up on an analyzer similar to the one in the preceding example, except that all node-to-node resistors must now be capable of adjustment. Negative resistors are needed only in node-to-ground positions, as before.

Forced Oscillations

If a function of x is added to the right-hand side of equation 1 the equation becomes inhomogeneous, and a solution is possible for any value of λ. This corresponds to forced simple-harmonic vibration of a shaft, for example, and can be simulated by inserting appropriate currents into the various nodes of the network analyzer. Thus, problems in forced vibrations of distributed-parameter systems can be solved quite conveniently on the analyzer.

Solutions of Boundary-Value Problems on Automatic Computing Equipment

FRANK M. VERZUH
ASSOCIATE MEMBER AIEE

THIS investigation is primarily concerned with the solution of boundary-value problems by means of automatic computing equipment. Specifically, it is concerned with the solution of ordinary differential equations in which certain conditions (boundary values) are specified at two or more values of the independent variable. Such problems are generally called boundary-value problems; however, it must be emphasized that this report is restricted to the solution of ordinary differential equations, and not to the solution of partial differential equations.

It is clearly evident that the solution of boundary-value problems is inherently more difficult than the solution of initial-value problems, in which all conditions are specified at a single value of the independent variable. The particular problems studied are further complicated by the fact that their solutions are required over an infinite range of the independent variable, a range which contains regions of nonanalyticity. The presence of such singularities materially complicates the solution of the problem.

The following digital computers were used in this study:

1. Conventional 10-digit desk calculator;
2. Type-*602A* Electromechanical Calculator;
3. Type-*604* Electronic Calculator;
4. Card-Programmed Calculator;
5. Massachusetts Institute of Technology (MIT) Whirlwind Computer.

In addition analogue studies were obtained by means of the MIT Rockefeller Differential Analyzer.

There are at least four methods for solving the boundary-value problem:

1. Direct algebraic method—solution of simultaneous algebraic equations;

Paper 53-395, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 1–4, 1953. Manuscript submitted March 18, 1953; made available for printing August 13, 1953.

Frank M. Verzuh is with the Massachusetts Institute of Technology, Cambridge, Mass.

This paper is based on some of the research investigations which were performed as part of a Doctorate Thesis at the Massachusetts Institute of Technology.

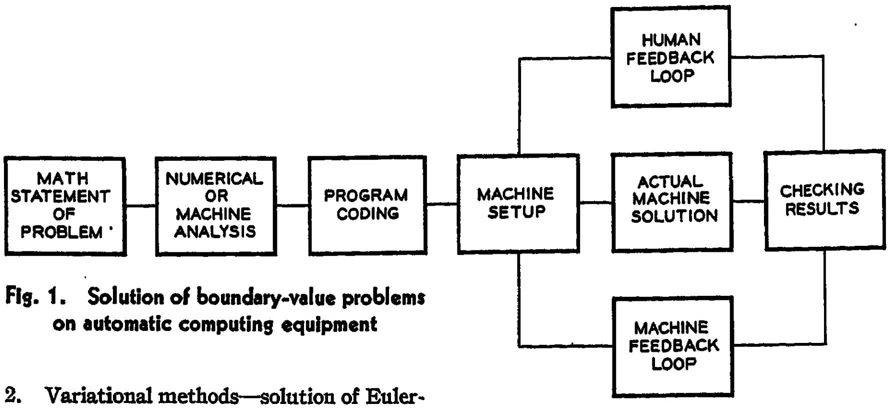

Fig. 1. Solution of boundary-value problems on automatic computing equipment

2. Variational methods—solution of Euler-Lagrange equations;

3. Integral-equation method—solution of the integral equation by integration;

4. Trial-and-error method—successive solution of the initial-value problems.

In the course of this research all of these methods were employed with a varying degree of success. The trial-and-error method of solution was found to be most amenable to solution by means of automatic computing equipment, and all succeeding comments will be concerned with this method of solution of the boundary-value problem.

The utilization of digital computing equipment for the solution of the boundary-value problem naturally raises the following questions:

1. How many decimal digits D must be carried during the computation to insure an accuracy of S significant digits in the final results?

2. Since the inherent use of an approximation formula introduces a truncation error T in the computation, what type of approximation formula is most suitable for the computation?

3. The choice of the interval of integration h strongly influences the round-off error incurred in the computation as well as the truncation error. What is the optimum interval of integration to be used to insure a maximum accuracy of computation?

4. How is the accuracy of computation S influenced by the presence of singularities in the problem?

5. Is the proposed computational procedure amenable to solution by the available automatic computing equipment?

6. Is the automatic machine solution justified from the standpoint of sound economic and engineering considerations?

This investigation provided definite answers to these questions. Obviously, these answers are influenced by the type of computer used in the computations as well as by the method of solution. The next section contains a computational philosophy which describes the basic elements involved in the computational procedure.

Comments on Computational Philosophy

The effective mechanization of a computational procedure is largely determined by the particular characteristics of the computer which is used to perform the computation. However, there are other factors which must be considered, and some of these are shown in Fig. 1.

Fig. 1 is a block diagram which illustrates the basic steps involved in the solution of the boundary-value problem on automatic computing equipment. Admittedly, this diagram is quite general, since it is applicable to both analogue and digital computing equipment. Correspondingly, the amount of work which must be performed to complete each step in this diagram will vary with the type of computer employed in the computation.

Specifically, if we assume that a complete mathematical statement of the problem is available, the first step is to perform the necessary numerical analysis of the problem. In the case of the digital computer, this phase is concerned with the replacement of the given differential equation by some type of approximation formula, for example, by a suitable set of difference equations, etc. This process may be referred to as the arithmetization of the problem. At this stage a careful study of the probable excursion of the variables must be made to insure that adequate counter capacities are provided. The possibility that a variable may exceed the available capacity of a particular unit on the computer, must be considered and suitable scale factors must be employed.

The second step is concerned with the preparation of the program which is needed in instructing the computer precisely what to do. The actual amount of detailed information which is needed to instruct a computer will vary with the particular machine. A computing machine does not think, and it will exercise only that judgment which has been specifically conveyed to it in the form of instructions (either by virtue of its particular physical design and construction, or by means of programmed instructions). Therefore, the preparation of an accurate program for a digital computer may be an extremely time-consuming task on certain machines. This point is empha-

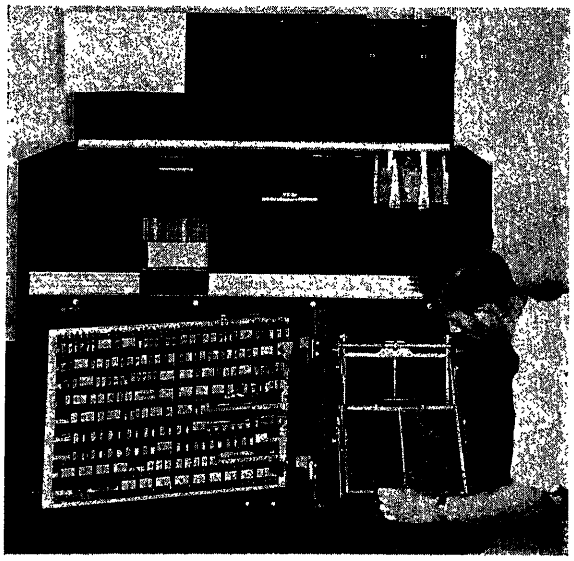

Fig. 2 (left). 602A Electromechanical Calculating Punch

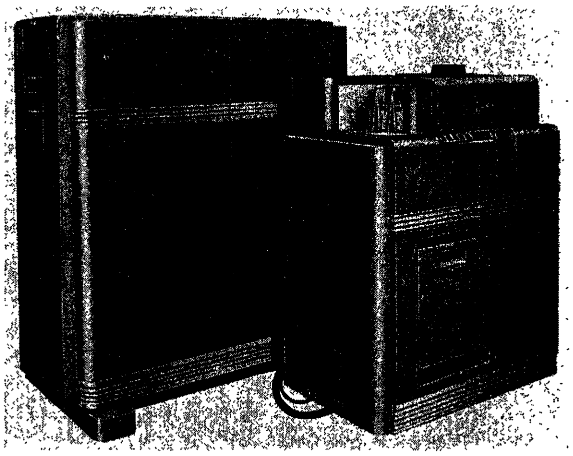

Fig. 3 (right). 604 IBM Electronic Calculating Punch

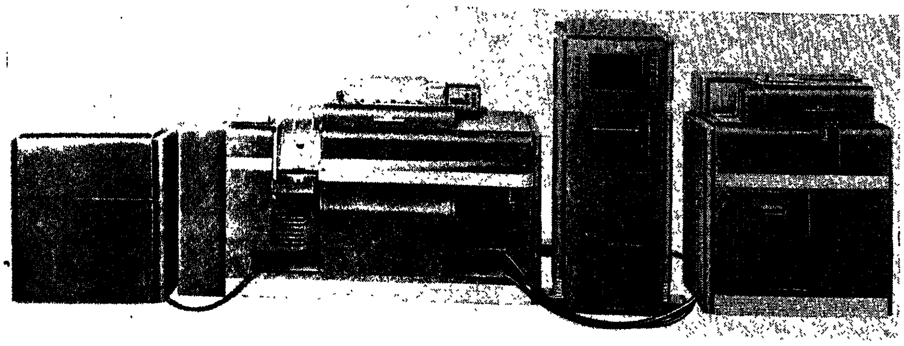

Fig. 4. Card-Programmed Calculator

sized not to detract from the capabilities of such devices; but rather to avoid creating an intoxicating misconception of the capabilities of computers.

The third step on the block diagram is concerned with the insertion of instructions into the computer, that is, actually setting-up the machine to do a particular task. Many different media are used for this purpose; punched paper tape, wired plugboards, punched International Business Machines (IBM) cards, flexowriter tapes, magnetic tapes, etc. In this operation we are concerned with overcoming an effective "language barrier" which exists between the computer and the outside world. That is to say, the computer understands a language which is quite different from that generally spoken. Hence some means of interpretation is needed to overcome the existing language barrier. Again, the actual moment of real time required to effect this operation will vary considerably, depending upon the actual computer under consideration.

The fourth step in the mechanized process is the actual machine solution. Here again, the actual real time expended for a particular example will vary greatly with different computers. Comparative solution times are presented in a later section.

The fifth step is concerned with the checking of the results obtained from the computer. This may consist of an inspection of graphical or tabulated data and an evaluation of the physical significance of the end result. Obviously, the use of a previously-prepared test solution to provide a check of the overall computational program is highly recommended. In the case of the boundary-value problem solved by trial-and-error techniques, a check must be made to determine the agreement between the terminal conditions obtained and the specified second boundary conditions.

The final step in the process is the feedback loop which is always required in an iterative-type solution. In the case of the boundary-value problem, the feedback loop is the operation by means of which the new trial eigenvalue is selected. This step may be a manual operation in which case all available human resources, such as previous experience, judgment, intuition, ingenuity, etc., may be used to an advantage. However, in the machine feedback loop the decision must be based on a previously-determined set of rules. The prime advantage of machine feedback is the possible utilization of the machine's high computing speed.

It is apparent from the preceding introductory remarks that a detailed consideration of each of the individual blocks of Fig. 1 is required. The importance of a well-balanced time distribution among the various steps in the computational process can not be overemphasized!

Brief Physical Description of the Computers

The following photographs are presented in an attempt to provide a concept of the physical dimensions of some of the computers employed in this study. Fig. 2 is a photograph of the *602A* Electro-mechanical Calculator. The principal instructions for this machine are conveyed to it by means of wires on the control panel, that is, manually inserted wires serve to instruct the calculator to perform the various arithmetic operations of addition, subtraction, multiplication, and division. Twelve separate program steps are available for inserting time-sequenced operations. The *602A* is basically an 8-digit fixed-decimal calculator, and the speed of operation varies between 6 and 50 cards per minute.

Fig. 3 illustrates the physical dimensions of the *604* Electronic Calculator. The calculator operates with 5 decimal-digit numbers at a basic repetition frequency of 50,000 cycles per second. This clock frequency is sufficiently high to permit the execution of 60 different program steps for each punched card passing through the calculator. The machine performs all calculations at a constant speed of 100 cards per minute. In the solution of the boundary-value problem the *604* Calculator is wired to perform 12 decimal-digit arithmetic using a fixed-decimal number system.

Fig. 4 shows the four separate machine units which are interconnected to form the Card-Programmed Calculator (CPC):

1. *412* Accounting Machine;
2. *605* Electronic Calculation;
3. *527* Punch;
4. *941* Storage Unit.

The principal distinction between the CPC and the previously-described *602A* and *604* Calculators is that the CPC receives its instructions in the form of punched cards. Hence, it is no longer necessary to manually wire a control panel for each new computation. One need prepare only the corresponding instruction cards. In this study a so-called general purpose control board was used in the computation. This control panel permits 8 decimal-digit arithmetic using a floating-decimal number system.

Fig. 5 shows the MIT Rockefeller Dif-

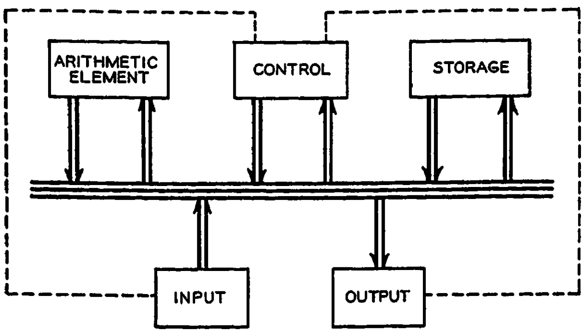

Fig. 6. Typical digital computer block diagram

ferential Analyzer (RDA). This is an analogue machine which is unique because it is the only differential analyzer in existence which receives its instructions on a punched paper tape. It is also the most accurate wheel-and-disc analyzer ever constructed. The machine is designed to provide a maximum accuracy of 5 decimal digits. Specific comments regarding the overall accuracy attained in the solution of the boundary-value problem is given in a later section.

The Functional Characteristics of Computers

During the past decade there has been a tremendous development in the field of digital computation. A host of digital computers have been developed which possess a wide variety of basic characteristics and associated capabilities. Much has been written about these computers, and, therefore, no effort will be made here to repeat what has been said. An attempt will be made, however, to illustrate the relative advantages and limitations of the various computers employed in this investigation.

A digital computer is a device which performs the four fundamental arithmetic operations and makes a few simple decisions upon discrete numerical data. The distinction between the digital computer which employs discontinuous information, and the analogue computer which employs continuous information should be noted. Fig. 6 is a block diagram of the basic computer elements of a digital computer. The diagram illustrates the basic computer elements as separate and distinct units. Actually, this is an oversimplification of the facts. Very often no clear distinction exists between some of these functional blocks; however, as presented, they do provide a basis for a discussion of the relative merits of the different computers.

The over-all effectiveness of digital computers for computational purposes is dependent on the following characteristics:

1. The type of instructions required by the computer. This determines the amount of time required to program the computer.
2. The actual form in which the instructions and input data must be presented to the computer; for example, binary, octal, decimal, etc. This influences the time required to code a problem for the computer.
3. The rate at which the computer accepts data into its internal storage. That is, the speed of the input device affects the time required to set up the computer.
4. The speed with which the arithmetic element performs the different arithmetic operations. This determines the actual internal machine solution time of a problem.
5. The internal high-speed storage capacity of the computer. This characteristic dictates the complexity of the problem which may be conveniently solved on the computer. The distinction between the high-speed internal storage and the low-speed external storage should be emphasized.
6. The accuracy with which a computer performs its operations. This is very important and is largely determined by the actual digital capacity of the registers or counters used in the arithmetic operations.
7. The speed of the output unit. Naturally this strongly influences the capabilities of a computer. Furthermore, the actual form of the output data is of considerable importance.

In addition to the characteristics just mentioned, a true determination of the figure-of-merit of a digital computer must include certain economic considerations such as the initial investment cost, the maintenance and operating costs.

It is evident that a well-designed computer will possess a set of characteristics which is based on a judicious selection of the desirable qualities just mentioned. Admittedly, the ideal computer has yet to be designed; however, each of the succeeding models illustrate remarkable improvements. Since the computers used in this investigation are far from ideal, a just evaluation of their capabilities must include a fair evaluation of the over-all characteristics.

Fig. 7 illustrates the functional characteristics of the *604* Electronic Calculator. The numerical digits indicate the decimal digit capacity of each internal unit. One of the most attractive features of this machine is an 8-decimal-digit channel which permits the internal transfer of information among the various units in a single program step. This provision of a common channel for the data transmission eliminates the need for manually providing a data transmission path of the type required on the *602A* Calculator.

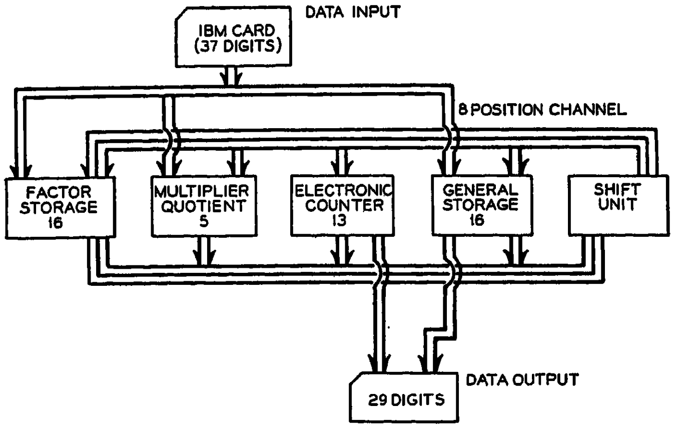

Fig. 7. Block diagram of the 604 Electronic Calculator

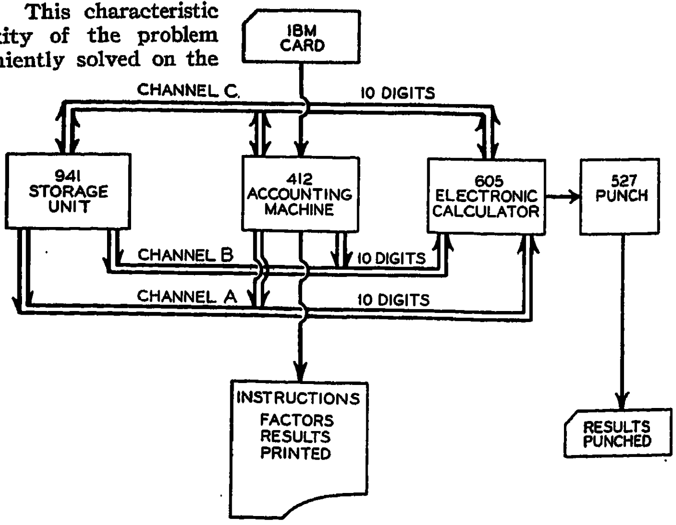

Fig. 8. Block diagram of Card-Programmed Calculator

Furthermore, the existence of undesirable back circuits is thereby precluded, and as a result, the wiring is enormously simplified and the machine set-up time is correspondingly reduced.

Fig. 8 illustrates the functional character of the individual units contained in the CPC. The punched card input to the CPC contains two types of cards, the instruction cards and the data cards. These cards are accepted by the *412* Accounting Machine at a rate 100 or 150 cards per minute. The *412* machine interprets the instruction cards and acts as a control unit for the CPC. If desired, a continuous printed record of the instructions, the factors involved, and the results of the operation is available as the computation progresses. Needless to say, a printed record of this type is extremely valuable to check the results of a computation and also to perform error-diagnostic studies. In this manner, information both before and after the computation is printed for inspection, should the need arise.

The *605* Electronic Calculator performs all of the electronic arithmetic operations, and it may therefore be referred to as the arithmetic element of the CPC. If desired, the results of a computation may be sent to the *527* unit, which punches the answer on IBM punched cards.

Solution of the Boundary-Value Problem

As an illustration of the manner in which a boundary-value problem may be handled on the CPC, consider the solution of the following equation

$$\frac{d^2p}{dx^2}+\left\{2E+\frac{2Z_p}{x}-\frac{l(l+1)}{x^2}\right\}P=0 \tag{1}$$

subject to the boundary conditions

$$P(x=0)=0 \text{ and } P(x=\infty)=0 \tag{2}$$

The physical interpretation of this problem is of no particular concern as far as programming of automatic computing equipment is concerned; hence, no further discussion will be given.

However, if the following definitions are employed

$$G(x)=\left[\frac{l(l+1)}{x^2}-\frac{2Z_p}{x}\right] \tag{3}$$

and

$$\lambda=-2E, \tag{4}$$

then equation 1 may be written as

$$\frac{d^2p}{dx^2}=(\lambda+G)P \tag{5}$$

The next step is to replace the second-order derivative by a suitable difference formula—a formula designed to minimize the truncation error (the first term ignored in a power-series expansion of a function).

A new variable

$$y_n=p_n-\frac{h^2}{12}\left(\frac{d^2p}{dx^2}\right)_n \tag{6}$$

is now chosen, which is designed to eliminate the fourth derivative in a Taylor-series expansion of the function y_n. Using the familiar second-order formula

$$\Delta_n''y=y_{n+1}-2y_n+y_{n-1} \tag{7}$$

and a Taylor-series expansion for the functions y_n, we obtain

$$\Delta_n''y=h^2\left(\frac{d^2p}{dx^2}\right)_n-\frac{h^6}{240}\left(\frac{d^6p}{dx^6}\right)_n+\cdots \tag{8}$$

If only the first term in equation 8 is used to approximate the second derivative, the truncation error thus incurred is given by

$$T\simeq\frac{h^6}{240}\left(\frac{d^6p}{dx^6}\right)_n \tag{9}$$

If this approximation is applied to equation 5, equations 10 are obtained

$$\begin{aligned} P_n&=\left[\frac{1}{1-\frac{h^2}{12}(\lambda+G_n)}\right]Y_n \\ \Delta_n''Y&=h^2(\lambda+G_n)P_n \\ \underset{n+1/2}{\Delta}{}'Y&=\Delta_n''Y+\underset{n-1/2}{\Delta}{}'Y \\ Y_{n+1}&=\underset{n+1/2}{\Delta}{}'Y+Y_n \end{aligned} \tag{10}$$

These equations are applicable as long as the interval of integration h remains constant.

Fig. 9 illustrates the graphical character of the solution of Schrödinger's equation. The sensitivity of the machine solution to the particular eigenvalue used in the trial solution is clearly evident. For example, an accuracy of 6 decimal digits may be obtained for the eigenvalue. The critical behavior of the solution at the second boundary is also apparent.

The planning chart shown in Fig. 10 illustrates the manner in which the *602A* Calculator is used to solve equations 10. These equations represent the difference equations which are used to solve Schrödinger's equation. It is quite apparent from this chart that the capacity of the *602A* Calculator is taxed to the limit.

The internal storage capacities of the *602A* and *604* Calculators are inadequate to permit the solution of Schrödinger's equation at a point of interval change. However, the CPC may be used for this purpose. Fig. 11 illustrates a CPC planning chart which contains 14 instruction cards used to solve equations 10. Admittedly, 14 instruction cards are more than is needed for this problem; however, no effort was made to economize on the number of cards used.

The flow chart shown in Fig. 12 illustrates the manner in which Schrödinger's equation was solved on the Whirlwind Computer. First, it must be noted that both single- and double-register-length

$$2Z_p=Kr+F$$

numbers were employed. This was necessary to conserve storage space and still provide the desired accuracy. Computations were performed using 24 binary-digit numbers (approximately 7 decimal digits) and a floating-binary number system. The comparison test is used to automatically instruct the computer to select an appropriate computational subroutine. Specifically, as long as the interval of integration remains constant, the computer solves equations 10. However, at a point of interval change a different set of equations, 11 in number, must be solved, using a different subroutine.

The entire procedure described in the foregoing must be repeated as many times as there are interval points. That is, the flow chart illustrates the computation performed at a specific interval point. In this particular diagram the trial eigenvalue is contained in a manually-preset toggle-switch storage register, and it is manually altered for each new solution.

Analogue Computer Method of Solution

There are a number of special-purpose analogue computers in existence which are capable of solving the boundary-value problem, but they all possess a certain accuracy limitation which is inherent in any measurement-type device. It is true, however, that in general they perform very well on the particular class of problems for which they have been designed. This discussion is concerned with the solution of boundary-value problems on the RDA, but the techniques are applicable to the various types of analogue equipment.

Fig. 13 is a conventional machine diagram for the solution of Schrödinger's equation. It should be observed that only five of the integrators are used to solve the basic equation, whereas the remaining three integrators are used to solve the three additional equations listed in the subcaption.

On the basis of this investigation it is evident that, on the average, three or four significant figures is the maximum accuracy with which the eigenvalues may be ascertained. The computational accuracy decreases during the solution of the higher eigenvalues.

Conclusion

This paper has described the manner in which a boundary-value problem can be solved on automatic computing equipment. Space does not permit a detailed discussion of many of the pertinent factors involved in this study, that is, accuracy of solution, error-analysis tech-

niques, cost per solution, etc. Table I contains a comparison of the machine solution time for the six different computers employed in the study. It is apparent that the *604* Electronic Calculator is the most favorable computer for the particular problem under consideration because of its relatively short machine solution time (3 minutes for 150 interval points). The relatively-long solution time encountered on the Whirlwind Computer was predicated by the limitation in the output typewriter. This work was performed in April 1952, and at that time the output element consisted of a relatively slow output typewriter. This output unit increased the effective solution time enormously; for example, 19 minutes were required to print the results of one trial solution. This is to be contrasted with an actual computation time of 2 minutes, indicating a 17 minute loss of time for printing purposes.

The preceding discussion of computational philosophy emphasized the importance of a consideration of the overall computational problem of the type indicated in Fig. 1. It is therefore imperative that the problem preparation time be considered. Generally speaking, the time required to set up a digital computer is greater than that required for an analogue computer. Specifically, the necessary RDA schematics and control tapes were prepared and the first solution obtained in one 8-hour day. However, approximately 1 week (40 hours) was required to wire the control panel for the *602A* Calculator. The corresponding set-up time for the *604* Calculator was much less—only 8 hours were needed to set up a similar *604* control panel.

The CPC has the minimum set-up time. For example, 3 hours were required to prepare the planning charts and instruction cards required to solve the general interval-change equations previously described. Hence an actual solution was obtained in 4 hours.

It is with considerable hesitancy that the corresponding figures for the set-up time of the Whirlwind Computer are presented. Several weeks were required to prepare the final program shown in Fig. 12. Part of this long problem preparation time is attributed to personal inexperience with the Whirlwind code, and the details associated with its application. However, it is evident that the coding of the digital computer in which actual "bits" of numbers are to be manipulated is necessarily more exacting than a code in which arithmetic and trigonometric operations are simply coded with a single operational code. Clearly, the recent development of the Library of Subroutines by the Whirlwind staff will serve to materially decrease the time required to set-up such a problem.

Nondestructive Sensing of Magnetic Cores

DUDLEY A. BUCK
NONMEMBER AIEE

WERNER I. FRANK
NONMEMBER AIEE

Synopsis: A nondestructive method for sensing the information state of magnetic-memory cores is under development. This new method involves the use of a quadrature magnetic field which, when pulsed, produces an output voltage. The polarity of the output voltage contains the information: a positive output pulse represents a ONE, and a negative pulse a ZERO. Reading in this manner can be repeated indefinitely without destroying the information held by the core. The method has proven to be exceedingly fast, giving output pulses of 0.2 microsecond in duration, and because of the rapid flux change when sensing, the output voltage has been observed in excess of 1 volt per turn.

MAGNETIC cores with rectangular hysteresis loops are of interest to the field of digital computers because of their ability to hold, or "remember," the direction in which they have been magnetized. In digital computer terminology, a magnetic core may be said to contain a binary ZERO if its remanent flux is positive or a ONE if its remanent flux is negative. A group of magnetic cores can therefore hold a pattern of ZEROS and ONES which make up a binary number.

How Information is Stored in and Read out of a Magnetic Memory Core

Fig. 1 shows a single magnetic memory core together with a somewhat idealized plot of its rectangular hysteresis loop, i.e., a graph of the amount of magnetic flux (Φ) present in the core as a function of the magnetizing force (NI) impressed on that core.

To write a ZERO in the core, a pulse of current is made to flow in the magnetizing winding in a positive direction, setting up magnetic flux in a clockwise direction. This corresponds to a movement to the right (positive direction) on the Φ versus NI graph. It can be seen that if we move far enough to the right, following the curve, we will eventually end up on the upper horizontal slope of the hysteresis loop. We will have saturated the core, and regardless of how much the magnetizing force is increased, the flux in the core remains the same. When the magnetizing force is removed corresponding to a displacement to the left in the Φ-NI plane, we move along the upper horizontal slope until we come to rest at its intersection with the center line (no magnetizing force) marked "0." The graph indicates that almost the entire saturation flux is retained even after the magnetizing force has been removed. The core now holds a ZERO.

Conversely, in order to write a ONE, negative current sets up negative flux, i.e., counterclockwise. In terms of the Φ-NI plane this means that the core is moving to the left along the curve until it hits the bottom horizontal slope. When the magnetizing current is stopped, the core comes to rest at the intersection of the bottom horizontal and the vertical centerline. The core then holds a ONE.

The read process makes use of the fact that when a magnetic flux change occurs inside a coil, a voltage is generated in that coil. An output winding is placed on the memory core (bottom of sketch in Fig. 1), and a sensing pulse is applied to the input winding. The sensing pulse, also called "read" pulse, indeed, is nothing but a "write-ZERO" pulse. When it is applied, two possibilities exist: either the core holds a ONE or it holds a ZERO.

If the core holds a ONE, it starts out at the bottom, center, of the hysteresis loop marked "1" and begins to move to the right. The extent of this motion is indicated by the arrow marked "sensing pulse." As the core gets around the knee of this curve, a large change of flux occurs while we move from the bottom to the top of the rectangular hysteresis loop. This large change of flux generates a large voltage in the output winding, thus indicating that the core had held a ONE.

If the core holds a ZERO, (i.e., rests at the top, center, of the hysteresis loop) and a sensing pulse is applied, all that happens is that the core moves out to the right on the graph along an essentially horizontal line. Thus very little flux change occurs; therefore no voltage, or only a very small voltage, appears across the output winding, thus indicating that the core had held a ZERO.

A somewhat simpler way of looking at this read process is to imagine that it consists in magnetizing or "switching" the core into the ZERO position. If the core was initially in the ONE state, the flux has to be reversed, and therefore a change of flux occurs which generates an output voltage. If the core was already in the ZERO position, no change of flux is needed and no output signal is generated.

As shown in the foregoing, this system of reading destroys the stored information: after having been read, a core will always find itself in the ZERO, or "cleared" state regardless of whether it contained a ONE or a ZERO just prior to reading. If information is to be retained for further use, it must be rewritten into the core. The challenge, quite naturally, arose to devise a system of extracting information which would not destroy that information in the process. This paper describes one such nondestructive read system.

A Nondestructive Read System

This particular nondestructive read system is based on the tendency of materials with rectangular hysteresis loops to maintain their remanent flux in certain easy directions of magnetization. These materials behave in many ways like a single ferromagnetic crystal, or cube, with easy directions of magnetization along its edges. In the absence of an external field, the residual magnetization vector of such a cube will lie in one of these easy directions (Fig. 2, left). With this diagram reduced to a 2-dimensional picture (Fig. 2, right), a hard direction of magnetization can be imagined between each of the easy directions, as shown. If a magnetic field were applied at right angles to the remanent-flux vector, the vector would tend to align itself with the field and would thus be rotated away from its

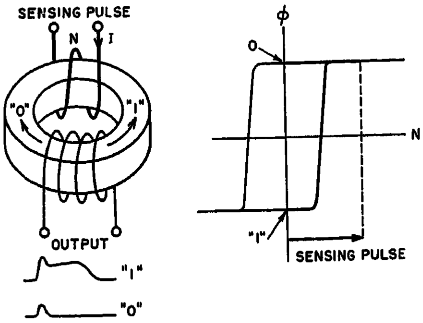

Fig. 1. Destructive sensing

Paper 53-409, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2–6, 1953. Manuscript submitted June 2, 1953; made available for printing October 2, 1953.

DUDLEY A. BUCK and WERNER I. FRANK are with the Massachusetts Institute of Technology, Cambridge, Mass.

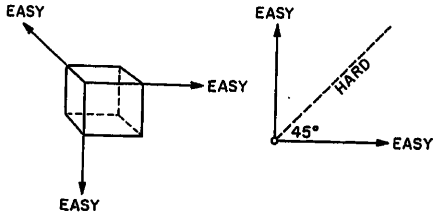

Fig. 2. Easy directions of magnetization

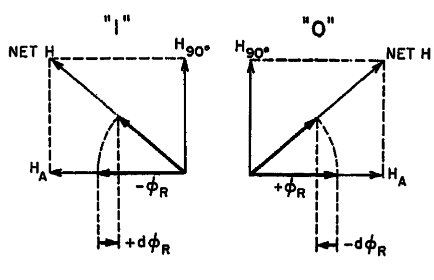

Fig. 3. Vector representation of nondestructive sensing

preferred direction toward a hard direction of magnetization. If this quadrature field were not strong enough to rotate the remanent-flux vector past the hard direction, this vector would snap back to its original easy direction as soon as the quadrature field was removed. (For easier identification, the usual magnetizing field on a core will henceforth also be referred to as the α field, while the quadrature field will also be called a β field.)

This same principle may be used in conjunction with larger masses of rectangular-hysteresis-loop materials. These materials may be thought of as made up of individual crystals all oriented in such a manner that one of their easy directions of magnetization lies in the direction in which the magnetizing (α) field is to be applied. In the case of a ring-shaped core, this means that one of the easy directions would be the tangential.

Fig. 3 illustrates what happens when a magnetic field is applied at right angle to the remanent flux of a memory core. The remanent flux (Φ_R) originally lies along the α direction (in line with $\mathbf{H}_A$). If the core contains a ONE, this will be in the negative direction ($-\Phi_R$); if it contains a ZERO, in the positive direction ($+\Phi_R$). When the quadrature magnetic field ($H_{90\ \mathrm{degrees}}$) is applied at right angle to $\mathbf{H}_A$, the two will combine, vectorially, to form a resultant field (net **H**). The remanent flux Φ_R will then line up with this combined field; i.e., it is rotated away from its easy direction of magnetization (along the dotted arc in Fig. 3). The magnitude of the flux, however, will remain essentially unchanged, since in a rectangular-hysteresis-loop material the remanent flux is practically the same as the full saturation flux. Therefore, the output winding on that core effectively will see the flux reduced from Φ_R to $\Phi_R \cos\theta$ (where θ is the angle of vector rotation), and a voltage is induced in the output winding. In the case of a zero with the remanent flux in the positive direction, the winding will see a negative change of flux ($-d\Phi_R$) as the β field is applied, and a positive change of flux as the β field is removed and the remanent flux is allowed to snap back into its preferred direction. Conversely, in the case of a ONE with the remanent flux in the negative direction, a positive voltage will be induced upon application of the β field, and a negative voltage upon removal of the β field. Thus, merely by observation of the polarity of the voltage induced in the winding of the memory core upon application of a β field, the state of magnetization of this core may be ascertained. In other words, the memory core may be read without destroying the information it contains.

It might be well to note here that this sensing operation does not switch the magnetic flux in the core, and that therefore it does not involve the destruction and formation of domain boundaries. This means that very little hysteresis loss is incurred and that the system is, potentially, very fast.

Experimental Setups and Techniques

As soon as it was attempted to try the proposed nondestructive read scheme, the question arose as to how to generate the β field. Two possibilities were envisaged: an externally generated β field, and an internally generated β field.

The Externally Generated β Field

A magnetic path, made of iron or some other material without a rectangular hysteresis loop, is so constructed that it contains a gap into which a memory core may be inserted (Fig. 4). Through a winding on the iron path, a short current pulse is driven which induces magnetic flux at right angles to the remanent flux of the memory core. The remament-flux vector is rotated for as long as the quadrature-field current flows, and the sensing winding (or output winding) sees the change of flux in the tangential direction. This change of flux, ideally, occurs just as rapidly as the current in the β-field winding can build up. Now, the voltage induced in the sensing winding is proportional to the time rate of change in flux which this winding sees; so that, although the flux change is relatively small, the voltage output might be quite large if the change can be made to take place in a very short time.

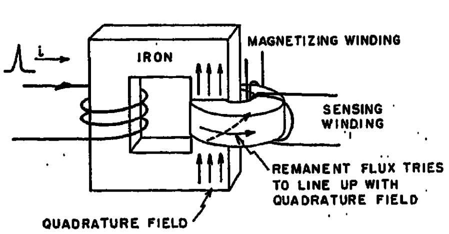

Fig. 4. Externally generated β field

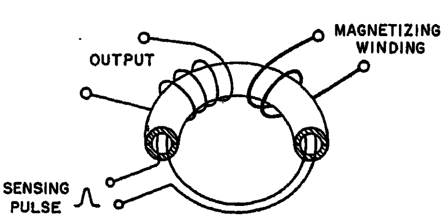

Fig. 5. Hollow toroid geometry

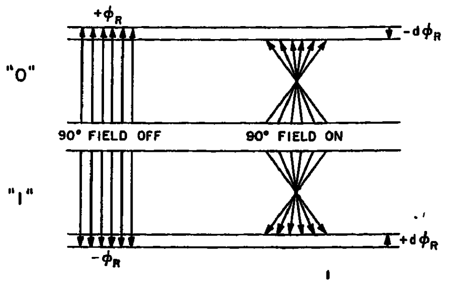

Fig. 6. Vector representation of hollow toroid sensing

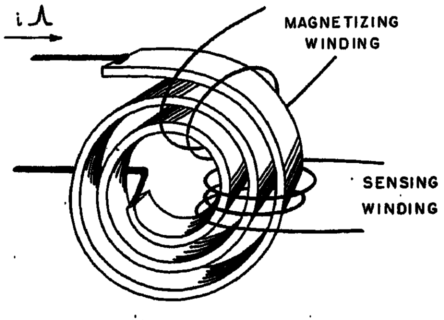

Fig. 7. Metallic-ribbon-type memory core connected to generate β field internally

The Internally Generated β Field

Consider a hollow, toroidal magnetic-memory core (Fig. 5) with a conductor placed circumferentially inside the hollow. The magnetizing winding occupies its usual place, and, after current has been allowed to flow through it, residual flux will exist along the large circumference. When a current pulse is sent through the conductor inside this hollow toroid, a field will temporarily exist around the conductor, deflecting the circumferential remanent flux in either a clockwise or counterclockwise direction. The effect may be compared to that obtained by

twisting a handful of "Chinese sticks" (Fig. 6). Again, in the case of a ZERO we will first see a negative change of flux as the 90-degree field is turned on, followed by a positive change as the field is removed, and the vectors revert to their original positions; conversely, in the case of a ONE we will see a positive change followed by a negative one.

K. H. Olsen suggested, and first tried, a different way of generating internal β fields in ribbon-wound cores. With leads attached directly to the two ends of the metallic tape (Fig. 7), the core itself forms the path for the quadrature-field current.

In Fig. 8 is shown a perpendicular cross section of the metallic tape. The large arrow protruding from the face of the section represents a quadrature-field-current vector surrounded by its associated magnetic field (counterclockwise). Since the entire tape conducts current, the total resultant quadrature field will be strongest around the outside edges of the section (represented by the six thin arrows in the plane of the section). The remanent-flux vectors perpendicular to the plane of the section are deviated by this field as shown; again a sensing winding will detect the change of flux.

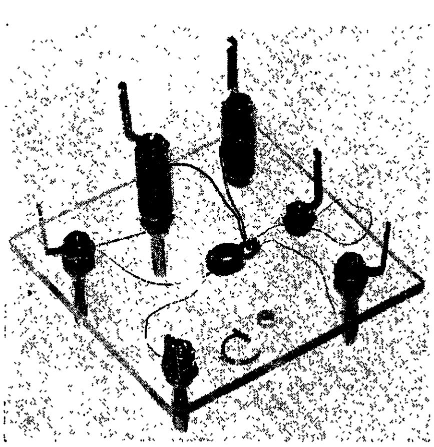

Fig. 9. Arrangement for an externally generated β field

OTHER QUADRATURE FIELDS

The possibility was also envisaged of using a third field at right angles to both the initial remanent flux (α field) and the 90-degree field (β field). This might be called the γ field and might be useful for some sort of coincident-field selection scheme, in which, for instance, the β field is pulsed along the rows and the γ field along the columns of a matrix. A ONE, say, would be indicated by coincidence of pulses on two output windings, one sensitive to β excitation and the other to γ excitation.

TYPICAL SETUPS

Fig. 9 shows a typical arrangement for an externally generated β field: The memory core is a rectangular-loop ferrite (*MF-1118*, made by General Ceramics and Steatite Corp., Keasbey, N. J., die size *F-259*) with a 1-turn magnetizing winding and a 20-turn sensing (output) winding. The quadrature field is developed across a slot cut in a larger core, also a ferrite (*MF-666*, made by the same company, die size *F-262*, outside diameter about 3/8 inch), with a 20-turn exciting winding. The Lucite board measures 3 by 3 inches. Fig. 10 shows a metallic-ribbon type of core set up for an internally generated β field. The core is wound of 15 wraps of a rectangular-loop nickel-iron alloy (Deltamax, made by Allegheny - Ludlum Steel Corporation, Brackenridge, Pa.) 0.001 inch thick and 1/4 inch wide, with an inside diameter of about 2 inches, and a 20-turn sensing (output) winding. Fig. 11, another internal β-field setup, shows a core made up of 10 wraps of a nickel-iron-molybdenum alloy ribbon (*4-79* Mo-Permalloy, made by Magnetics, Inc., Butler, Pa.), 1/4 mil thick and 1/8 inch wide, with a 2-turn magnetizing winding and a 20-turn sensing winding.

EQUIPMENT USED

Most of the data were obtained using the core-testing setup shown in Fig. 12. This arrangement is made up largely of Massachusetts Institute of Technology (MIT) Digital Computer Laboratory standard test-equipment building blocks. It furnishes, for magnetizing and sensing circuits, three pulses, one of maximum amplitude 750 milliamperes ($\mathbf{H}_m$) and two each with a maximum of about 400 milliamperes ($1/2\mathbf{H}_m$), which may be combined to form one pulse of 800 milliamperes.

The no. 3 pulse will always follow a no. 1 pulse (unless, of course, the switches 1 or 2 are opened), after which from 0 to well over 100 no. 2 pulses may be inserted. The length of these pulses may be varied by adjusting the time delay between the input to and the output from the gate and delay unit no. 2 (near the bottom of the block diagram of Fig. 12) from about 0.2 microsecond to well over 100 microseconds. For every particular setting, all three pulses will be of equal width. The repetition rate is varied by changing the free-running frequency of the high-frequency multivibrator in the multivibrator

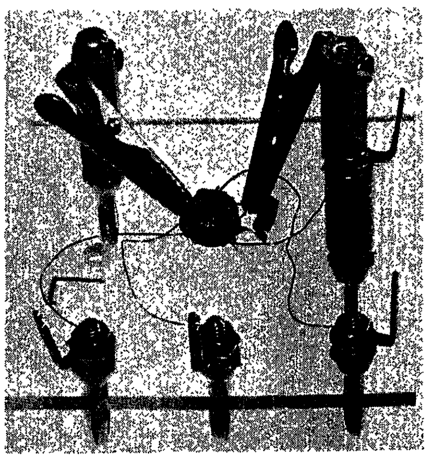

Fig. 11. 1/4-mil Mo-Permalloy with internal β field

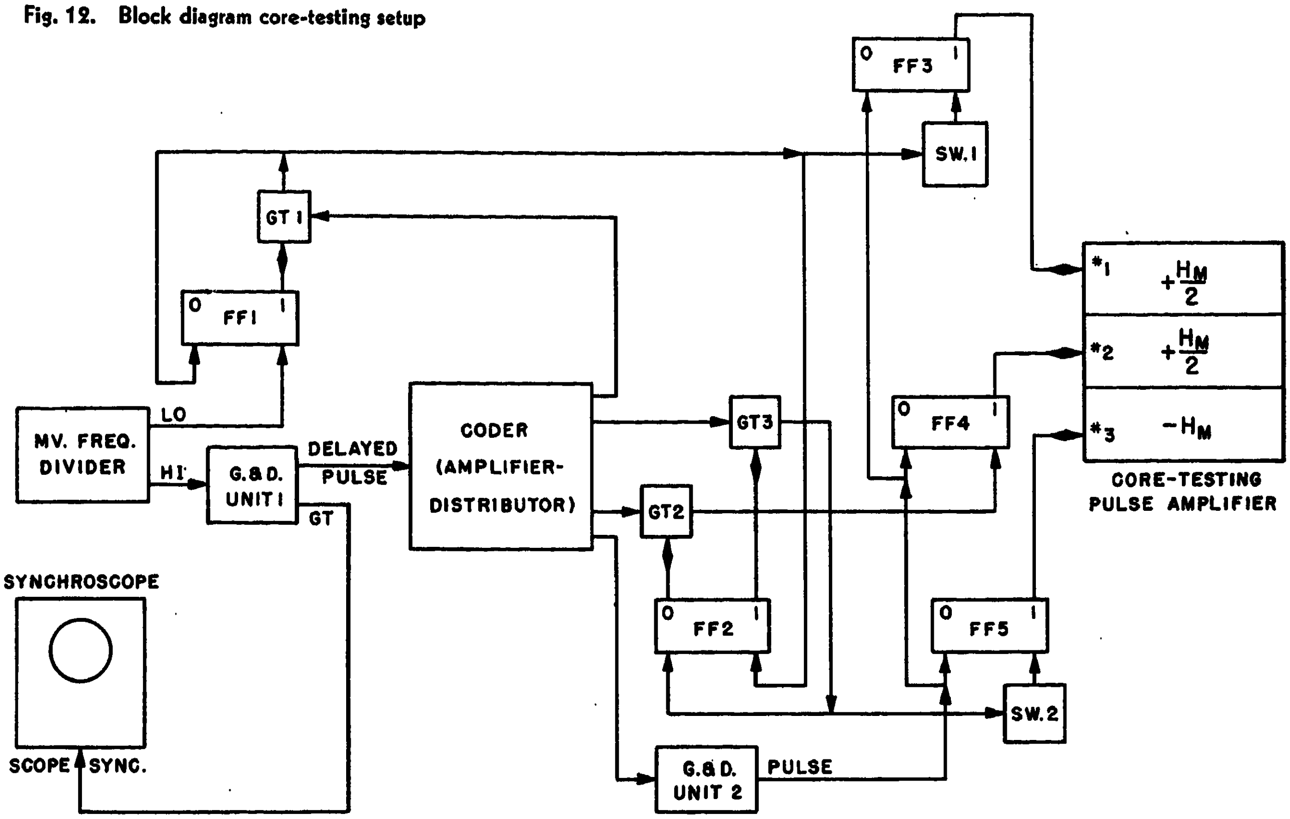

Fig. 12. Block diagram core-testing setup

frequency divider from about 2 to about 250 kc.

The amplitude of the current pulses is variable from 0 to about 750 milliamperes. For those tests requiring larger currents, a thyratron pulse generator was used varying from about 0.8 ampere to 3.8 amperes. The number of no. 2 pulses inserted between nos. 3 and 1 is varied by varying the low frequency of the multivibrator frequency divider.

Oscilloscopes

All measurements (except d-c resistance measurements), readings, and photographs were taken on either a type *513D* or a type *514D* Tektronix scope, both having a 1-megohm and 40-micromicrofarad input impedance.

Steady-State Measurements

For steady-state measurements, the core was switched into ZERO and ONE position by means of a battery, a key, a variable resistor, and a reversing switch. Once the information had thus been stored, only one pulse was needed: the quadrature-field readout pulse.

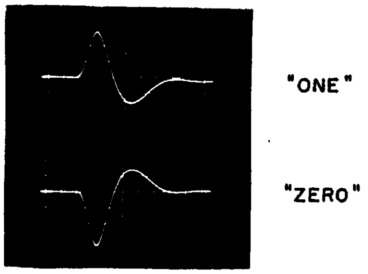

Fig. 13. Typical wave forms in an unterminated output winding

Transient Measurements

For transient measurements, again, the information was stored, initially, by means of the outside battery. Then, with *SW* 1 open, the quadrature-field leads were connected to pulse no. 2 and the magnetizing winding of the core to pulse no. 3. Thus a variable number of readout pulses could be set up, followed by a remagnetizing pulse.

Experimental Results

Typical Wave Forms

Fig. 13 shows typical wave forms (voltage versus time) obtained with an open output winding. The top wave form shows the output of a memory core holding a ONE. It illustrates the positive change in flux (represented by the positive voltage induced in the sensing winding) as the β field is turned on, followed by a negative change as the β field is removed and the remanent flux returns to its easy direction of magnetization. When the information held by the core is changed to a ZERO (Fig. 13, bottom), a pattern of opposite polarity is observed.

Fig. 14 shows the output of a metallic-ribbon type of core into a 20-turn sensing winding terminated in 93 ohms, with both internally and externally generated β field. As may be seen, the loading of the output winding has the effect of slowing down the return of the disturbed remanent-flux vector to its easy direction of magnetization, so that the output signal is essentially confined to a single positive pulse for a ONE and a negative pulse for a ZERO.

There is a striking similarity between

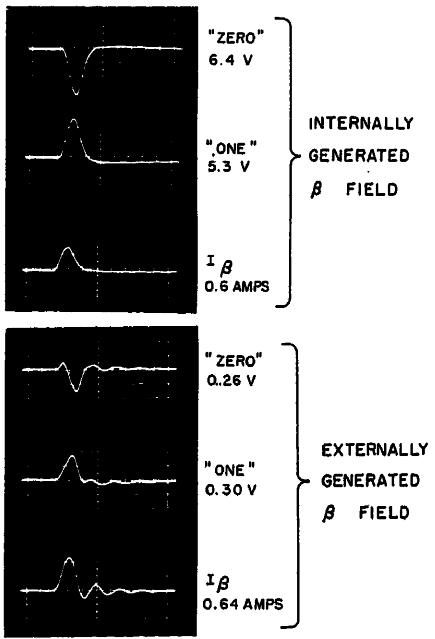

Fig. 14. Typical wave forms in an output winding terminated with 93 ohms

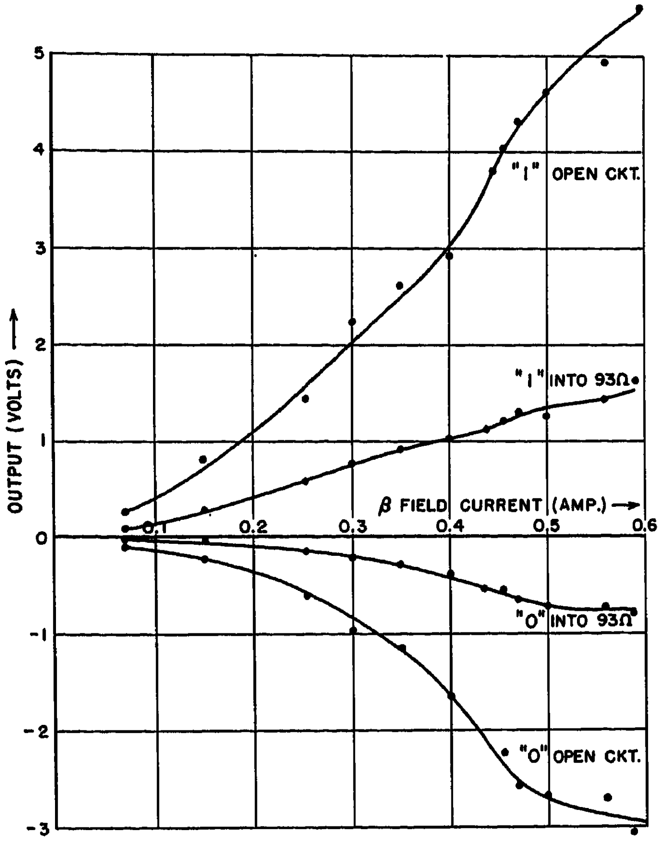

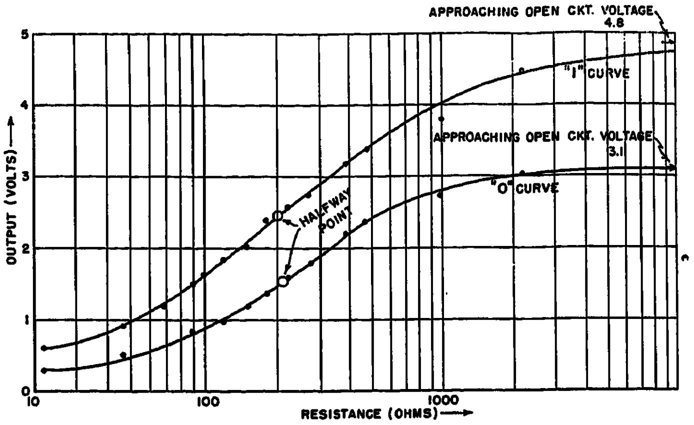

Fig. 15 (left). 6-wrap Mo-Permalloy core—graph of output voltage versus β field current

Fig. 16 (above). 6-wrap Mo-Permalloy core—graph of output voltage versus terminating resistance

results obtained with the two different methods of generating the β field. Except for a scale factor and some oscillation introduced by the external β field, the results may be said to be alike. This is as it should be: the output of the memory core should not depend on the manner in which the quadrature field pulse is generated. Material used is a 40-wrap, 1/8-inch wide, 1/4-mil thick Mo-Permalloy core with a 20-turn output winding. The external β field was generated in a Ferramic-*D* core with a 10-turn exciting winding.

It should also be noted here how closely the output voltage follows the shape of the quadrature-field current pulse. The photographs in each series were taken to the same time scale; all of these pulses are about 0.2 microsecond long with a 0.1-microsecond rise time.

Output Voltage as a Function of Quadrature Field Currents

In the relationship between the magnitude of the output voltage and β-field current, only the internally generated field offers any sensible basis for comparison.

For the case of the external quadrature field, too many variables exist outside the memory core; the size of the quadrature field magnet (relative to that of the memory core), its magnetization curve, the amount of residual flux it retains, and the smoothness of the mechanical fit between it and the memory core are just a few of these variables. With the internally generated β field, all these parameters are fixed for each core.

Fig. 15 shows the output into 93 ohms and open-circuit voltages of a 6-wrap Mo-Permalloy core 1/4 mil thick, 1/8 inch wide, pulsed with a current-pulse 0.2 microsecond long, the amplitude of which was varied from about 0.07 ampere to over 0.6 ampere. The output winding has 20 turns. The curves are typical of many others, obtained both with externally and internally generated β fields.

There is a long, essentially linear (or slightly concave) rise of output voltage as the β-field current is increased, followed by a flattening out and finally (not shown in this graph) a rapid decrease of output as the nondestructive limit is exceeded. The decrease is probably caused by the quadrature field deflecting the remanent-flux vectors ϕ_n more than 45 degrees from their original position along H_A (see Fig. 3),so that they then line up along $H_{90\,\mathrm{degrees}}$ instead of dropping back to the H_A direction.

A certain asymmetry is noticeable in these curves; the ONE outputs are consistently larger than the ZEROS. This is caused by the β-field-current lead attached to the inside end of the metallic-ribbon memory core; since the current flows in from one side only, the magnetic field surrounding it will boost one direction of magnetization while bucking the other. Subsequently, an experiment was tried where two leads, one from each side, were attached to the inside end of the core. Through a pair of matched resistors, equal current flow through both leads was assured; as expected, most of the asymmetry disappeared.

Voltage Output as a Function of Terminating Resistance

Variation of the output voltage of the memory core with changes in the terminating resistance was observed in the same 6-wrap Mo-Permalloy core described in the foregoing. The plot in Fig. 16 on semilog scale, beginning with very low voltages for small values of terminating resistances, passes through a fairly straight region between 70 and 700 ohms and then, asymptotically, approaches the open-circuit voltage. The halfway point, or point of maximum power transfer, is reached near 200 ohms. A common way of specifying impedance of a winding on a magnetic core is in the unit "ohms per turn squared." For our 20-turn sensing winding, its apparent 200-ohm internal impedance gives, in these units, 1/2 ohm per turn squared. The quadrature-current pulse was 0.64 ampere maximum, about 0.25 microsecond long at the base.

Output Voltage as a Function of the Amount of Magnetic Material in the Memory Core

It soon became apparent that the output of a given magnetic core varies a good deal according to its size or the amount of material used. Moreover, the variations seemed to follow different patterns, depending on whether externally or internally generated β fields were used for the readout.

Externally Generated Quadrature Field

One set of metallic-tape cores was ordered containing 1, 2, 4, 8, 16, 32, and 64

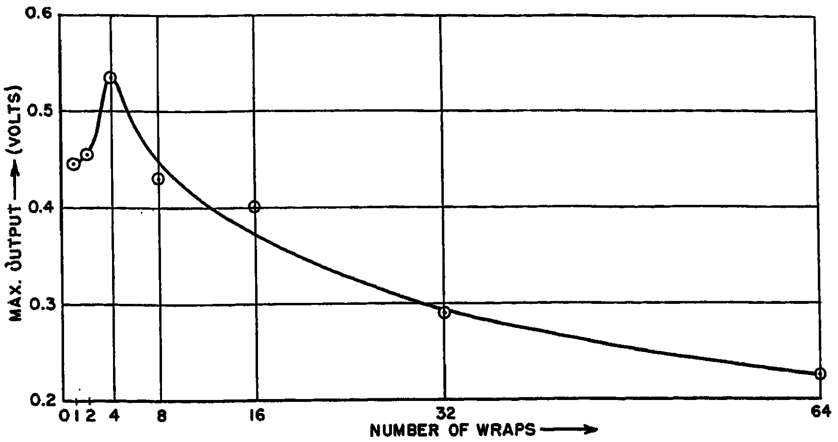

Fig. 17 (above). Output voltage as a function of the number of wraps (external β field)

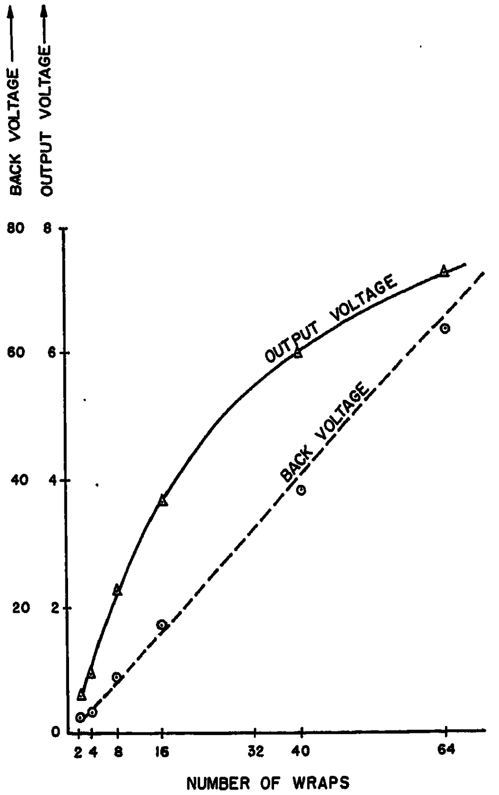

Fig. 18 (right). Output voltage and back voltage as a function of the number of wraps (internal β field)

wraps respectively. A Ferramic-*D* core with a 10-turn exciting winding was prepared by grinding a slot into it just wide enough to receive the metallic memory cores. The latter were Mo-Permalloy 1/4-mil thick and 1/8-inch wide, with 20-turn sensing windings. Then, with a constant β-field pulse of 0.72 ampere and 0.2 microsecond long, maximum output was recorded for each core. Fig. 17 shows the maximum output for each core in that series plotted against the number of wraps in each. The result seems odd at first; one would expect to find an increased output as the amount of material in the core is increased. But it should be realized that there exists an air gap between the edges of the β-field magnet and the memory core material of at least the thickness of the two flanges of the bobbin on which the metallic tape is wound. The β-field flux is therefore fairly constant no matter how many wraps of material are inserted; however, the flux density will be smaller the more wraps of material are on the memory core. Below four wraps, leakage or saturation (or both) reverses the normal trend.

Internally Generated β Field

The curve of output versus number of wraps of material for the internal β field, the solid line in Fig. 18, starts out quite linearly but soon begins to rise more slowly. Presumably, above a certain large number of wraps no further rise in output would be noticeable as the amount of material is increased.

The back voltage versus number of wraps (broken line) indicates a linear relationship between these two variables, as had been expected. Back voltage in all cases amounted to several times the output voltage.

BACK VOLTAGE AND POWER CONSIDERATION

When considering the nondestructive read system from the point of view of power economy, one is immediately aware of its very low efficiency as a power transformer.

An indication of the peak power involved may be had by multiplying the current peak by the peak of the back voltage. These peaks, from observation, occur simultaneously. Peak power output will then be given by

$$P_{\text{out}} = \frac{(E_{\text{out}})^2}{R}$$

where E_{out} is the peak voltage appearing across the sensing winding and R is the terminating resistance. Four typical cores are illustrated in Table I; setups L and N_{02} used internally generated β fields, setups C and M_{04}, externally generated β fields.

The materials used in Table I are:

Setup C (shown in Fig. 9)
  Memory core: *MF-1118* size *F-259* ferrite core, with 20-turn sensing winding.
  Quadrature-field magnet: *MF-666* size *F-262* with 20-turn exciting winding.

Setup M_{04}
  Memory core: 4-wrap 1/4-mil-thick 1/8-inch wide Mo-Permalloy, 20-turn output winding.
  Quadrature-field magnet: Ferramic *D* 13/16-inch outside diameter with 10-turn exciting winding.

Setup *L* (shown in Figure 11)
  Mo-Permalloy core 1/4-mil thick, 1/8-inch wide, 10-wrap, with 20-turn sensing winding.

Setup N_{02}
  Mo-Permalloy core 1/4-mil-thick, 1/8-inch wide, 2-wrap, with 20-turn sensing winding.

Table I. Approximate Efficiency Calculations

Peak	Setup			
	External β Field		Internal β Field	
	C	M_{04}	L	N_{02}
I_{Beta}(ampere)	1.0	0.72	0.72	0.168
V_{Back}(volt)	130	39.0	3.5	0.5
P_{in} (VA)	130	28.1	2.52	0.084
E_{out} (volt)	0.55	0.6	0.6	0.1
R (ohm)	93	93	100	93
P_{out} (watt)	0.0033	0.0039	0.0036	0.00011
Ratio: $\frac{P_{\text{in}}}{P_{\text{out}}}$	39,000	7,200	700	760

As may be seen, back voltages vary a great deal. In the four cases shown they range from 130 to 1/2 volt.

For applications where outputs of 0.1 volt would be sufficient and where small back voltages are desirable, setup N_{02} might be suitable. For applications where large output voltages are needed, a 120-wrap Deltamax core might be useful. Open-circuit outputs of over 50 volts in a 20-turn sensing winding have been obtained with a fast-rising 3.2-ampere β-field-current pulse. This same setup yielded over 20 volts into a 93-ohm terminator.

TRANSIENT BEHAVIOR

An important question arose early in the investigation: how permanent is this nondestructive read system? It was ob-

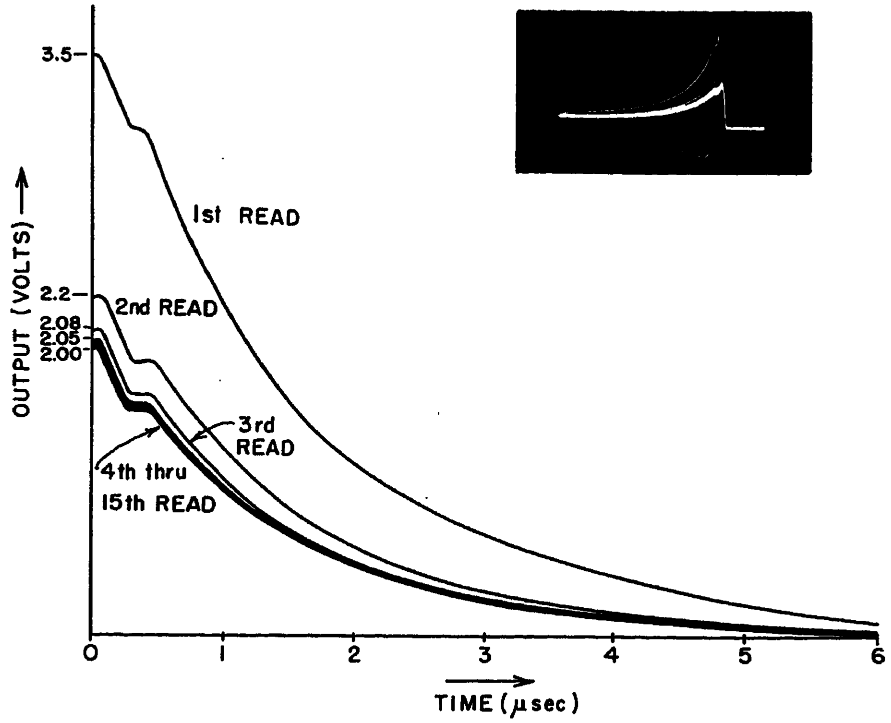

Fig. 19. First 15 readouts from a freshly magnetized core

served that for a quadrature-field pulse of given magnitude and length, the readout signal did not always remain constant. With relatively short pulses of small amplitude, no change could be detected; but when the quadrature-field pulse approached the limit of the nondestructive system, a definite change could be observed in the magnitude of the readout signal. From a maximum output obtained with a freshly magnetized core, the output would shrink, rapidly at first and then more slowly, until it finally settled at some steady value.

Fig. 19 shows the traces, as observed on the oscilloscope, of the first 15 nondestructive readout signals obtained from a freshly magnetized core with internally generated β-field pulses. (The actual photograph is reproduced in the insert; for better visibility the traces were redrawn to a much larger scale.) The pulse was 0.36 ampere high and 6.5 microseconds long, which, for the type of core used, is very near the destructive limit.

The transient behavior appears to be of an exponential nature. The values obtained are given in Table II. The core used was a 1/4-mil-thick 1/8-inch-wide 40-wrap Mo-Permalloy core. Repetition rate was 4 kc. At this relatively slow rate, the steady state was reached after about 2 to 3 seconds; for over an hour thereafter no further changes were observed. Other endurance tests were run up to 1,200,000,000 readouts, and in all cases no further deterioration of the output signal was noted once it had settled down. The number of pulses needed to reach a steady state seems to be inversely related to the magnitude of the quadrature-field pulse. In several cases involving short pulses (0.2 microsecond), steady state is reached after the second reading.

Readout Time

As far as was observed, the lower limit of the readout time seems to depend only on the rise time and length of the β-field-current pulses which the available equipment is able to provide. The fastest pulses so far have been of 0.1-microsecond rise time and 0.2-microsecond total length. As illustrated in Figs. 13 and 14, the readout signal occurs almost simultaneously with the quadrature-field pulse. There seems to be every reason to expect, if even steeper and narrower quadrature-current pulses could be provided, that the readout signal would also become steeper and narrower, and the voltage correspondingly higher.

Some Further Experiments

Effects of Reinforcing Residual Flux

An investigation was made to see what happens when direct current is allowed to flow in the memory core's magnetizing winding (α-field winding) while β-field pulses are applied. The effect of the direct current is to increase the α field. Because of the rectangularity of its hysteresis loop, the magnitude of the residual flux is almost unchanged, but its position is more firmly held in the α direction: it has been reinforced. Measurements were taken of the core output caused by a given magnitude of the β-field pulse, first without the reinforcing current and then with it.

With a small quadrature-field read pulse the output signal decreased as the residual flux was reinforced. With a relatively large quadrature pulse the output increased when the residual flux was reinforced. W. N. Papian of MIT's Digital Computer Laboratory explained this phenomenon as follows.

As the small β field causes the residual-flux vector to rotate, the sensing winding sees a certain flux change, $\Delta\phi$ in Fig. 20 (A). When the residual flux is reinforced, the vector is still of the same magnitude but can no longer be rotated as easily as before, Fig. 20(B), resulting in a smaller flux change and hence in a smaller voltage output.

The large β-field pulses, in the absence of direct current in the magnetizing winding, are powerful enough to switch some of the smaller domains into the 90-degree direction, Fig. 20(C), and the residual flux in the α direction reaches a steady state somewhat below its saturation value. The domains still in the α direction are deflected as usual; again, the sensing winding effectively sees a change of flux, $\Delta\phi$. Now, when sufficient direct current is allowed to flow in the magnetizing winding, the small domains are reswitched into the α direction, and thus the total residual flux in that direction is larger than before. If the rotation caused by the β-field pulses is not too much reduced, the sensing winding will see a larger change of flux than before.

Switching Time of a Memory Core While β Field is Applied

The primary function of the β field is to rotate the remanent flux away from its easy direction of magnetization, that is,

Table II. Successive Output Voltages

Read Pulse		Output (V)
1st		3.5
2nd		2.2
3rd	(estimated 2.08)	2.0–2.1
4th	(estimated 2.05)	2.0–2.1
.....		.....

15,000,000th		1.5

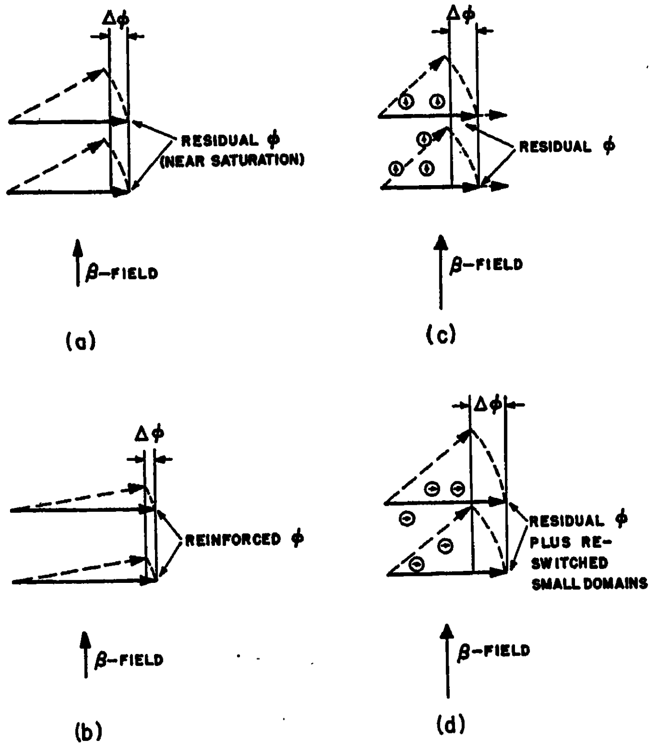

Fig. 20. Effect of reinforced residual flux

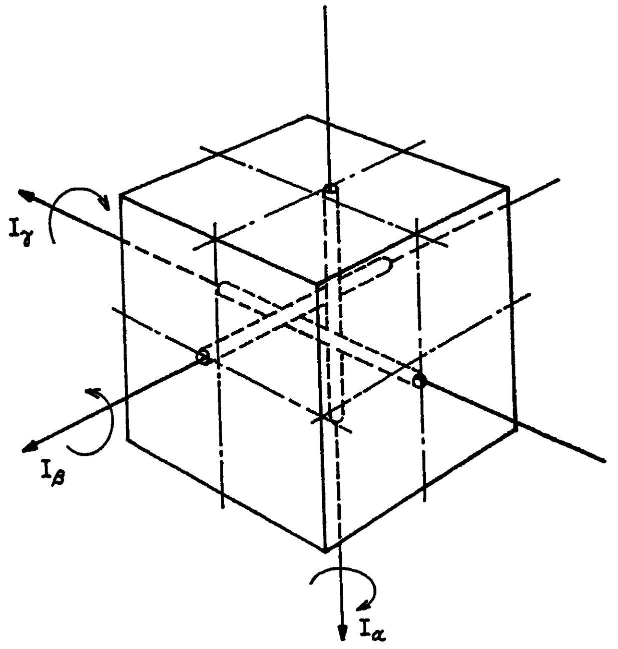

Fig. 21. Internally generated quadrature fields for ferrite material

away from its most stable state. It was thought that the application of a β field while the α direction was being switched, say, from a ZERO to a ONE would facilitate this switching process and thereby reduce the switching time of the core. Indeed, it was found that switching time could thus be reduced by up to 30 per cent for a given number of ampere-turns.

Regenerative Effect

During the attempt to find the maximum amplitude and length of the quadrature pulse which various memory cores would tolerate and still yield a nondestructive readout signal, an unexpected phenomenon was observed: under certain circumstances, when information retained by a memory core had been largely destroyed by the application of too powerful a quadrature field, this information could be restored merely by shorting the sensing (output) winding of the memory core during the application of a few quadrature-field pulses. For simplicity's sake, this effect will be referred to as the regenerative effect.

The effect is by no means found in all cases. So far, it has been observed in only four of the metallic cores, out of over 30 which were used during this investigation, and in none of the ferrite cores.

In a typical case, a 40-wrap 1/4-mil-thick 1/8-inch-wide Mo-Permalloy core with a 20-turn unterminated output winding was used. With a 0.5-ampere current pulse of 0.1-microsecond rise time and 0.2-microsecond length, a ONE output of 13.5 volts was obtained. As the current-pulse length was gradually increased, the output fell, rapidly at first and then more slowly, until at 50-microsecond pulse length only 1.4 volts was measured. The pulse length was then gradually reduced back to 0.2 microsecond; the output, however, did not rise above 2 volts, indicating that the information had been largely destroyed, probably because most of the domains had switched into the 90-degree direction of the β field.

The output winding was then short-circuited while the β-field pulses continued, and regeneration took place; i.e., after the short circuit across the output winding had been removed, the output voltage again stood at 13.5 volts, suggesting the remanent flux had been restored to its original magnitude.

When instead of a short circuit a small resistor was placed across the output winding, the gradual regeneration could actually be observed on the oscilloscope. Similar results were obtained when the core was magnetized along minor hysteresis loops: application of quadrature field pulses to the core, while its output winding was short-circuited, brought the remanent flux back to its full saturation value. No satisfactory explanation of this phenomenon has yet been found. Any thoughts the reader might have about it would be appreciated.

Internal β Field for Ceramic Cores

A system for generating a β field, and even a γ field, internally, was proposed by R. F. Jenney of MIT's Digital Computer Laboratory. A small cube of ferrite material, Fig. 21, is drilled in the three perpendicular directions in such a manner that the three hollows thus obtained pass near one another without actually intersecting. The cube may then be regarded as a core, with the α-current (I_α) conductor representing the magnetizing winding and the β- and γ-current conductors carrying the quadrature field currents.

Tests with such a drilled-out block of ferrite *MF-1326B* show that nondestructive reading can be obtained by this scheme.

Some Possible Applications

Applications for the nondestructive read system could be found wherever permanent or semipermanent memories are used in computers or similar machines. A magnetic-core binary counter (currently being investigated at the MIT Digital Computer Laboratory) could be equipped with this nondestructive read system, so that the actual count at any one instant could be ascertained without interruption of the process. A permanent register could be built consisting of, say, 16 cores which might be set up by individual toggle switches. If their quadrature fields could be pulsed in series, or possibly if they could all be disturbed by the same quadrature field, all 16 cores could yield their information simultaneously, without the necessity of having to rewrite the information.

Another possibility might be the use of

internally generated β field in a static read system for magnetic-tape recorders or memories using metallic tapes. Finally, Dr. M. S. Blois suggested the ferromagnetic relaxation oscillator. An oscillator based on the deviation of the magnetic vector under the influence of the quadrature field plus the gyroscopic precession to which this vector would be subject, might be stable, since only atomic phenomena are involved, in an ultrahigh-frequency region not accessible to quartz resonators. Frequency should be about 5 megacycles per gauss.

Conclusions

The principal conclusion to be drawn is that this nondestructive read system works; it furnishes positive information as to the state of magnetization of a memory core without changing that state. The system is fast, and readout times of well below 1 microsecond are easy to achieve; the lower limits of the system's time response have not yet been found. The system is versatile: several types of material are suitable to be used with it, and two variations of the system have been successfully demonstrated. Furthermore, the effect is not a small one; outputs of over 1 volt per turn have been achieved.

More specifically: the internally generated β field seems to have several advantages over the external one: it is more compact and more efficient; back voltage can be reduced to reasonably small values (for mass applications); and, above all, output does not depend on position, air gaps, and other variables. External fields, however, would allow the use of a second quadrature field, perpendicular to both the α and the β field

No Discussion

Type-7 Crossbar Selector

ROBERT W. HUTTON
NONMEMBER AIEE

THE TYPE-7 crossbar selector is a mechanism for selecting one of several trunk groups in a dial telephone switching system. Each of these trunk groups may lead to a subsequent rank of group selectors, to connectors (final selectors), to outgoing trunks, or to one of several special services. Switching in this case is based on a system of decimal numbering; consequently the selector, in response to a single pull or digit of a telephone dial-calling device, provides a choice of one trunk group out of 10. The selector consists of a group of relays, a magnetic impulse counter to register the digit, and certain permanently associated portions of several crossbar switches. Generally, each selector has access to 100 outlets, which are arranged in 10 groups of 10 paths each.

In modern telephone practice, it is widely recognized that to provide trunking flexibility, group selectors are desirable, and often a necessity, even in small initial installations, such as a community dial office. The ease of equipment growth thus gained is self-evident. With the advent of nation-wide toll dialing and customer toll dialing, the area and exchange numbering plans frequently demand the use of so-called 2–5 numbering in the exchange, that is, 2 letters followed by 5 numerals. It is generally more practical and economical to accomplish this by the use of group selectors at the outset, at the same time providing for an orderly growth beyond an initial equipment of, say, 60 or 80 line terminals. The fundamental operation of the type-7 selector and the division of available outlets into groups of 10 are based on well-known practices. However, the use of crossbar switches for establishing the selected path on a direct-access basis involves several details of operation that differ somewhat from those generally used in decimal systems. The following descriptions and illustrations are presented for the engineer and technician who are interested in the circuits, apparatus, and equipment arrangements employed.

Elements of the Selector Equipment

The type-7 selector uses the 4000-type relay, which consists of a spring bank assembly, heel iron, relay coil, and armature assembly as shown in Fig. 1. The spring bank assembly consists of contact springs, insulators, lifting cards (or ladders), and clamping plates. The contact springs have conventional terminals for soldered wire connections. The complete spring bank for a relay is clamped between two metal plates and held by three screws. The spring bank is fastened to the heel iron by two assembly screws.

The winding of the relay coil is made up of layers of enameled magnet wire with a sheet of cellulose acetate between adjacent layers. When the winding operation is completed, the protruding ends of the interleaved cellulose-acetate sheets are coalesced to seal the coil against entry of moisture.

The relay coil and spring bank are assembled to a conventional L-shaped heel iron, to which the armature assembly is also attached.

People in the communications field have long understood the possibility of completing an electric path by connecting two crossbars where they intersect. For example, the peg-type telegraph switchboard, which is shown in Fig. 2, has been in use for more than 50 years. It should be noted that, with a considerable number of lines, it is possible to connect any two of them together by connecting both to a commonly accessible link. For example, as shown in Fig. 2, *L*-3 is connected to *L*-12.

The crossbar switch differs somewhat from other types of telephone switches, in so far as direct electric paths are established through precious-metal contacts with only two rapid relaylike operations. Associated apparatus that assists in making the connection is subsequently released for further calls. The crossbar switch, Fig. 3, is composed of a formed metal frame on which is mounted a multiple bank comprising a number of horizontal and vertical paths, the cross-point selecting and establishing mechanisms, and magnets.

Located at the ends of the switch are

Manuscript submitted August 11, 1953; made available for printing September 23, 1953.

ROBERT W. HUTTON is with the Kellogg Switchboard and Supply Company, Chicago, Ill.

The author acknowledges the contributions of other engineers in the development of the type-7 crossbar selector, particularly C. A. Adams, who did much of the basic work, and A. T. Sigo and K. L. Liston, whose consultation and encouragement contributed greatly to the project.

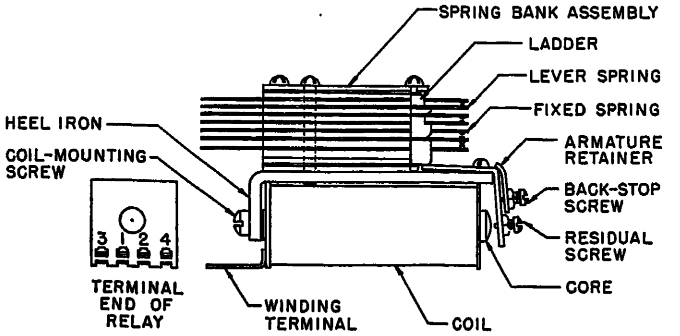

Fig. 1 (left). A 4000-type relay

five or six pairs of select magnets, each pair controlling the rotation of a select rod. The select rods span the distance between the switch-frame ends on the underside and carry a number of finger springs corresponding to the number of vertical-path elements the switch contains. Fig. 4 shows how these finger springs actuate select levers, which are mounted on the armature assembly of each vertical element. When the switch is in an unoperated condition, each select lever rests between two adjacent ladders. When a select magnet is energized, the select rod rotates a few degrees causing the finger springs to move each of the select levers under one of its adjacent ladders. The direction in which the select lever moves depends on which of its two controlling magnets is energized. When the select-rod action has taken place, Fig. 4, the hold magnet of the appropriate vertical path is energized, operating its armature and causing the select lever to lift the ladder, closing the contacts of the selected vertical and horizontal paths. The select magnet is then released, restoring the select rod and all other finger springs to their normal positions. The switch is then available for another selection. The hold-magnet armature remains operated until the subscriber releases the circuit.

The magnetic impulse counter pictured in Fig. 5 is fundamentally a 2-step relay. However, instead of the usual single armature it has 10 armatures. The armatures operate in sequence, each one responding to its respective pulse of current in the driving coil. Once operated, the armatures are held by the residual magnetism in the core. The counter is shown schematically in Fig. 6.

The counter-coil has in addition to its driving or pulsing winding, a second winding that is used to bring about the release of any operated armatures. Release is effected by passing direct current through the release winding in the proper direction to induce into the core a magnetic flux of opposite polarity to that induced by the operating pulses. The release flux is of sufficient intensity to neutralize the residual flux left by the operating pulses, and the tension of the spring stacks is then sufficient to cause the armatures to restore to their normal positions.

Each armature acts on its own set, or stack, of contact springs. The springs are similar to the type used in many conventional relays. The counter used in the type-7 group selector is equipped with one pair of normally closed contacts and one pair of normally open contacts in each of its 10 spring stacks.

Equipment Arrangement

The equipment used in the group-selecting stage of a type-7 office, shown diagrammatically in Fig. 7, consists of the selector relay units, crossbar switches and the common test circuits. Each selector relay unit has a group of relays and a magnetic impulse counter that perform the usual functions of digit registration, holding, etc. Also, each selector relay unit is permanently wired to a horizontal path of one or more crossbar switches, depending on the number of outlets required.

A test relay circuit is provided to serve each 12 selector relay units. It is capable of testing all paths in the selected group of outlets simultaneously, choosing the idle path of the lowest number, and directing the crossbar switch to establish a connection to the chosen outlet. Such operation permits the trunks individually accessible to selectors of a group to be taken into use whenever available, reserving those commonly accessible to a greater number of selector groups for use when the individuals are all engaged.

Operation of the Selector

Operation of the typical type-7 selector circuit is illustrated by Fig. 8. The calling party lifting the telephone handset causes a selector to become associated with his line by way of a line finder. The selector relay unit returns dial tone to the calling party, indicating that it is prepared to receive signals from the telephone dial. The calling party dials the first digit of the number, and the cut-through action of the selector is accomplished in the following manner.

The series relay, which operates on the first pulse, will release after the last pulse of the digit is received, extending ground

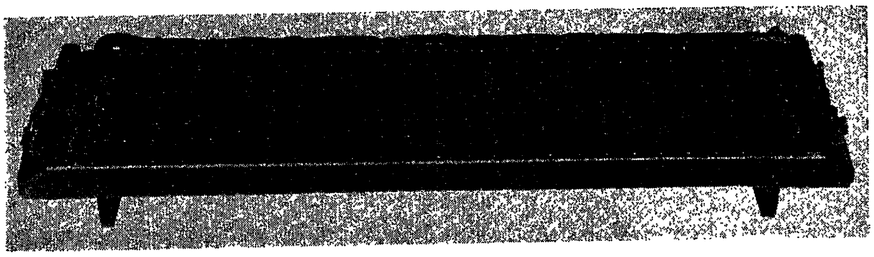

Fig. 3. Crossbar switch

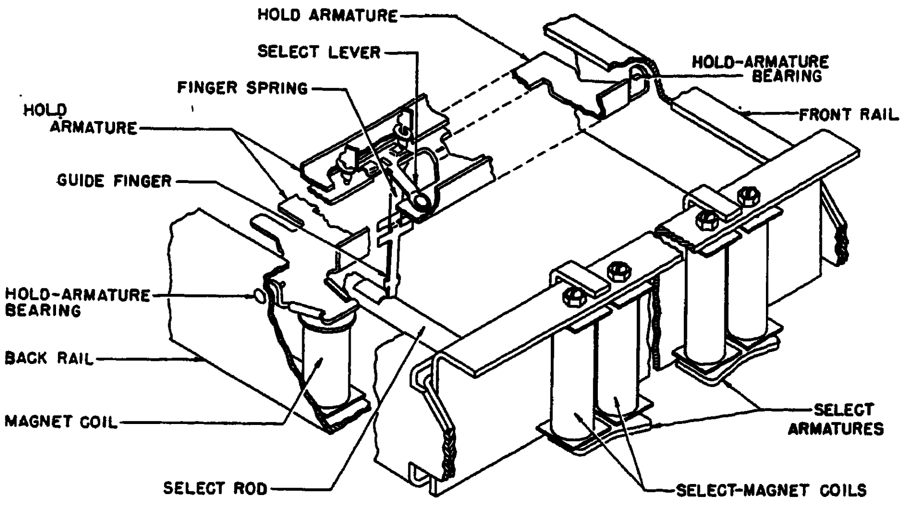

Fig. 4. Select-and-hold magnet mechanism

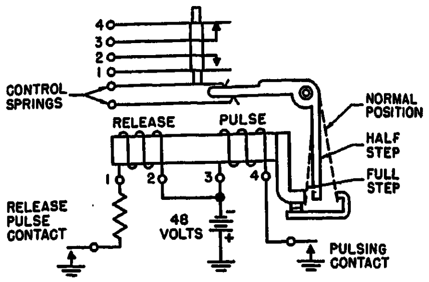

Fig. 6. Operation of magnetic counter

through the off-normal contacts of the magnetic impulse counter to operate the chain relay of the selector. The chain relays (one in each selector) are interconnected so that only one can be operated at a given time. The operation of the chain relay connects ground through the selected path of the magnetic impulse counter to operate the call-in relays of the trunk group, corresponding to the digit dialed. These relays connect the sleeve leads of the selected trunk group to the common test relays, and prepare the select-magnet and hold-magnet operate paths to the associated crossbar switch. The chain relay also closes ground through contacts of the select magnet operate relay to energize a select magnet of the crossbar switch. Since the selector relay circuit involved in the call being considered is permanently associated with a specific horizontal path in the crossbar switch, it is necessarily associated with a particular select magnet of the switch.

The trunk sleeve conductors, which have been "called in," are connected to the test relay circuit. There usually are 10 test relays, so arranged that only one of them can be fully operated at a time. They are adjusted so that they will operate in series with 250 ohms to negative battery (indicating an idle-path condition); however, two relays testing the same sleeve wire cannot operate because of the current-limiting effect of the 250-ohm resistor. This prevents double selection of trunks on simultaneous testing by two selector groups. Operation of any common test relay chooses the path to the next stage. The select magnet operating closes off normal ground through contacts of the operated test relay to energize the corresponding hold magnet of the crossbar switch.

Operation of the hold magnet of the crossbar switch closes the selected crosspoint, and in turn grounds the sleeve to operate the cut-off relay in the selector relay unit. The cut-off relay releases the chain relay, which in turn releases the common test relay circuit. The hold magnet locks to ground on the sleeve and the loop of the calling line is extended through the operated crosspoints of the crossbar switch to the selected circuit in the next stage. Operation of the selector cut-off relay releases the line and hold relays of the selector, but the next-stage circuit returns ground on the sleeve conductor to maintain the established path. The magnetic impulse counter remains operated until the selector cut-off relay restores on release of the connection.

While at a given instant, only one call in a group of 12 selector circuits may be in the process of actual switching, the operation is so rapid that a single test circuit is well able to perform the tasks for the group. Only after the selecting digit has been recorded on its counter, is the selector permitted to demand the test circuit. The test circuit acts in a fraction of a second and, having completed the switching operation for that call, becomes available for the next demand which may come from any other selector circuit in the same group.

If the common test relay circuit finds that all trunks are busy, the busy relay of the selector relay unit will be operated. Associated common equipment will be released, and busy tone returned to the calling party.

It should be pointed out that the selector just described is the basic one, and that there are variations to meet special requirements. One of these variations is the digit-absorbing selector. The necessity for such a switching device frequently arises because of the technical requirements of nation-wide operator toll dialing, and nation-wide customer toll dialing. Normally, the directory numbers in an exchange include only the digits necessary for the local switching and selecting functions. However, the introduction of long-distance dialing, with the nation-wide numbering plan, necessitates in

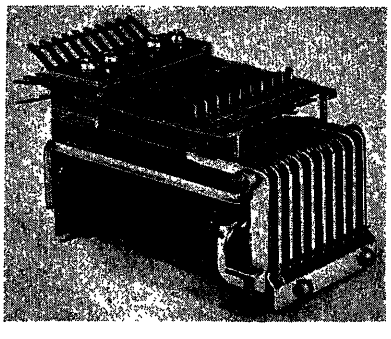

Fig. 5. Magnetic impulse counter

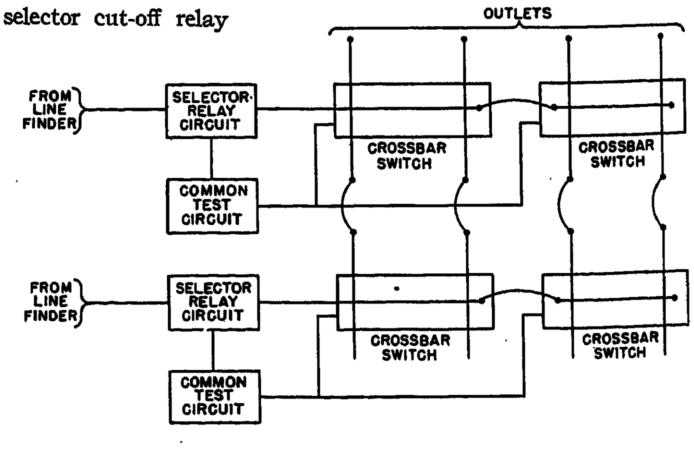

Fig. 7 (right). Block diagram of type-7 selector

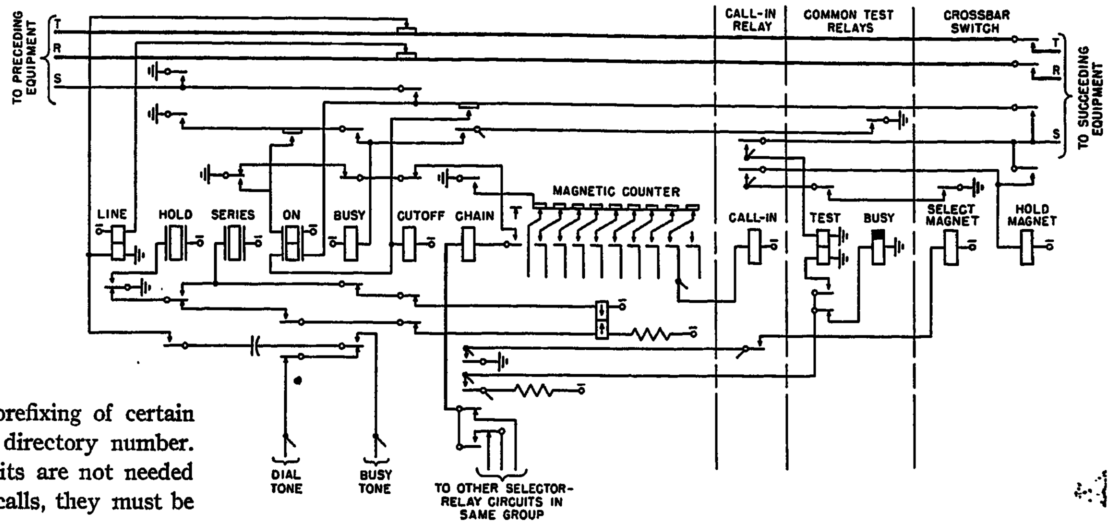
Fig. 8. Schematic diagram of type-7 selector



some exchanges the prefixing of certain digits to the normal directory number. Since these prefix digits are not needed for locally originated calls, they must be absorbed.

The absorption of unneeded prefix digits is accomplished in the type-7 selector by registering them on the magnetic counter in the usual manner and, if the digit is to be absorbed, the counter is released so it will be prepared to receive the next digit. On receipt of a significant digit, the selector action proceeds as in the basic selector already described.

It should be mentioned that the connector (or final selector) of the type-7 crossbar system utilizes the same type of crossbar switches, relays, and magnetic counters used in the group selector. However, the connector normally permits selection of a particular line terminal in a group of 100, rather than choosing an idle path in a selected group of trunks.

Conclusion

While a crossbar switch associated with a selector group may have several of its transmission paths closed at a given time, only one path may be in the process of closing at a given instant. To minimize the time required in testing available paths and in closing the desired crosspoints, the type-7 selector has been arranged to test all available outlets of the selected group simultaneously rather than in sequence. By this method, the testing and connecting time is no greater for the last-choice path than for the first-choice path. These factors made possible the design of a direct-access decimal-type crossbar group selector that readily cooperates with decimal systems of other types.

The Diode Matrix as a Component in Relay Switching Circuits

G. L. BUSH
MEMBER AIEE

THE diode matrix is usually thought of as a component in electronic circuits using diodes of small physical size and having current-carrying capacity in microamperes. This paper describes an application of the diode matrix in a relay switching circuit, where the diodes are small selenium rectifiers with current-carrying capacity sufficient to operate relays. In this application an effort was made to use commercially available selenium-rectifier units for economy in purchasing the small quantity involved.

Statement of the Problem

The problem leading to this development was the introduction of magnetic-drum storage into a stock-exchange quotation system, to distribute bid-ask quotations to brokers in the vicinity of the exchange. It is an automatic system through which the broker receives the bid-ask prices on a stock ticker by dialing a 3-digit code number assigned to the stock. The major components of the system are shown in Fig. 1.

The operation of the system can best be described by following the progress of a call through the various blocks of equipment shown in the figure. The broker desiring the current price looks up the three digit code number for the stock in a code-assignment list. When he is ready to dial, he presses a request button on his dial set. The operation of this button connects his dialing circuit and ticker line through the line connecting equipment to one of the 24 transmitters which may be idle at the time. When the connection to the transmitter is complete, a ready lamp lights on the brokers' dial set, telling him that the equipment is ready to receive his dialing. The operation thus far is similar to the operation of a telephone system when the subscriber picks up the hand set and receives a dial tone. The dialed code-number digits are stored in the transmitter while waiting access to the magnetic drum storage unit where the desired price information is stored. The transmitter also contains the ticker transmitting equipment and the dialed digits stored in the transmitter are sent back to the

brokers' ticker during this waiting period as a check of his dialing.

The magnetic-drum storage equipment is time shared between the 24 transmitters and the 6 operators' positions through the seeker. The purpose of the operators' positions is to keep the prices stored on the magnetic drum up to date with the trading. The seeker is a relay-switching device which connects the next transmitter or operators' position awaiting access to the magnetic-drum storage equipment at the end of the operation of fulfilling the previous request. When a transmitter gets access to the magnetic-drum storage, the 3-digit code number stored in the transmitter is translated by the selector into the energization of one of 600 single-wire selection leads previously used to connect the transmitter to a section of the display-board storage, where the "bid" and "ask" prices of the stocks are stored. In the new system, these leads are coded by use of the diode matrix with the position code of the same information on the magnetic-drum storage. When a transmitter has access to the magnetic-drum storage, the electronic equipment is caused to read the price information stored in the section of the drum selected and store it in the transmitter for retransmission over the ticker line to the brokers' ticker. If an operators' position has been given access to the magnetic-drum storage equipment, it causes the electronic equipment to write the price information stored on the operators' keyset in the section of the magnetic drum selected by one of 100 keys on the operators' keyset.

The components described in this paper are shown in heavy outline on the block diagram. As shown in the diagram, the problem is to provide a magnetic-drum position-selection code for each of the 600 leads used to select an indicator storage

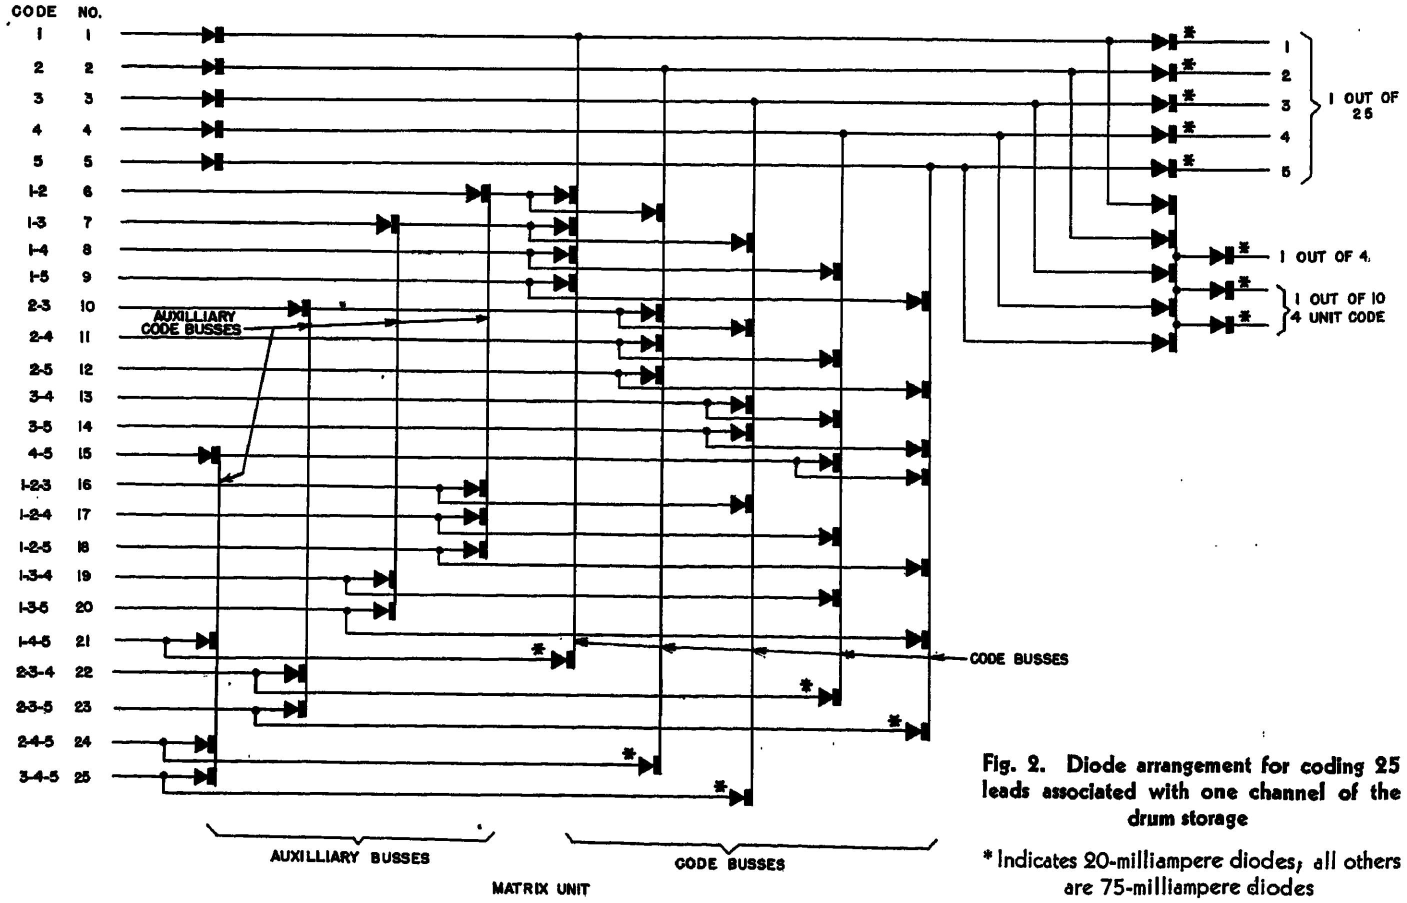

Fig. 2. Diode arrangement for coding 25 leads associated with one channel of the drum storage

* Indicates 20-milliampere diodes; all others are 75-milliampere diodes

in the old system, and now used by both operators' positions and transmitters to locate the same stored information on the magnetic drum. The requirements of the problem are more closely defined by the character of the magnetic storage and the distribution of stocks between the operators' positions. Storage space on the drum is divided into forty channels around the drum, each capable of storing the prices for 25 stocks. Each operator is equipped to record the prices for 100 stocks on the display boards and on the drum storage. The storage facilities must be made available to the operators for changing the price, and to the brokers for reading out the price. Since the drum storage is arranged to process only one call at a time, the storage facilities must be time shared between the calling transmitters and the operators. This is accomplished through the seeker, which permits only one call to enter the storage at a time. This means that only one of the 600 leads will be energized at a time.

Selection of Codes

For coding purposes, the selection is broken down into three groups, based on the characteristics of the rotary drum storage and the operators' positions. The first group is a selection of 1 out of 25 stocks stored in any one of the 40 channels on the drum storage. The smallest number of code elements to be used, is determined by the value of n in the quantity 2^n, which is larger than 25.

$2^4 = 16$

$2^5 = 32$

The 5-element code is therefore the smallest that will have combinations enough to code 25 things. The coding assigned uses all the combinations of the 5 elements of the code taken one, two, and three at a time, as shown in Table I.

Since each operator is equipped to post 100 stocks, or 4 groups of 25, the second group is a 1-out-of-4 selection for the group of 25 in each 100. In this case, so little is gained by use of a permutation code that four separate leads are used in the selection circuit. The third group is a selection of 1-out-of-10 operators positions, provision being made to increase the capacity of the system to 1,000 stocks and 10 operators' positions. The smallest number of elements for coding ten things is four, since $2^3=8$ and $2^4=16$. The codes assigned use all the combinations of the four elements of the code, taken one and two at a time, as shown in Table I, last column.

The Equivalent Relay Circuit

An effort was made to design a relay circuit to perform the selection operation, using double-winding relays to set up the 5-unit codes for the selection of 1 out of 25. In this circuit 60 single-make relays, 168 double-make relays, and 134 triple-make relays were required. If it were practical to provide relays with three or more windings each sufficient to operate the contact pileup with a reasonable current, the number of relays could be greatly reduced. In the circuit proposed, a winding on each of the 1-out-of-25 selection relays operates in series with a common relay with three make contacts, to mark the 1-out-of-4 and 1-out-of-10 selections.

Building Up the Matrix

As a more economical alternative, it was decided to use a diode-matrix translator. In the buildup of a matrix to perform this coding function, it was found desirable to unitize the selection equipment by providing a separate matrix unit for each group of 25 selection leads. This coding unit has 25 inputs and 8 outputs. The eight outputs provide the five code leads for the 1-out-of-25 selection, one lead for the 1-out-of-4 selection, and two leads for the 1-out-of-10 selection. One of the two leads for the 1-out-of-10 selection is not required for the first four operators' positions, but it is provided in every case to make the units interchangeable.

The design of the matrix itself is based on the quality of a selenium diode to be a reasonably good conductor in one direction and a practical insulator in the other. It is evident that only 1 of the 25 input leads can be energized at a time. In order that the energizating of one input lead will not feed another, every connection from an input to the coding busses must be through a diode. If the matrix is built up on this basis, the number of diodes required will be equal to the sum of the number of times each code element appears in the 25 codes, or 55, see Table I. An examination of the codes shows

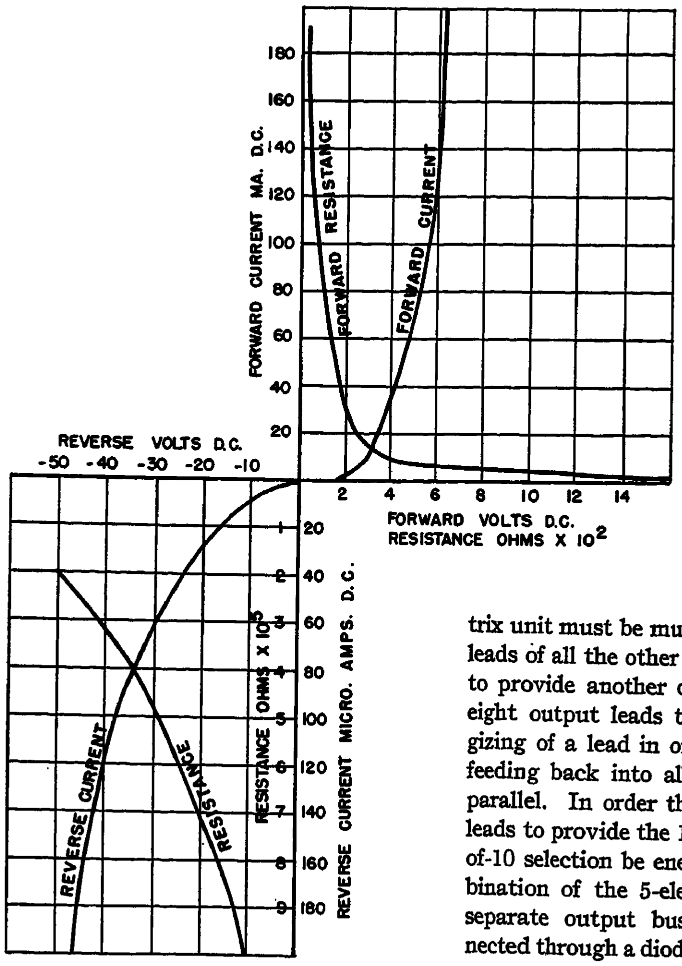

Fig. 4. Characteristics of the 0.075 - ampere 6-plate selenium rectifier (1-inch square plates)

however, that certain combinations of code elements are repeated several times. If an auxiliary bus is provided in the coding circuit for each group of combinations used more than twice, a saving of one diode for each combination more than two can be realized. In the matrix used as shown in Fig. 2, a saving of six diodes was realized by providing busses for the combination groups 1-2, 1-3, 2-3, and 4-5, reducing the total number of diodes to 49.

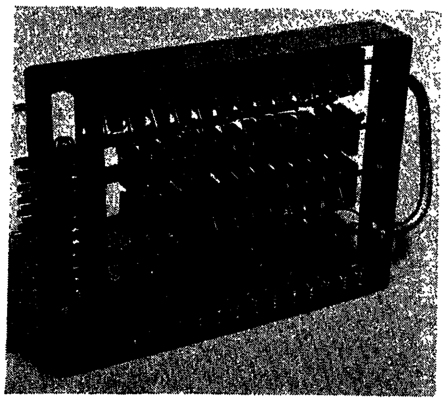

Fig. 5. Diode matrix unit assembly with cover removed

Since the eight output leads of the matrix unit must be multipled to the output leads of all the other units, it is necessary to provide another diode in each of the eight output leads to prevent the energizing of a lead in one unit matrix from feeding back into all the other units in parallel. In order that the three output leads to provide the 1-out-of-4 and 1-out-of-10 selection be energized for any combination of the 5-element code leads, a separate output bus is provided, connected through a diode to each of them.

The multipling of all the 24 diode units to operate the 13 coding relays is shown in Fig. 3. In this circuit it will be noticed that the five code leads from each of the 24 matrix units are multipled and connected to the five coding relays for the 1-out-of-25 selection. One output lead of each matrix unit, representing the first 25 stocks of the 100 at each operator's position, is multipled to similar leads from the first matrix unit at the other operators' positions and connected to the no. 1 relay in the 1-out-of-4 selection. Matrix units representing the other groups of 25 are multipled in a similar manner and connected to relays 2, 3, and 4 of the 1-out-of-4 selection group. The remaining two output leads are each multipled for each operator's position, and connected to the four coding relays of the 1-out-of-10 selection, according to the code shown in Table I.

Selection of Diodes

The choice of diodes is based on the relay currents involved, the operating voltage, and the ratio of forward to backward resistance of the diodes to give safe operation. The relay circuit is designed with a preliminary-make locking contact on each relay, so that current through the matrix need be only enough to operate the one spring. The current is further limited in time of application by being applied to the relay through a break contact, which limits the time of application of the current to the operate time of the relay, which is about 0.012 second, see Fig. 3. The operate-readjust current for the preliminary-make spring with the 1,300-ohm coil used is 0.010 ampere. The resistance of the operate circuit is adjusted to give an operate current of about twice this value, for safe operation on 50 volts. This made the total resistance of the operate circuit

$$R=\frac{E}{I}=\frac{50}{0.020}=2,500 \text{ ohms}$$

of which 2,300 ohms is in the relay coil and a resistance in series with the operate lead, the remainder being in the matrix. The maximum load carried by any diode in the matrix occurs when a lead with the code combinations 1-2, 1-3, 2-3, or 4-5 is energized. For these combinations, current through the input diode must be sufficient to operate 5 code relays, or 5×0.020=0.10 ampere. The next largest current through a single input diode occurs when the leads with codes 1, 2, 3, 4, or 5 are energized. In this case, four code relays must operate, with a resulting current of 4×0.02=0.080 ampere. In all other cases, the relay load is divided between two or more input diodes, and the current for each will be considerably less.

Since the selenium rectifier will carry considerably more than its average rated current for short periods of time, a smaller diode may be used than would be indicated by the maximum current values

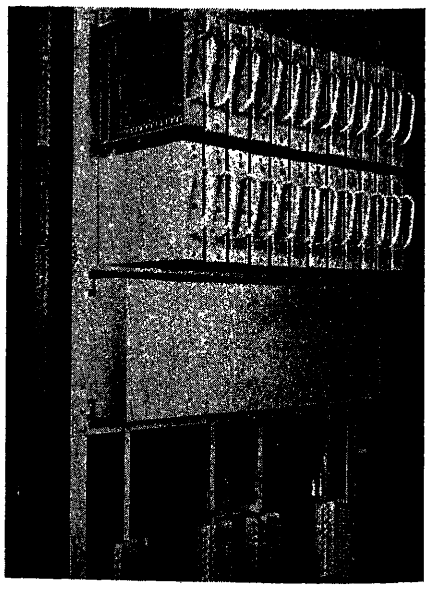

Fig. 6. Mounting of 24 matrix units on the equipment rack

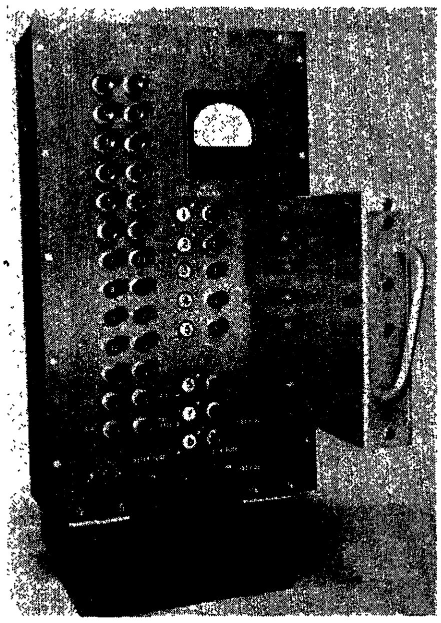

Fig. 7. Diode matrix test set with matrix unit plugged in (front view)

shown above. For this application, commercial rectifiers rated at 0.075 ampere were used, when required to operate two or more code relays. Diodes which carry the current of only one code relay, such as those in the output circuit, are commercial selenium rectifiers, rated at 0.020 ampere. The locations of the 0.02-ampere diodes in the circuit are shown by an asterisk in Fig. 2.

For the operating voltage used (50), rectifiers with only two or three plates would be required. Rectifiers with three plates were tried in this application, but it was found that they could not be made in production quantities with sufficiently high back resistance for safe operation. The rectifiers used were commercial 6-plate units, designed for use on 120-volt a-c circuits. The average characteristics of these units is shown in Fig. 4.

As shown in this figure, the forward resistance for the current used is from 50 ohms to 170 ohms, and the reverse resistance at the 45 volts available across the feedback circuits is about 260,000 ohms. The limiting feedback circuit is that which is trying to operate the fourth and fifth code relays when there are three code relays operated. The feedback path to operate these relays falsely consists of 7 of these reverse circuits in parallel, or 260,000/7 = 37,143 ohms. This gives a current of 45/37,143 = 0.0012 ampere. The current required to just operate the relay is 0.010 ampere. This gives a safety factor against false operation of 0.010/0.0012 = 8.3. The 0.02-ampere diodes are operated at near their rated current, and have an average forward resistance of 70 ohms, and a reverse resistance on 45 volts of over 5 megohms.

Construction of the Equipment

As mentioned earlier the complete matrix is broken down into units each capable of coding 25 stocks. These units are made up into jack-mounted unit assemblies. One of these units with the cover removed is shown in Fig. 5.

The 49 0.075-ampere diodes consist of six 1-inch square plates, assembled in two groups of three. The 13 0.020-ampere diodes are mounted on a terminal strip at the bottom of the unit. These are also commercial 120-volt units, in a tubular construction. The assembly of the 24 matrix units onto the equipment rack is shown in Fig. 6.

Testing Equipment

In equipment such as this, where so many interlocking circuits are involved, it seemed advisable to provide with the equipment adequate testing facilities. This test equipment is shown in Figs. 7 and 8. As shown in Fig. 7, provision is made to plug the matrix units into the test set. The circuit in which the units are tested is the same as that used in actual operation, see Fig. 9.

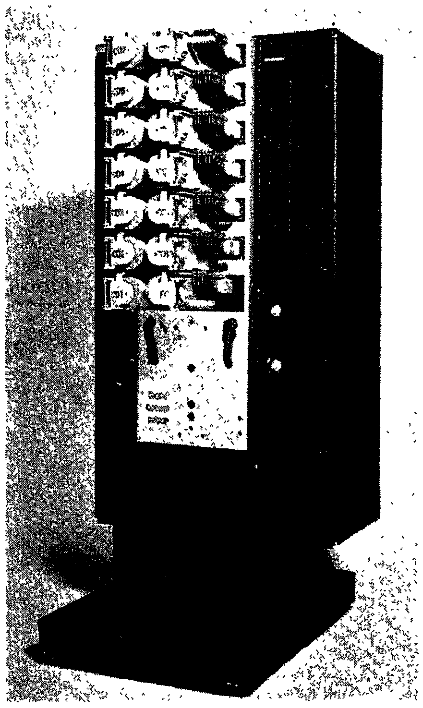

Fig. 8. Diode matrix test set showing coding relay base in place (rear view)

The coding-relay base, shown plugged into the back of the test set in Fig. 9, is the spare coding-relay base for use in the service equipment. Provision is made on the test panel to energize each of the 25 input leads individually. The operation of the coding relays is indicated on lamps marked with the code elements they represent. A key beside each code lamp switches the output lead involved to an equivalent circuit in series with a 25-milliampere meter, which reads the current to operate the coding relay. The equivalent circuit was necessary because the coding relay opens its own operate circuit before a meter reading can be obtained. The coding relays which operate

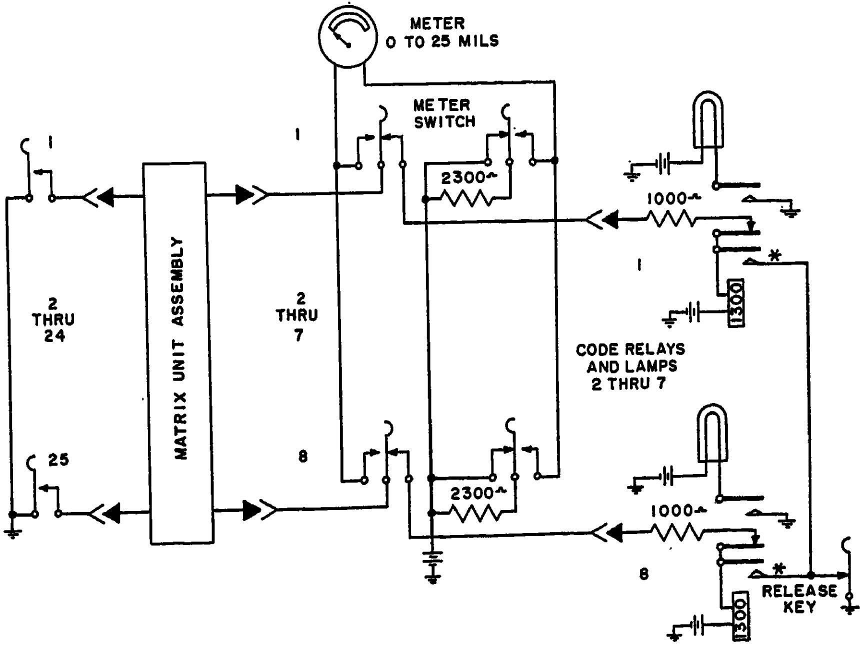

Fig. 9. Schematic circuit of the diode matrix testing equipment

* Indicates preliminary make

lock-up to a release key on the test set, so that the code registered may be observed as long as desired. Even though the test equipment is seldom used in service, its construction was justified to test the wiring and operation of the matrix units during manufacture.

Conclusion

This selection system is designed conservatively, in that it overloads the diode only 25 per cent for a short pulse: only long enough to operate a relay probably not oftener than once every 30 seconds. It is believed that similar circuits can be designed which utilize the instantaneous overload characteristics of the selenium diode to a much greater degree, with satisfactory operation. By permitting an overload of 500 per cent, the small 20-milliampere diodes could be used throughout, with considerable saving in space. By introducing a tube at the input to each relay circuit, it may be possible to use still smaller diodes, but the tubes may require more maintenance than the larger diodes. There is some question as to whether the characteristics of the diode will change with age, especially those which are only occasionally energized. The operation of this system will be a test of the selenium-diode matrix as a tool in relay switching circuits; how good a tool it is only time will tell.

Development of Television Service Standards and Application to Design of a Television Broadcast Network

O. W. B. REED, JR.
ASSOCIATE MEMBER AIEE

IN APRIL 1952, the Federal Communications Commission released its final report and order in television (TV) allocation proceedings which had been instituted in May 1948. In the intervening 4-year period, almost every shred of engineering information and evidence relative to the TV broadcasting service problem was examined and further explored by the industry itself and by working committees composed of industry and government members. This was, in part, the period of the famous, or infamous, TV "freeze" during which public clamor for TV service was at times reflected in Congressional rumblings. An examination of the data used by these engineers, and a study of the hypotheses wrought, yields an insight to the TV service standards of today as they are being applied in the development of TV broadcasting in the United States. We are now just entering upon the proof-of-performance phase for these standards. From the five stations operating before and during World War II, through the artificial period when the number of TV stations hovered around the 100 mark during the freeze period, we have emerged during the past year to a point when the number of stations operating has reached approximately 200, the total number of stations authorized has reached approximately 500, and the present channel assignment table of the Federal Communications Commission provides for 2,000 stations in 1,285 cities and towns.

It will be amply proved before many illustrations are set forth in this paper that the standards as developed should be regarded as guideposts, and carefully qualified. Basic qualifications will be evident in the course of background development and the limitations to the application of the standards as an absolute procedure cannot be overemphasized. Some broad appreciation of this point can be gleaned when one stops to realize that the average citizen has entered the TV field in a way distinctly reminiscent of the early days of radio broadcasting when crystal sets were standard equipment

It has been noted by Jansky and Bailey[1] that: "A broadcast system may be said to consist of (1) a transmitting installation, (2) a transmission medium, and (3) the particular receiving installations which, at the time in question, are used for the reception of programs. Of these three parts, the one least subject to human control, the one concerning which the least knowledge is available, the one subject to the greatest variation in characteristics, and yet the one involved in all problems of governmental regulation is the transmission medium."

The transmission medium in the period 1948–1952 remained as the fountainhead of uncertainties with respect to propagation of signals, which lead various commissioners of the Federal Communications Commission to complain from the bench on many occasions concerning the necessity of allocating frequencies on the basis of inadequate knowledge. One of the basic reasons for this was that frequencies suitable for TV use had but lately been occupied and only a meager amount of measured data was available.

The complexities of this situation were by no means eased by the manner in which broadcasting matured. From even a cursory study of the record, haphazard growth is indicated. The space available for TV today in the region below 300 megacycles (mc) is less than that which was available before the war. Tremendous demands of other services, such as the safety and mobile services, have made it necessary to decrease the number of TV channels in this portion of the spectrum. In 1936, frequency requirements for TV were explored, and in the following year 19 channels were allocated to TV. In 1941, after a lengthy period of experimentation and development culminating in joint consideration by the first National Television Systems Committee, standards were adopted. Provision at this time was made for 18 commercial channels. As a result of further allocation, proceedings commenced in 1944 and, extending over a period of several years, the number of TV channels was reduced to thirteen, twelve of which were to be shared with fixed and mobile services. The TV rules adopted in 1945 contained a table showing the allocation of TV channels to 140 metropolitan districts in the

Paper 53-414, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2–6, 1953. Manuscript submitted July 9, 1953; made available for printing September 1, 1953.

O. W. B. REED, JR., is with Jansky and Bailey, Inc., Washington, D. C.

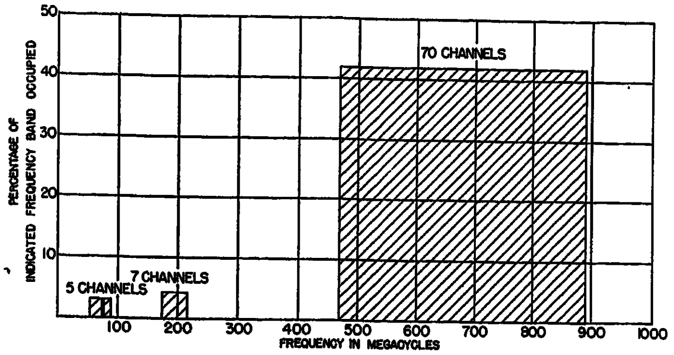

Fig. 1. Distribution of VHF and UHF television channels in the radio frequency spectrum

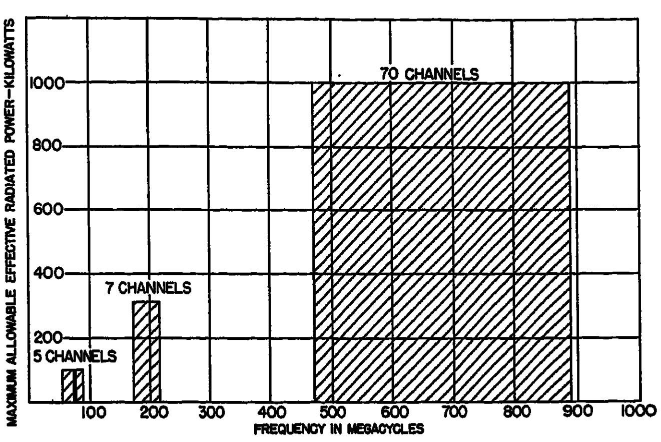

Fig. 2. Maximum allowable effective radiated power in the horizontal plane on VHF and UHF channels

United States. Subsequent to the adoption of these rules, it became apparent that it would not be satisfactory to have frequency sharing between TV and the fixed and mobile services. Therefore, after further hearing, TV channel no. 1 was deleted and reallocated for fixed and mobile use.

In the period of 1948–1952, the necessity was recognized of providing TV service in many cities and towns not covered by the original table. Also, the need was seen for taking into account the deletion of channel 1. These contradictory aims were later to be reflected in the ultimate recognition of the need for more TV channels and additional space in the radio frequency spectrum.

Fig. 1 illustrates the status of TV channel allocations which prevails today as a result of the Commission decision of April, 1952. There are 12 very high frequency (VHF) channels lying between 30 and 300 mc in the spectrum. Five of the channels are between 54 and 88 mc, and seven of them lie in a continuous series between 174 and 216 mc. The ultra-high frequency (UHF) channels lying between 300 and 3,000 mc in the spectrum number 70. These lie in a continuous band of frequencies between 470 and 890 mc. The TV channels are each 6 mc wide. The carrier frequency for the visual transmitter is located 1.25 mc from the lower frequency edge of the channel, and the carrier frequency for the aural transmitter is located 0.25 mc below the higher frequency edge of the channel. It will be noted that collectively the space in the spectrum allocated for TV use closely approximates one-half the frequency band between 1 and 1,000 mc.

The groundwork for development of an allocation table of assignments to various cities lies in engineering considerations involving numerous assumptions, some of which, as we have noted at the transmitting point and at the receiving point are, within limits, under the control of the developer. At the transmitter, assumptions can be imposed to standardize, over some variable range, effective radiated power and antenna height. At the point of reception, the receiver, the type of antenna to be employed, its average height above the surrounding terrain, and some knowledge of undesired noise levels present can be framed within certain points of reference. Certain assumptions concerning receiver selectivity characteristics which affect adjacent channel responses are of considerable importance. In between these two control points, if we may call them that for a moment, lies as we have stressed, the transmission medium with all its propagation vagaries to be defined over a tremendous frequency range. While it would be tempting to treat each of these three factors as an isolated case, the hopelessness of doing this can be appreciated when it is realized that the number of television channels available for use in any city, the number of cities for which channels can be provided, and the coverage attainable in such cases are all closely interrelated. In addition to the foregoing correlation, subjective factors had to be evaluated to determine the ratio of desired to undesired signals necessary to avoid interference between stations operating on the same and adjacent channels. Studies of this latter subject several years ago resulted in a first introduction of a number of citizens to picture quality factors in TV.

Some of the variables at the transmitting and receiving terminals were fixed by the Commission, perhaps arbitrarily, in establishing the present allocation plan. However, with one eye on the present state of the art as regards ability to generate power at the frequencies concerned and the nature of receiving equipment, and the other eye on the transmission medium, the present rules and standards were evolved. At this point we can oversimplify somewhat and say that those matters which were subject to policy decisions resulting in a "fixing" of a few of the variables were placed in the list of rules, while those engineering

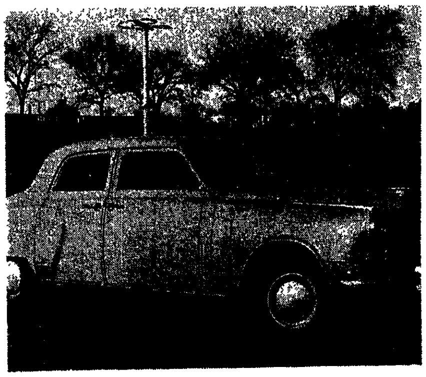

Fig. 3. Field car showing receiving antenna in recording position

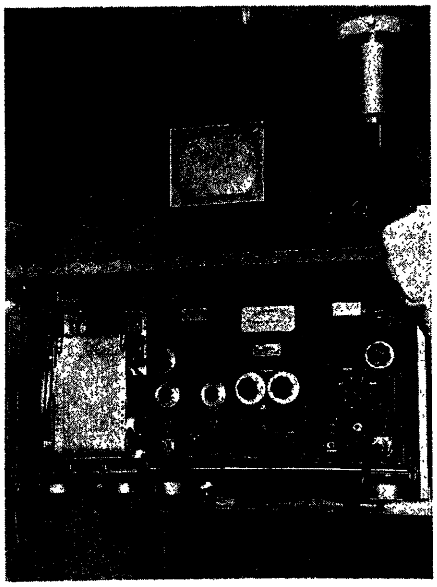

Fig. 4. Interior of field car showing field intensity recording and monitoring equipment

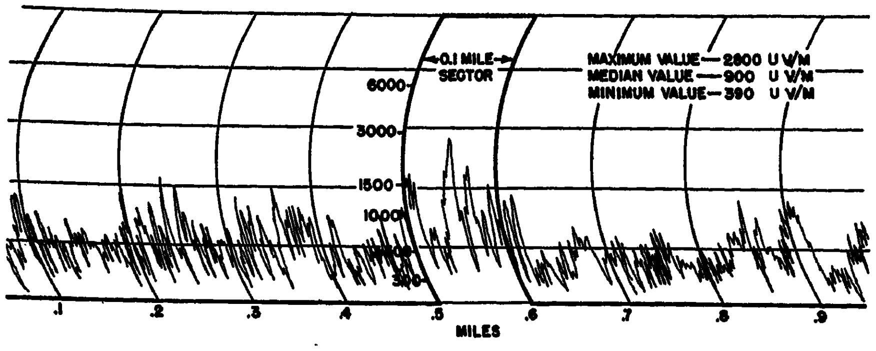

Fig. 5 (above). Typical section of recorder chart with mobile field intensity recorded data

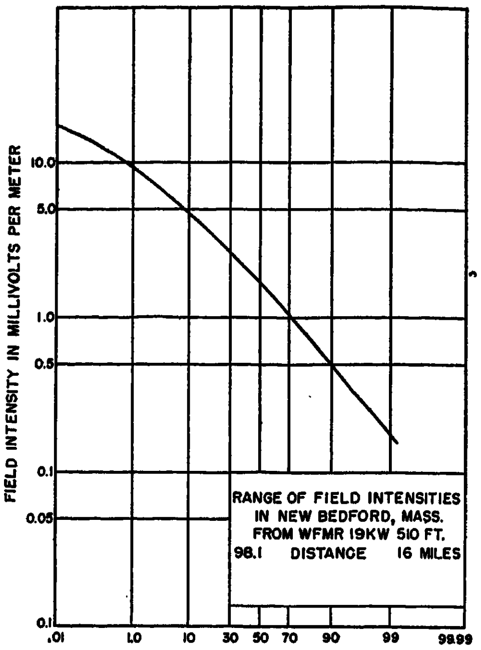

Fig. 6 (right). Probability analysis of mobile field intensity recorded data. Per cent of distance field intensity is greater than indicated level

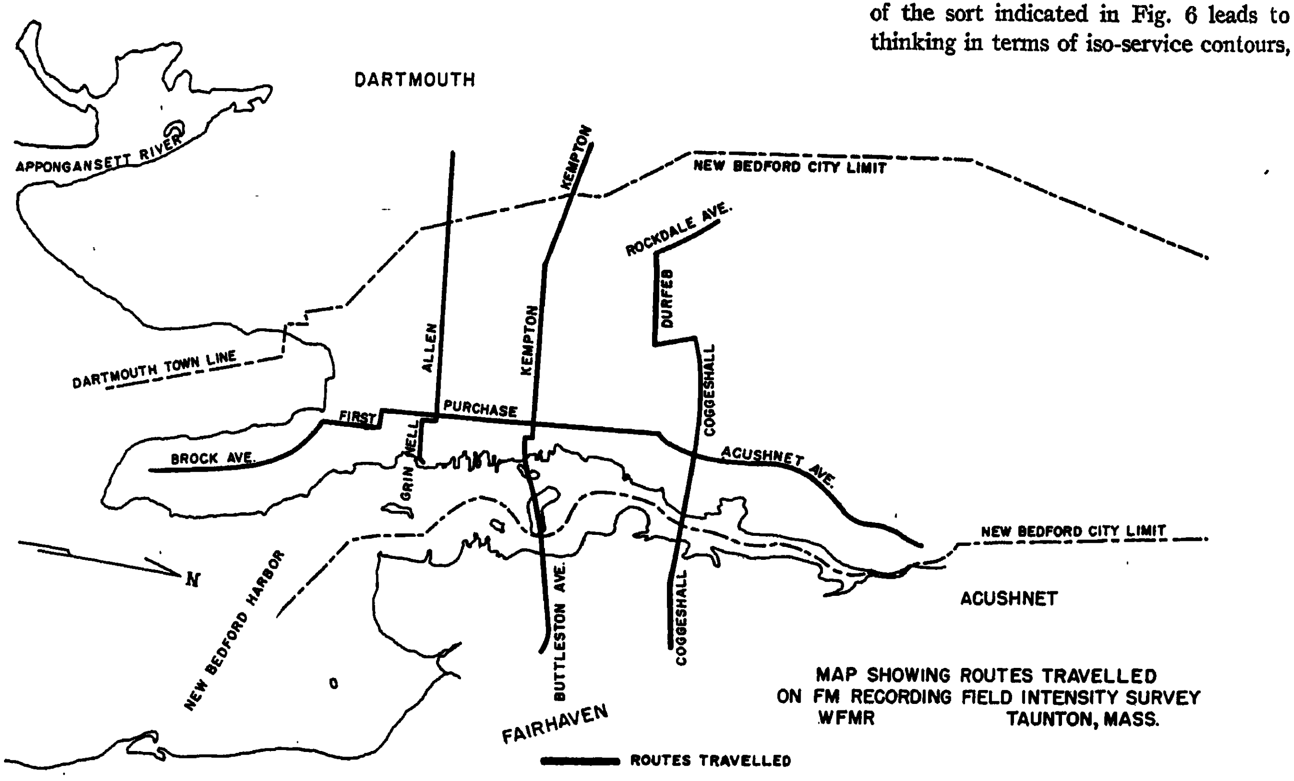
matters intrinsic to the development of these rules were relegated to the technical standards category. As an administrative convenience perhaps, the Commission has refused to dignify the Siamese relationship and blankets both these categories into "Rules Governing Television Stations."

Fig. 2, which is similar to the first figure in the abscissa presentation, shows the determination made by the Commission with respect to the maximum allowable effective radiated power to be employed in the three sections of the assigned spectrum. Basic to these determinations were factors affecting reception conditions in the several frequency bands.

A broadcast station produces, at any particular point of reference, an electrical field intensity or signal strength which may be measured by appropriately designed and calibrated apparatus. In broadcasting, it is important to emphasize that it is not the absolute value of field intensity or signal strength produced at a point of reception which determines whether or not the signal is satisfactory, but the ratio of the received intensity to the intensity of other electrical disturbances such as static or automotive ignition and interference from other stations on the same and adjacent channels. Measurements of broadcast signals in the higher frequency bands are most conveniently made by means of mobile field intensity recording arrangements typical of those illustrated in Figs. 3 and 4.

Fig. 5 contains a section of a recorder chart showing the analysis of one sector of a mobile field intensity recording obtained by use of the equipment illustrated. Within the space of approximately 500 feet it will be noted that the signal varies over a range of approximately seven to one. Several years' experience with measured data of this nature leads one to begin to abandon the use of contours of equal field intensity in terms of which broadcast signals were formerly defined. Summarization of data of the type collected in Fig. 5 by analysis of the sort indicated in Fig. 6 leads to thinking in terms of iso-service contours,



MAP SHOWING ROUTES TRAVELLED
ON FM RECORDING FIELD INTENSITY SURVEY
WFMR TAUNTON, MASS.

Fig. 7. Map showing routes traveled on recording field intensity city survey

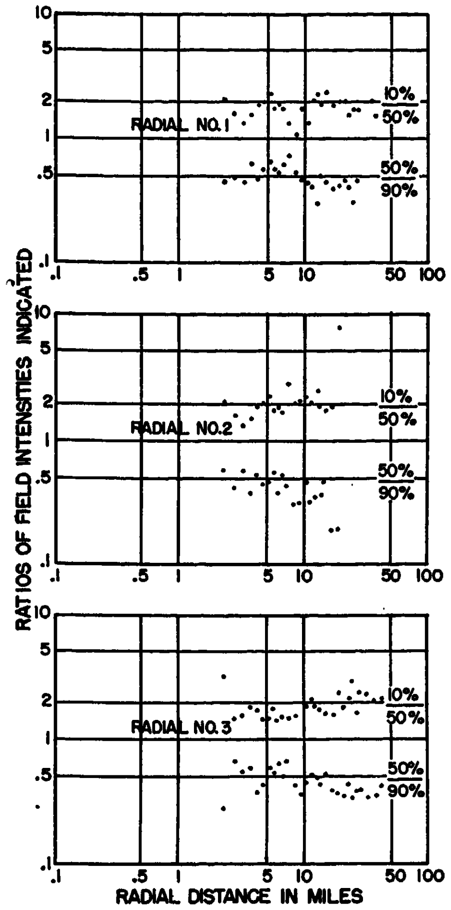


Fig. 8. Ratios and field intensities exceeded for 10 per cent and 90 per cent of the distance to the median value along radials from a transmitter

that is, contours along which the probability is equal that a certain percentage of possible receiving locations will receive a specified grade of service for a given percentage of the time. This principle recognizes another fact which became evident in the course of field intensity studies. Propagation conditions in both the VHF portions of the spectrum and the UHF portions are subject to wide variation with both time and location, and a statistical method is advisable in a study of the service problem. The former practice of never making a standard broadcast field intensity measurement without recording the time of day and date to reconcile ionospheric variations, was carried over into high-frequency work, where the dielectric constant of the air itself became of importance in the transmission medium.

While automatic recordings of the type shown in Fig. 5 are being taken of the field intensity distribution over a city, another receiving set connected to a second receiving antenna may be kept in operation. By this means, it is possible to observe receiving conditions in the car during the progress of each run. Such tests supplemented by several observations at fixed locations provide a base upon which to evaluate the media field intensity required to overcome local noise and interference.

Fig. 7 illustrates the application of the method outlined in a case involving a frequency modulation (FM) broadcast operation in New Bedford, Mass. In this figure the routes traveled by the field car are shown. The propagation vagaries of the radio frequency fields involved would be applicable to interpretation of TV propagation on the lower frequency TV channels. The data in Fig. 6 was compiled from an analysis of measurements taken over the city as illustrated in Fig. 7.

Fig. 8 presents an additional interpretation of recorder chart data similar to that of Fig. 5. The ratios of field intensities exceeded for 10 per cent and 90 per cent of the distance to the median, or 50-per-cent value, give a measure of the variability of the received signal. For this particular set of results it will be noted that the range of variability is independent of the distance from the transmitting station. It will be noted that, while we may be pleased to think in the simplified terms of the median value, it should none the less be kept in mind that for this particular set of circumstances, including frequency, type of terrain, and city characteristics, signal peaks of the order of twice the median value will frequently be experienced and, what is more important, signal minimums of the order of one-half the median signal will occur over any reasonable sector length.

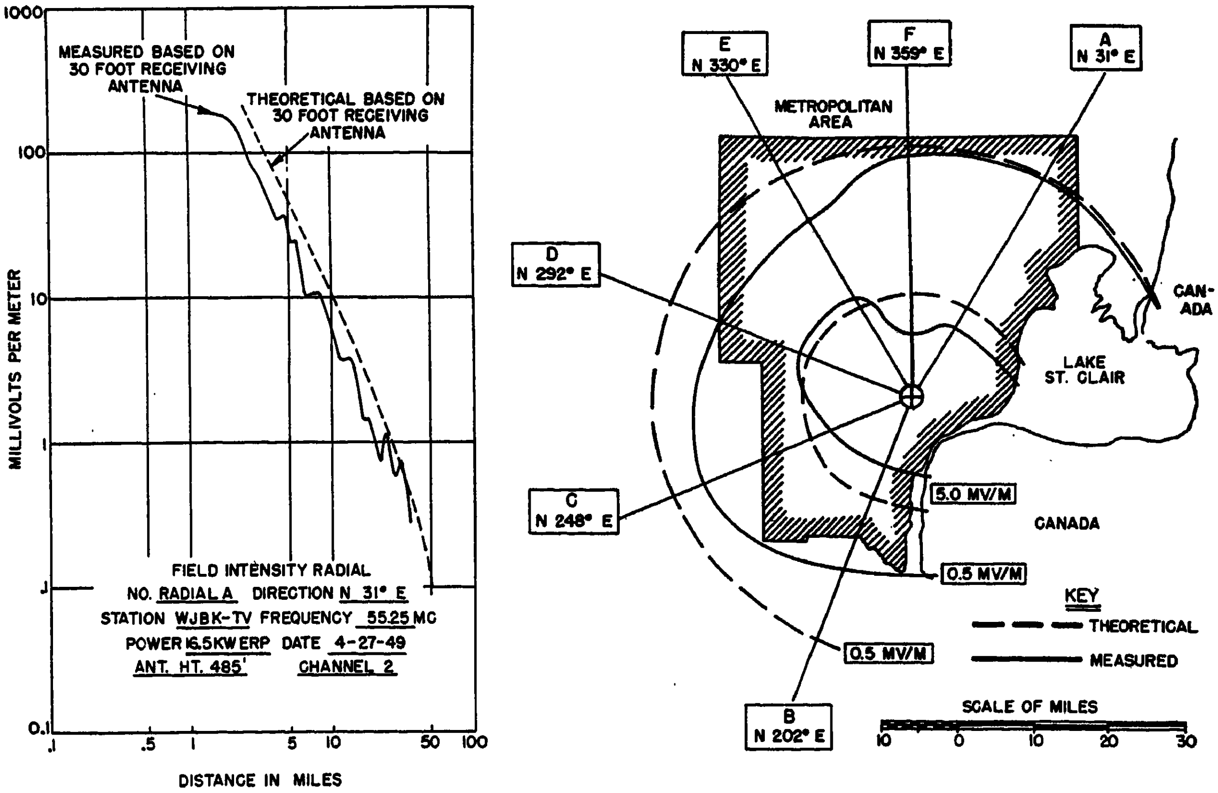

Fig. 9 Theoretical versus measured contours for a TV broadcast station and analysis of radial A

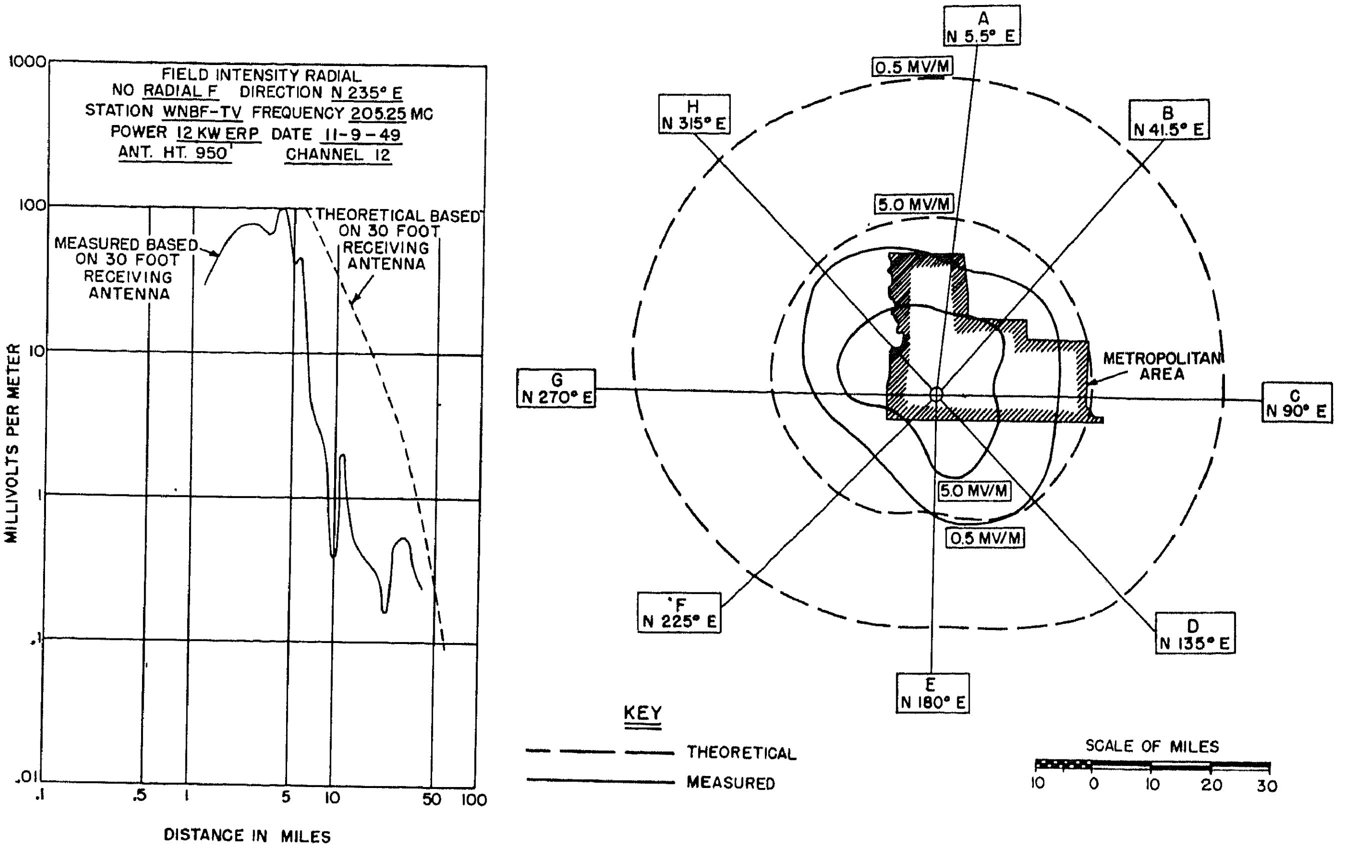

Fig. 10. Theoretical versus measured contours for a television broadcast station and analysis of radial F

Figs. 9 and 10 indicate typical data presented to the Federal Communication Commission in the form of proof-of-performance studies. The graphs and maps shown are more in the form of conclusions than of basic data, in that the curves are derived from sector analysis of mobile field intensity recordings previously described. Fig. 9 contains information with respect to a channel No. 2 (54 to 60-mc) operation in the Detroit Mich., area. Fig. 10 presents data for a channel No. 12 (204 to 210 mc) operation in the Binghamton, N. Y., area. The frequencies in these cases are illustrative of practically the total frequency range in the VHF portion of the spectrum. But one cannot draw comparisons here on the basis of two cases looking toward a frequency effect factor, because the terrain and even the types of cities involved are widely different. However, it may be appreciated that with proof of performance data for about 24 TV and FM operations available, some comparisons and trends could be developed. It was on the basis of just such data and methods of analysis, here very briefly outlined, that the working committees of the 1948–1952 period were able to piece together a hypothesis.

During the course of deliberations, which began in June 1948, it was apparent that tropospheric interference, which had been experienced in the FM band in the 100-mc region, could not be ignored in developing a nation-wide TV allocation plan. However, it was also apparent that very few basic data which could be used in studying the tropospheric effect existed, and that what data were available would require a great deal of study and analysis. Realizing that it would be unsafe to develop an allocation plan which ignored these effects, certain additional studies were proposed. It can be appreciated that under all these circumstances serious questions among engineers arose both as to the methods used in analyzing the meager data available and as to the results obtained. The imperative requirement of the Federal Communications Commission for an allocation plan had to be subordinated while new explorations of the transmission medium were made. The report of the working committee finally issued in 1949 made it clear that the results could best be classed as only rough approximations, although the curves contained therein have been used as the basis for the allocation. The following quotation from the introduction to their report is of interest: "The committee feels that the information it has had to work with is far too scant for it to consider the attached curves to be more than a relatively rough approximation to the propagation conditions to be expected throughout the United States."[2] It is important to emphasize also the fact that these deliberations were carried on without regard for UHF considerations where almost no experimental data were available at that time. The ultimate partial application to UHF problems of the curves developed in this report can therefore be regarded only as some order of further approximation based on the original rough approximation.

The aforementioned report[2] is limited in scope to the determination of engineering factors necessary to the prediction of service and interference from VHF stations. No attempt was made in it to determine how far apart stations should be placed on the same and adjacent channels, because it was felt that this involved policy decisions which would have to be made by the Commission itself. As noted, however, the report does contain the basic and fundamental engineering considerations necessary to the architecture of the TV allocation plan, particularly in so far as transmission medium factors of importance in the VHF portion of the spectrum are concerned. That these fundamentals were carried forward into UHF problems was not necessarily to be expected. Experience with UHF operation, in spite of the fact that no field intensity measurements are now required in TV proof-of-performance tests, may in time result in new yardsticks by which the wisdom of assumption, in part, of VHF factors for UHF application will be judged. If, as new assignments are activated, the allocation pattern appears to be substantially less than perfect and subject to the complications of the type encountered in the immediate postwar period, then we may again enter upon a new period of re-examination and re-evaluation.

The stated objectives of the Ad Hoc Committee provide in outline form a summarization of their approach to the problem.

> "A. Prediction of Service Field Intensities—This includes the effects of fine and gross terrain features upon the median signal levels and a realistic appraisal of the apparent antenna height of the transmitter.
>
> B. Evaluation of the Random Variations in Field Intensity from Median Levels due to Local Terrain and Buildings.
>
> C. Tropospheric Propagation Curves—The determination of methods for the evaluation and treatment of available data and of the methods and basis for extension of the data to other frequencies and antenna heights.
>
> D. Method of Combining the Effects of the Spatial and Time Variations of the Desired Signal and One or More Interfering Signals."

It is beyond the scope of this paper to deal in detail with all the factors and the reasoning behind the work of this committee, and to treat their findings exhaustively. However, before presenting the standards with respect to urban and rural grades of service employed in television allocations work, we can point out a few of the salient elements in the considerations.

Ground wave signal range curves customarily used by the Federal Communications Commission are based upon an unattenuated field reference of twice free-space field values for smooth-earth theoretical field calculations. The committee decided that, for the purpose of making statistical comparisons between measured and calculated values of field intensity, the standard curves should be modified to follow the free-space inverse distance value, rather than twice this value, to the point of departure of the smooth-earth theoretical curve below that value. This revision was made since the line corresponding to twice inverse distance values represents the envelope of values expected under smooth-earth conditions, rather than the median value as exemplified by the curves developed.

Although a number of methods were considered for expressing transmitting antenna height, the postwar practice of specifying the average height above terrain between 2 and 10 miles from the transmitter was retained. The Committee pointed out that, while alternative methods could be used and might indeed appear to be more applicable in special cases, if other methods were employed the statistical presentation relied upon in the instant report would not be valid for an alternative method.

A large portion of the data studied by the committee consisted of mobile recordings taken at receiving antenna heights of from 8 to 12 feet above ground. To relate these data to a 30-foot receiving antenna height used as a par by the Commission for several years, it was finally decided to use a linear height-gain relationship, although there appeared to be considerable doubt as to the

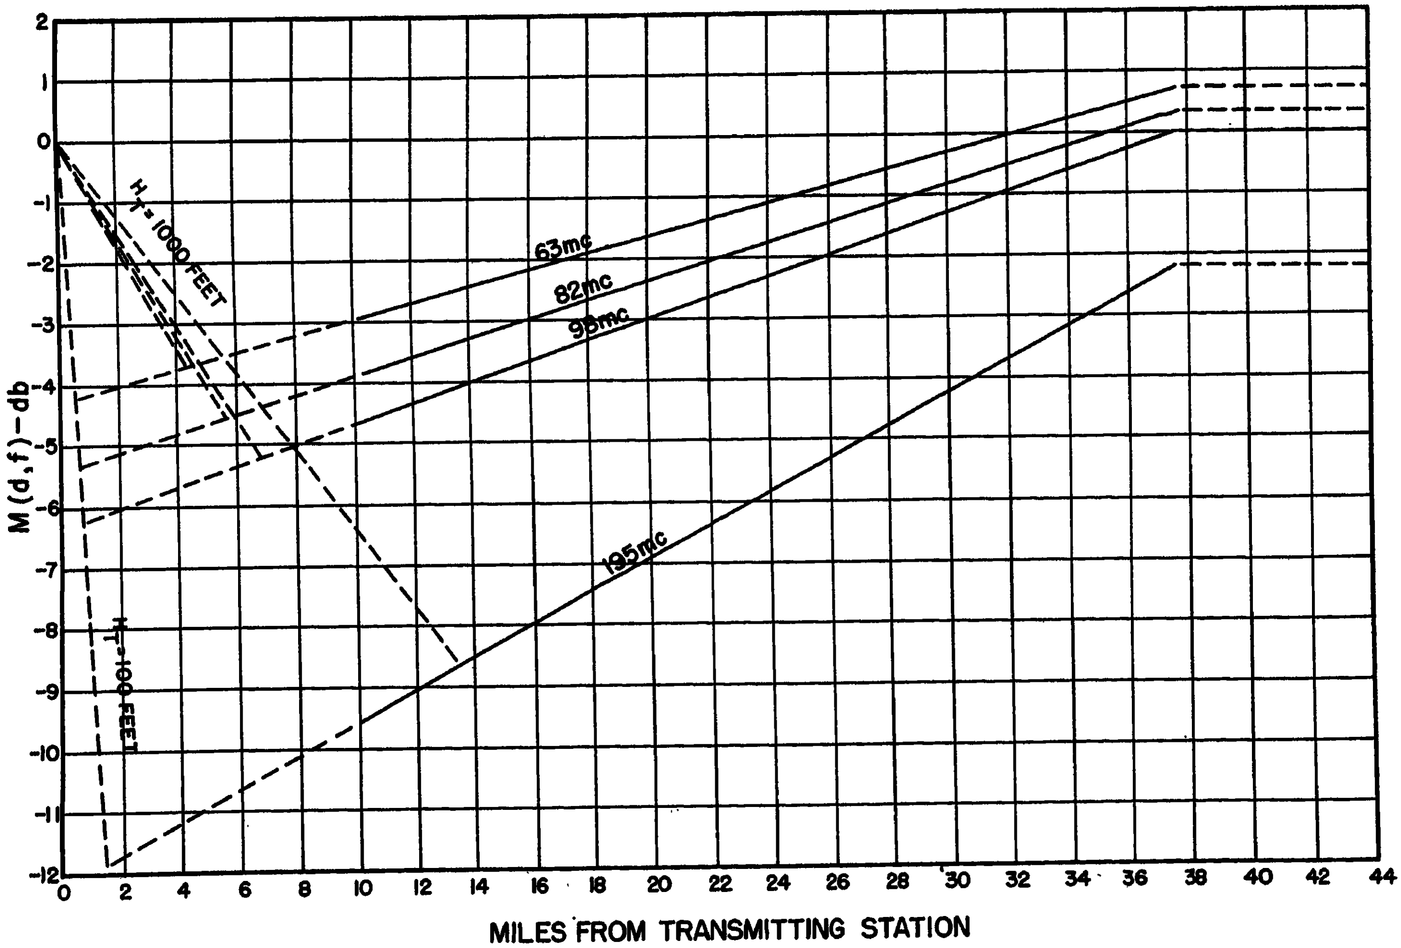

Fig. 11. Correction to the theoretical smooth-earth field intensity required to give the median of the fields to be expected over irregular terrain

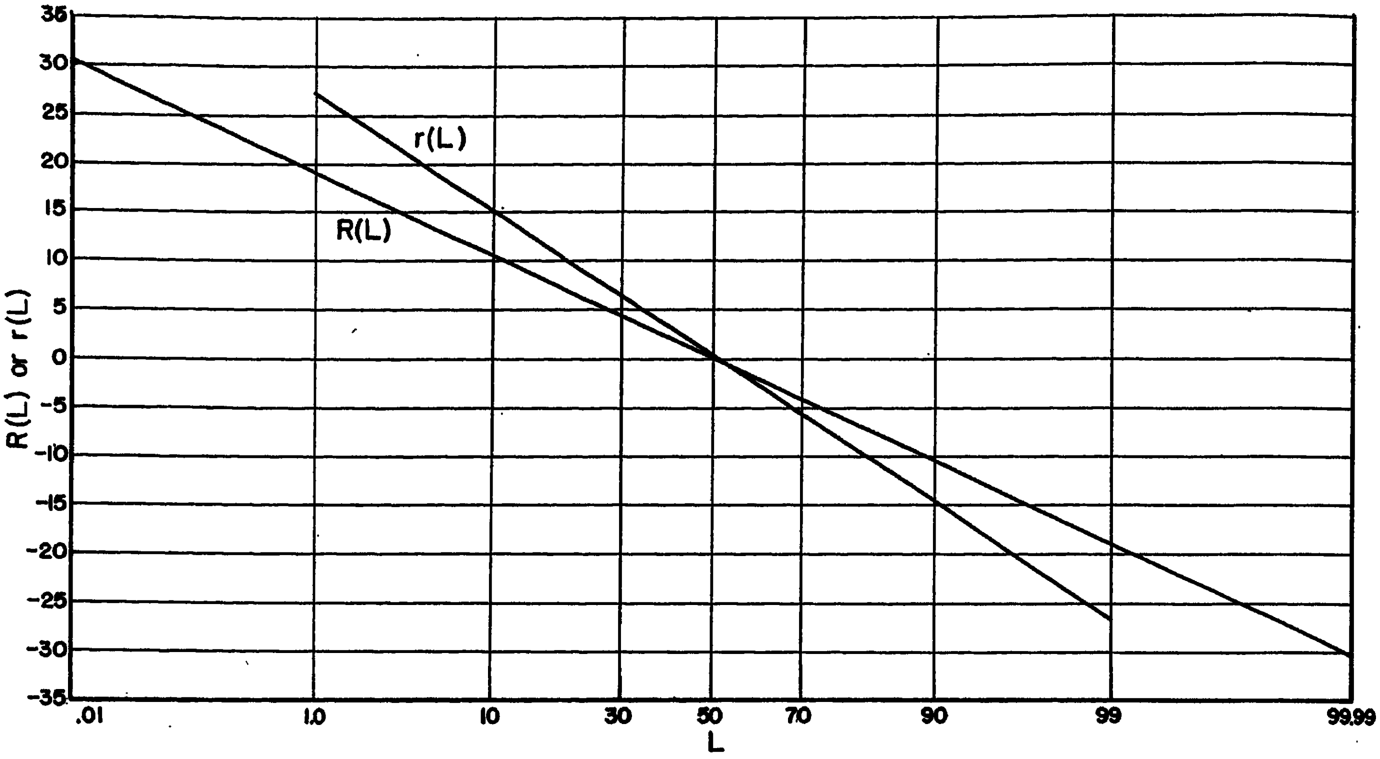

Fig. 12. Ratio in db of the field intensity exceeded at L per cent of the receiving locations to the field intensity exceeded at 50 per cent of the receiving locations for VHF and UHF TV frequencies

actual realization of such a relationship, particularly in mountainous terrain where considerable evidence to the contrary existed.

To develop correction factors for the older standard smooth-earth theoretical value curves, studies involving comparisons of the predicted and achieved coverage of 13 FM and TV stations in the VHF band were made.[3] The studies yielded factors which, applied to these curves, related them to median signal levels to be expected under average terrain conditions in the eastern part of the United States where the stations studied were located. These factors are shown graphically in Fig. 11. An appreciation may be gained from this figure of the reasoning which led to the effective radiated power differentials allowed on the several VHF channels. In Fig. 11, $M(d,f)$ is the correction to the smooth-earth field to give the expected median field over irregular terrain, and is expressed in decibels, where d is the distance in miles from the transmitting antenna and f_{mc} is the radio frequency expressed in megacycles. Special attention is directed to the dashed portions of these curves since these represent extrapolations and thus may not be so reliable as the values predicted for the intermediate distances.

Table I. Required Median Field Strengths, Grade-A Service

To Overcome Receiver Noise	Channels 2 to 6	Channels 7 to 13	Channels 14 to 83

To Overcome Receiver Noise or Local Noise, Whichever Is Greater			
Median field strengths, db	68	71	74

* The antenna is assumed to consist of a half-wave dipole for channels 2 to 13 and an antenna with 8-db gain for channels 14 to 83.

The theoretical smooth-earth field reference curve is determined, in part, by measuring the transmitter antenna height above the average level of the terrain between 2 and 10 miles from the transmitting antenna. The correction curves are considered applicable for receiving antennas up to 30 feet in height. However, at distances less than $12h_t'h_r'/\lambda$ the free-space field, rather than the theoretical smooth-earth field, is to be used as the reference curve. This limitation is illustrated graphically in Fig. 11 for transmitting antenna heights of 100 feet and 1,000 feet.

Studies such as those described were also used to derive a relationship for the estimation of the spatial distribution of field intensities in suburban and rural areas in going around a station at a fixed distance where the median field intensity has been predicted. This permits estimation as a function of the distance from the TV station of the percentage of the

receiving locations at which a particular field intensity is available. Thus the median field for 50 per cent of the locations 50 per cent of the time may be converted to a field for L per cent of the locations by the application of a proper factor. Fig. 12 shows the relationship developed as a result of the statistical studies. In this figure $R(L)$ is shown as a function of L. As an example, Fig. 12 indicates that the field at $L=10$ per cent of the receiving locations, $F(10,50)$, may be expected to be 11 decibels (db) larger than the median field $F(50,50)$. For the available data and the analysis employed, $R(L)$ was found to be approximately independent of the distance, the frequency, and the transmitting or receiving antenna height. The function of $r(L)$ shown on Fig. 12 represents an assumed distribution factor for UHF frequencies.[4]

In its TV standards the Commission has provided for two grades of service. Grade A service is so specified that a quality acceptable to the median observer is expected to prevail for at least 90 per cent of the time at the best 70 per cent of receiver locations at the outer limits of this service. For Grade B service the comparable figures are 90 per cent of the time at 50 per cent of the locations. The required median field strengths in db above one microvolt for these grades of service on the several channels were developed as shown in Tables I and II.

The use of these grades of service values for the several channels in conjunction with the $F(50,50)$ median field intensity charts in the Commission's standards results in establishment of the theoretical radial distances to various points on the grades of service limits when the effective radiated power and the transmitting height above average terrain are known.

The opportunity to develop educational television broadcast systems on an integrated basis came when the Federal Communications Commission provided in its allocation plan 242 channels for noncommercial educational television use. Several of the states have been interested in the utilization of channels assigned within their state, and the application of the foregoing knowledge to a typical example has been chosen as illustrative of these considerations. Furthermore, because it has not been possible to treat the Commission's standards in the detailed way desirable in one paper on the subject, the illustration will serve to point up several other pertinent features of the standards.

The table of assignments contained in the present list of rules[6] indicates the following reservations for educational use in the state of Iowa: Cedar Rapids, channel 26; Davenport, channel 30; Des Moines, channel 11; Iowa City, channel 12; Sioux City, channel 30; Waterloo, channel 22.

While these assignments are fairly well distributed geographically, it would not be feasible to provide state-wide coverage if a system were to be limited to the use of these six channels. Fortunately, the rules of the Commission provide a process whereby additional channels may be assigned to certain cities, providing the separation requirements of the standards for the various channels can be met. Accordingly, in our planning, studies were carried out looking toward the addition of several channels to the basic ones assigned. It will be noted that two of the reservations listed were for VHF channels, i.e., Des Moines and Iowa City, and the remainder are for UHF channels.

Prominent among the considerations in developing a state-wide system are the population characteristics of the region

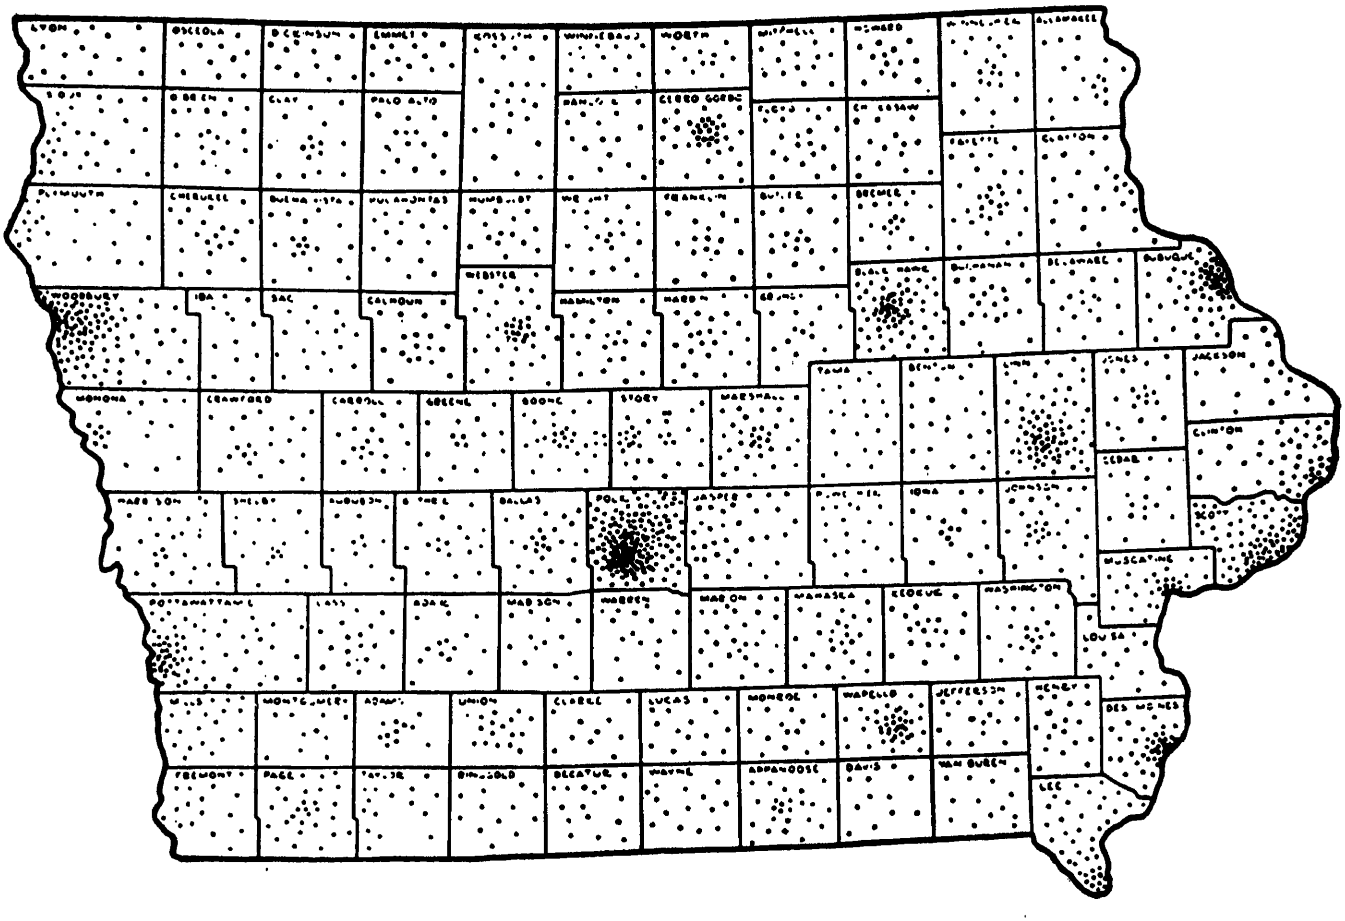

Fig. 13. Distribution of Iowa population. Each dot represents 1,000 persons. Population 2,643,000, Census Bureau estimate, July, 1949

Table IV. Limits for Field Intensity

Channels	Grade A	Grade B
2 to 6	68 dbu	47 dbu
7 to 13	71 dbu	56 dbu
14 to 83	74 dbu	64 dbu

to be served. The population of the state of Iowa, according to the 1950 census, totals 2,621,073. The state has a land area of 56,045 square miles, so that on the average there are approximately 47 inhabitants per square mile. Among the states, Iowa ranks twenty-second in both land area and population.

The urban population of Iowa numbers 1,250,938 persons or 47.7 per cent of the population of the state. In 1950, the urban population resided in 93 incorporated places and in other territory in the urban fringes of the three urbanized areas entirely in the state, and of the Iowa parts of three other urbanized areas partly in the state.

The rural population of Iowa comprises, 1,370,135 persons or 52.3 per cent of the population of the state. Of the rural population, approximately 200,000 reside in 126 incorporated places of 1,000 to 2,500 inhabitants.

There are 14 cities in the state having a population in excess of 20,000 and these are listed in Table III in the order of their size in descending order of magnitude. It should be noted that if Cedar Falls (population 14,334) and Waterloo were taken together as one unit, their population would total 79,532, which would rank this combination third among the cities listed.

Reference to the population dot map, Fig. 13, shows graphically the population concentrations listed in Table III. The 1950 report of the Bureau of the Census defines an urbanized area as an area containing at least one city with 50,000 inhabitants or more in 1940. An urbanized area may also contain two or more cities of 50,000. There are three urbanized areas entirely within Iowa and three partly within the state. There were 362,532 persons living in the first three areas, the Cedar Rapids, Des Moines, and Waterloo urbanized areas. There were 212,969 persons in the Iowa parts of the Davenport (Iowa) Rock Island, Moline (Illinois), Omaha (Nebraska), and Sioux City urbanized areas.[7] Of the 575,501 persons in the state living in urbanized areas, 473,999 were in the five central cities, Cedar Rapids, Davenport, Des Moines, Sioux City, and Waterloo, and 101,502 were in the urban fringes.

Also basic to the development of the system, of course, was the existing distribution of educational facilities within the state. It has been indicated in a report that provision should be made for establishing four major points for program origination.[6] These points were given as Ames, Cedar Falls, Des Moines, and Iowa City.

The availability of program material at each of these localities would provide a cross section of educational program material which might be used throughout the state. The report indicated that Iowa State Teachers College would fur-

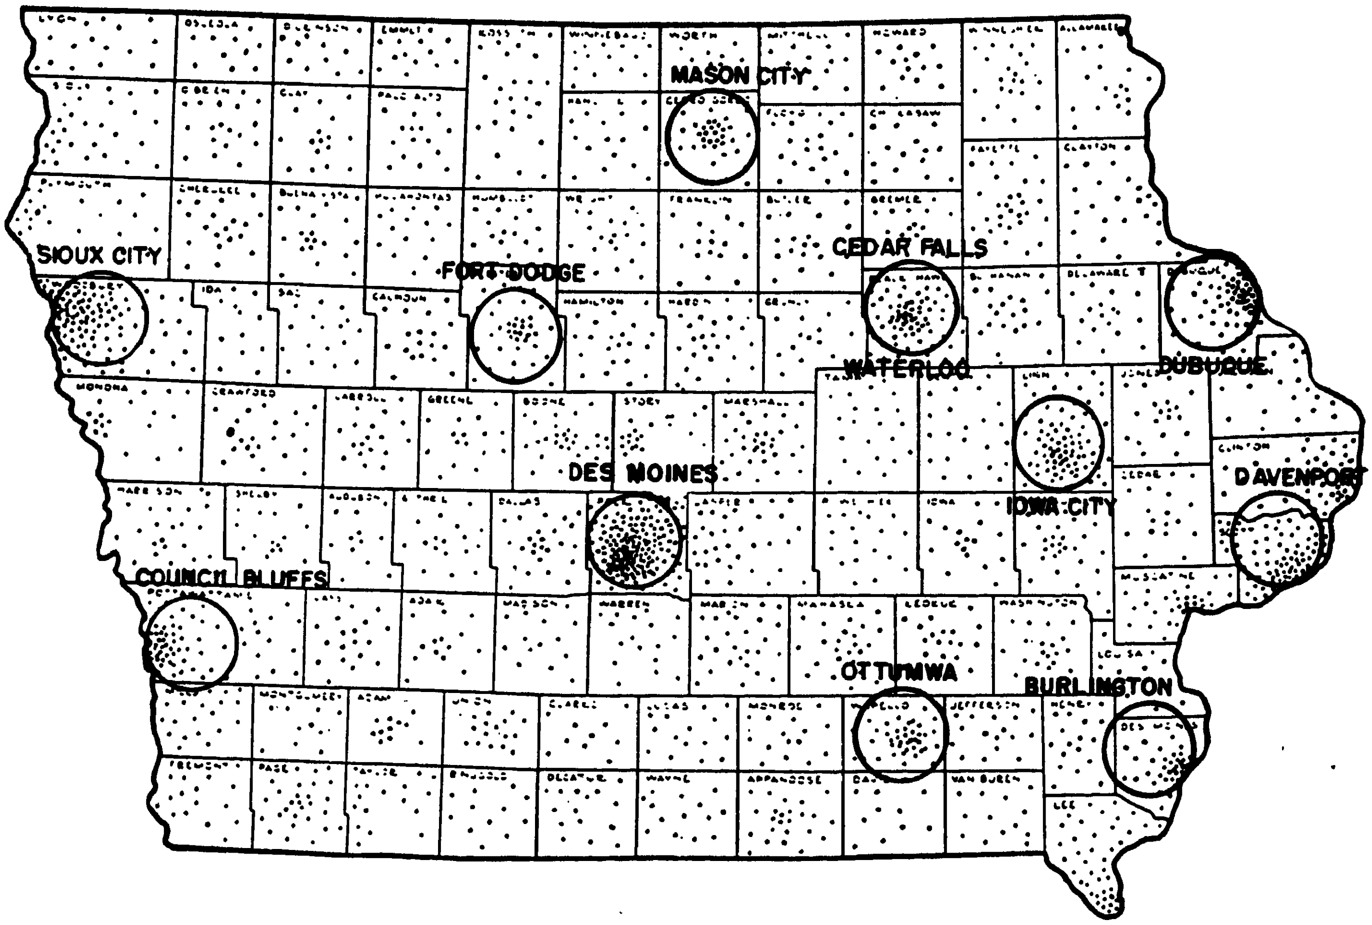

Fig. 14. Idealized distribution of educational TV broadcast stations to serve state of Iowa. Each dot represents 1,000 persons. Population 2,643,000, Census Bureau estimate, July, 1949 (circles do not indicate coverage)

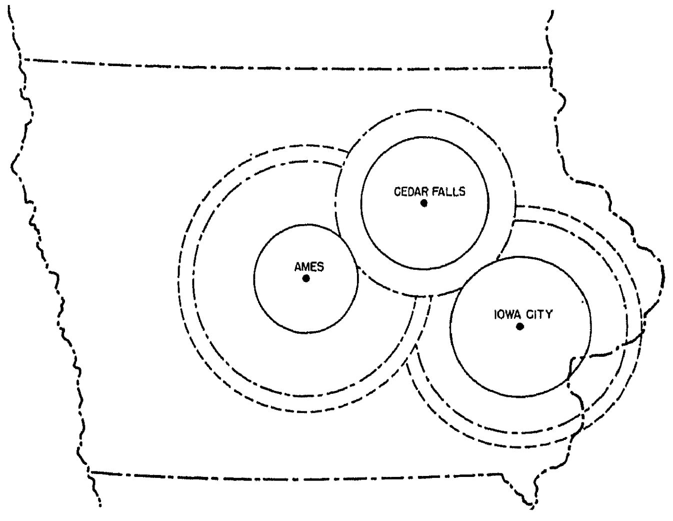

Fig. 15. Basic 3-station distribution for network, phase 1

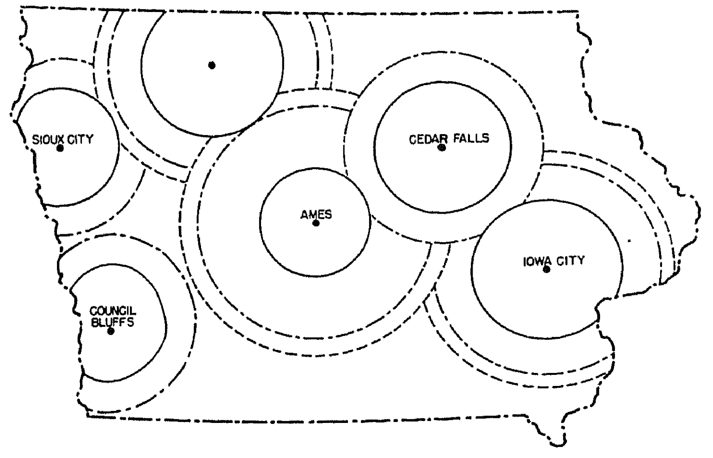

Fig. 16. Six-station distribution for network, phase 2

nish much of the material used for in-school purposes, while the State University of Iowa would contribute programs dealing with liberal arts and medicine, and Iowa State College would furnish programs relating to agricultural subjects, home economics, and engineering. Programming at Des Moines could include not only programs developed by the State Department of Public Instruction but also the many programs available from other state departments such as the Department of Health, the Board of Control, the Public Safety Department, the Iowa Development Commission, the Conservation Committee, and the Commission on Civil Defense. The desirability of being able to televise sessions of the legislature was also mentioned.

Consideration of the problem from the standpoint of an idealized station distribution is interesting, and involves a brief recapitulation of some of the points already covered. The technical standards regarding television contained in the list of rules of the Federal Communications Commission consider two grades of field intensity limit. These are defined as Grade *A* and Grade *B* limits for field intensities as noted in Table IV. The decibel-above-1-microvolt (dbu) reference level is 1 microvolt per meter.

The technical standards further provide, in connection with the location of the transmitter and antenna system, that the minimum field required over the entire principal community to be served shall be 74 dbu on channels 2 to 6, 77 dbu on channels 7 to 13, and 80 dbu on channels 14 to 83. It will be noted that these values are 6 db greater than grade-*A* values.

The requirements for the grades of service outlined were determined by making certain assumptions regarding receiver noise, transmission line losses antenna efficiencies, local noise and interference conditions, terrain factors, and time-fading factors. Based on these assumptions, the standards indicate that grade-*A* service for the VHF and UHF channels is, in effect, determined by the local noise and interference criteria under urban conditions, since the signal requirement based upon this condition equals or exceeds the signal levels required to meet other reception factors outlined in the foregoing.

In establishing the grade *B* service standards, the Commission contemplated that this reference would be operative only for rural location considerations and that the receiver factors, including the transmission line and antenna efficiencies and the terrain and fading factors, would be solely determinative.

The present charts contained in the technical standards of the Commission for predicting estimated field strengths are based upon median signal expectancy values. Specifically, these charts indicate estimated field strengths established at 50 per cent of the potential receiver locations for 50 per cent of the time at a receiving antenna height of 30 feet. To obviate the need for many charts showing field intensity for different percentages of time and location, all calculations are based upon the median value curves. Elevating the median values by the proper number of db secures the desired percentages contained in the standards for the various grades of service. Therefore, when performed in accordance with the present Commission technical standards, the interpretation of TV service is a statistical matter. In effect, the grade-*A* locus then becomes a limit at which, based upon average conditions, the service expectancy is for 70 per cent of the receiving locations 90 per cent of the time. Similarly, the grade *B*-limit line defines the locus at which the service epectancy is for 50 per cent of the locations 90 per cent of the time. It may be noted that the 90-per-cent time factor is a constant throughout and that on a statistical basis the percentage of locations at which satisfactory signals would be received would increase as the distance from the transmitter is decreased from either of the limits.

Based upon these considerations, it may be realized that any plan for statewide coverage of Iowa should endeavor to provide grade-*A* or better service over the urban areas of the state. In general, it may be stated that the more populous the area, the more stringent the service requirement. This leads to a recommendation for location of stations centered on the localities of urban concentration. Certain practical compromises with this approach are necessary, but for reference purposes, Fig. 14 portrays an idealized station distribution on the dot population map of Iowa. Each dot represents 1,000 persons and the location of the major urban areas is very evident.

In the case of UHF station considerations, the assumptions of the Federal Communications Commission for the various grades of service are numerically equal to the total of the receiver factor limitations under urban conditions without regard to noise and interference considerations. While receiver characteristics for the UHF frequencies may be expected to improve somewhat in the future, present factors indicate an even greater need for placing UHF facilities in the heart of the area to be served, whereas, because of superior receiver characteristics on the VHF channels, considerably more leeway in location is possible.

From the operation of TV stations to

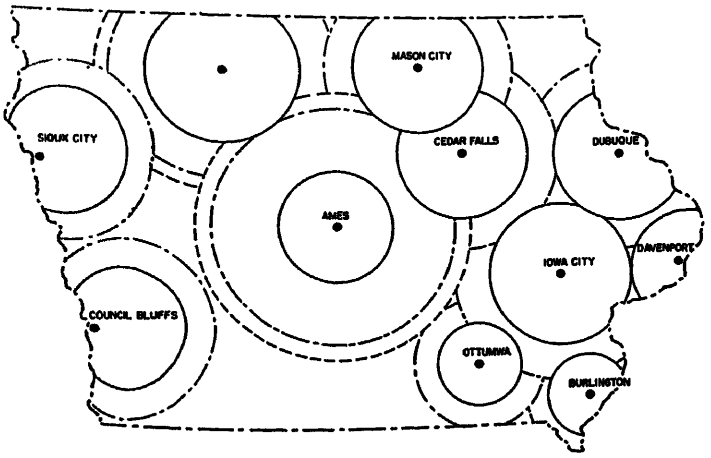

Fig. 17. Eleven-station distribution for network

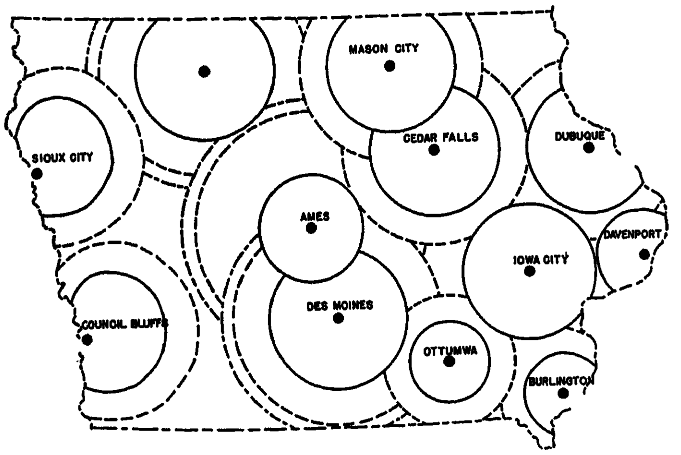

Fig. 18. Twelve-station distribution for network

date, we are well aware that the receiving public will, in many cases, make better than average installations in the way of antenna heights and antenna gain than those assumed in the development of the grade-*A* and grade-*B* service definitions outlined. Our experience is, of course, mainly limited to VHF considerations, since to date only a few of the TV stations operating are on UHF channels. In showing VHF service to the state of Iowa, we have assumed that 6-db more gain could be realized by the installation of better than average VHF receiving antennas or that a 12-db factor of gain is not unreasonable for a VHF antenna installation at a considerable distance from the transmitting station. It has not been possible to make a similar assumption to postulate a grade of service beyond the grade *B* limit in the case of UHF channels, because this service definition of the Commission already includes an assumption that a 13-db gain antenna will be employed on channels 14–83.

Experiments to date relative to the advantages to be gained by placing the receiving antennas at greater heights have been rather inconclusive. Therefore, while we recognize that many persons remote from the transmitter employ antennas installed at heights greater than 30 feet above ground, no extension of service factor based on this consideration has been incorporated in our hypothesis. It is possible, of course, that further experience with UHF receiving conditions will enable us to postulate improved coverage for this type of station in the future, based upon a combination of this and other factors. We do not, therefore, regard the limits indicated on the coverage maps as definitive in the sense that there will be a complete absence of signal in the several zones indicated. As a practical matter, we have endeavored to make these zones fall in areas where the population is most sparse, and where the local interfering factors are minimized.

The subcommittee[6] report has proposed that, as a first step in an over-all plan, TV broadcasting stations and program-originating facilities be established at Cedar Falls and Iowa City. These two additional stations would then be linked by program relay facilities with the existing station, WOI-TV, at Ames, Iowa, to provide a basic 3-station network. The report also investigated the establishment of a program-originating facility at Des Moines, Iowa. This latter facility could also be interconnected with the other three program-originating centers to form the nucleus of a state-wide system.

In the TV broadcasting service, as in other broadcast services, it is fairly common practice to have separate program-originating or studio facilities and transmitting plant facilities. As in the case of the present operation at WOI-TV it may ultimately be more expedient in securing optimum placement of transmitting facilities from a coverage standpoint to locate such transmitters remotely from the studio location, which may be kept at a more convenient and centralized location. This is done to secure the advantages of superior terrain elevation or to provide an improved geographical distribution for the transmitted signal. Interconnection of the studio and the transmitter in such cases is usually by means of a microwave radio relay link.

Fig. 15 indicates the expected distribution of TV broadcast coverage from the basic 3-station operation. This figure also forms the basis for consideration of a second step toward a state-wide system. It would appear logical at this point that provision should be made for service to the western portions of Iowa.

Reference to the population concentration map shows that the most stringent requirements in this area will be imposed by the population concentrations at Sioux City and Council Bluffs. Since the Commission Assignment Plan for Educational Television in Iowa provided channel 30 for Sioux City, but none for the Council Bluffs region, a study was made to determine if a channel would be available for use in this area upon the presentation of a proper rule-making request to the Commission. Study indicated that channel 55 could be employed in this area. This and similar other studies indicated that the coverage distribution for the combined first and second steps

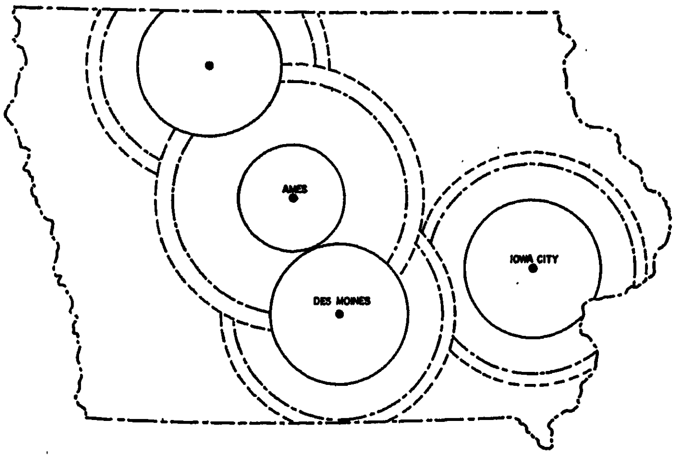

Fig. 19. Optimum distribution of stations for a VHF network

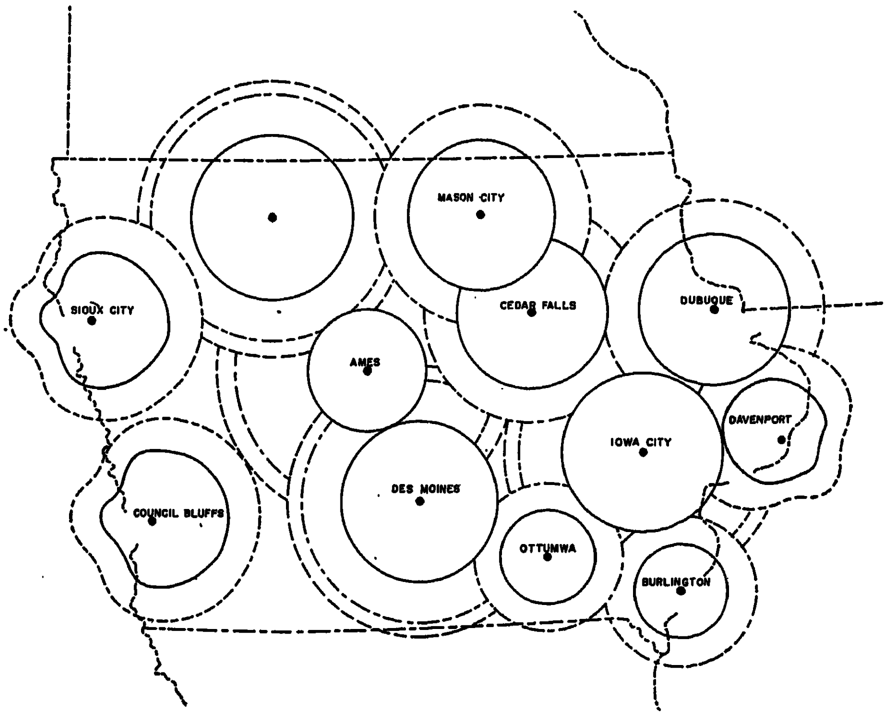

Fig. 20. Optimum distribution for 12-station network

in the envisioned program could be as shown in Fig. 16.

Reference to Fig. 16 and the dot population map of the state, Fig. 14, indicates the important urban and rural areas remaining in the state for which grade-*A* and grade-*B* service provisions should be made. By providing for a grade-*A* or better, service in Mason City, Dubuque Davenport, Burlington, and Ottumwa, most of the urban and rural gaps in Fig. 16 can be filled. Fig. 17 indicates the possibilities along this line.

Reference to Figures 17 and 14 indicates the possibility and the desirability of employing the channel 11 assignment at Des Moines to provide an improved grade of service in the major population center of Des Moines and in the rural central southern region of the state. Fig. 18 which has been prepared to illustrate this additional step in the development, is illustrative of one further important condition which involves consideration of the optimum distribution of the VHF channel assignments available for educational use in Iowa.

Since the receiving sets in the hands of the Iowa public today are 12-channel sets equipped to receive only VHF channels, we regard the VHF assignments available for the state program as a keystone of the state-wide service system for several years to come. Accordingly, it is important to consider as a separate facet of the problem the best employment of these facilities to secure the optimum coverage which they can provide within the limits of transmitter placement. The idealized distribution of these four VHF facilities is indicated in Fig. 19. Basically, this involves employment of the channel 11 facilities at Des Moines as far east and south of the city as it is practical to go, from a city service requirement standpoint, and the shift of the Ames transmitting facility to a locality more central with respect to the Des Moines and the assignment in the northwestern part of the state. This alternate arrangement would also more nearly satisfy the service requirement of Fort Dodge for a grade-*A* or better service. The composite coverage based upon activation of all the steps outlined is shown in Fig. 20.

The additional channels for the other cities requiring a grade-*A* service are summarized below. These are all UHF channels, since the VHF saturation technique employed by the Federal Communications Commission in developing its Table of Assignments precluded VHF assignments with the exception of one case: Burlington, Channel 63; Dubuque, Channel 68; Mason City, Channel 47; Ottumwa, Channel 41.

Table V gives a list of the proposed operations and the effective radiated power and type of antenna to be employed by each. The maximum allowable effective radiated power under the Commission's rules is 100 kw for channels 2 to 6, 316 kw for channels 7 to 13, and 1,000 kw for channels 14 to 83. The term effective radiated power as employed in the Commission standards is defined as the product of the antenna peak power input and the antenna power gain. The horizontal plane is the reference dimension for the antenna gain term. The conventional TV antenna employs elements, so phased and so arranged along a supporting member that radiation is concentrated toward the horizon, and radiation at the vertical angles minimized.

Effective antenna heights of 500 feet would be employed in all cases. Effective antenna height is defined by the Federal Communications Commission as the height of the electrical center of the TV radiating system above average ground elevation, determined in eight radial directions over a 2-to-10 mile interval of distance from the transmitter site. Supporting tower height requirements will therefore vary somewhat, depending on ability to locate transmitting tower sites at higher-than-average ground elevations for the several locations.

Directional antennas have been assumed in three instances to minimize the out-of-state coverage and the required number of stations. The rules of the Federal Communications Commission contemplate allowing directional antenna operation, providing that the degree of directionality employed is kept within certain limits, and that in no event is the maximum effective radiated power specified under the rules exceeded in any direction. Therefore, in the case of the Council Bluffs and Sioux City operations while the effective radiated power in an easterly direction is 1,000 kw, the average

Table V. Power and Antennas for Proposed Operations

City	Channel	Effective Radiated Power	Type of Operation
Ames	5 (VHF)	100 kw	nondirectional
Burlington	68	100 kw	nondirectional
Cedar Falls	22	1,000 kw	nondirectional
Council Bluffs	55	525 kw	directional
Davenport	30	200 kw	directional
Des Moines	11 (VHF)	1,000 kw	nondirectional
Dubuque	68	1,000 kw	nondirectional
	12 (VHF)	316 kw	nondirectional
Iowa City	12 (VHF)	316 kw	nondirectional
Mason City	47	1,000 kw	nondirectional
Ottumwa	41	100 kw	nondirectional
Sioux City	30	525 kw	directional

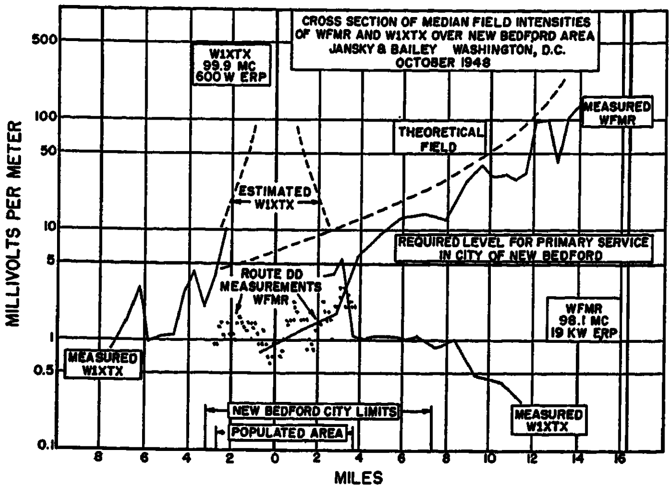

Fig. 21. Theoretical and measured field intensity distribution over a city illustrating importance of transmitter siting

power for the whole pattern employed is considerably less than this value. Maximum allowable power was proposed in all cases to provide the maximum possible signal in all areas, consistent with Commission standards.

In the case of the four VHF stations, commercial equipment to attain the maximum effective radiated powers specified is available on the present market. As regards UHF operations, however, commercially available equipment at present imposes a power ceiling of approximately 275 kw of effective radiated power. Higher powered equipment is still in the design stage at present, although certain preliminary cost estimates for equipment combinations to produce 1,000 kw of effective radiated power are available. Therefore, of necessity, an initial operation at Cedar Falls, under phase 1 of the program might be for a lower effective radiated power than that assumed. The prompt establishment of this station, however, albeit at a lower power, would enable measurements to be made and experience to be gained which could furnish an important guide in the development of the other phases of the system.

The importance of optimum transmitter siting in the development of a program such as outlined cannot be overemphasized. As an example, while it would be tempting to say that one transmitter located centrally with respect to Iowa City, Davenport, Burlington, and Ottumwa could adequately serve these four cities, the percentage of locations in each city where reception difficulty prevailed would undoubtedly be high. Fig. 21 illustrates a case in which a 600-watt FM station centrally located in the city concerned was found to be necessary to supplement the service from a 19-kw FM station located approximately 16 miles from the center of the city. While on a theoretical basis adequate coverage of the city was indicated, this did not prove to be the case in practice, as is shown. The path for route DD measurements, which was shown on Fig. 7, lies generally along the last portion of the path of the main radial run from the WFMR transmitter site. This case is an example of the importance of paying due respect to the statistical theory of city coverage. This theory may be stated approximately as follows: In any city in which the field intensity of a broadcast station is not at every point sufficient to provide a satisfactory service in the presence of the noise level at that point, there will be some percentage of the potential listeners who will not receive satisfactory service. This percentage will vary with the average field intensity, with the distribution and intensity of noise sources, and with the variability of the signal over the city.

Automatic Testing of Wired Relay Circuits

A. N. HANSON
MEMBER AIEE

PRACTICALLY all of the telephone switching equipment in an exchange is made up of wired assemblies—assemblies of relays and other components interconnected by a multiplicity of wires. These assemblies are on frameworks generally 11 feet 6 inches high. Many of these frameworks are made up of smaller components called relay circuit units composed mainly of relays. Rotary switches, resistors, capacitors, jacks, etc., necessary for the operation of switching circuits may also be included. These components vary in height up to about 24 inches and after testing they are mounted in the larger frameworks. A careful check of connections and electrical continuity is essential to assure that these units will function properly when connected to other circuits in a telephone exchange.

Buzzer continuity tests lack much in effectiveness and manually operated test sets are slow and tedious, and lead to human errors. Manual test sets, however, have the advantage of great flexibility in testing various types of circuits not usually found in automatic test sets. Automatic test sets have been in use for

Paper 53-407, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2–6, 1953. Manuscript submitted August 11, 1953; made available for printing September 23, 1953.

A. N. Hanson is with the Western Electric Company, Inc., Chicago, Ill.

Grateful acknowledgement is accorded to A. J. Ehlschlager, designer of the test set, and to F. L. Osborne, for their aid in preparing this paper.

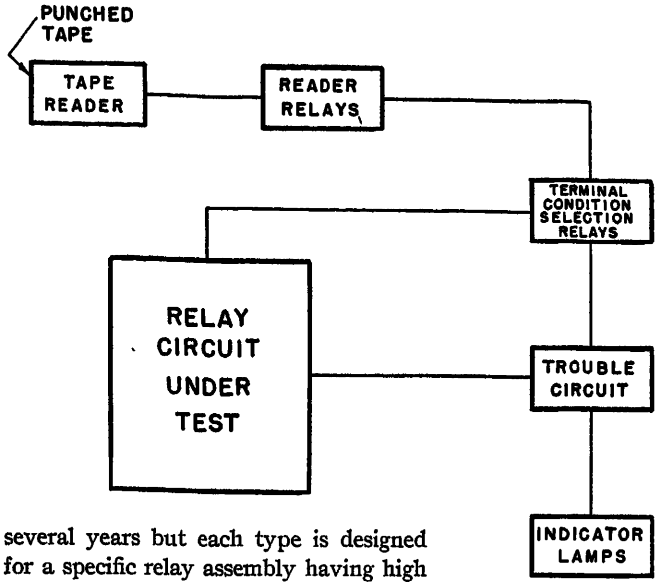

Fig. 1 (left). Test set functional block diagram

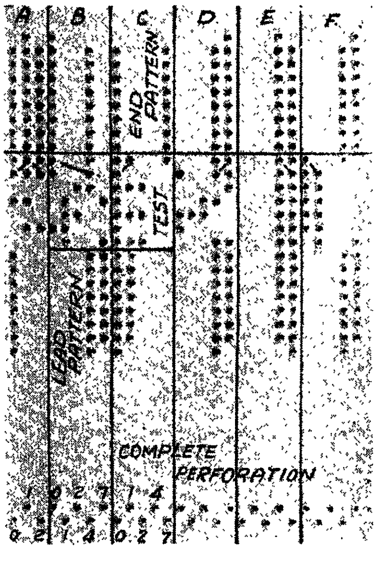

Fig. 2 (right). Section of perforated tape

several years but each type is designed for a specific relay assembly having high production requirements, and which is felt to be of stable character. The automatic sets are prepared for test by operating a few test set switches to a fixed position. A test set start-switch is then operated and the test proceeds to completion unless trouble is encountered. In the latter event, the test set stops and display lamps light to aid in locating the trouble. These automatic sets lack the flexibility of the manual sets and, to realize efficient production, they require the test man to be fully familiar with the circuit under test.

A new test set has been developed to eliminate the undesirable features of manual testing and still retain complete flexibility. The new test set reduces, sharply, the human equation as it automatically checks relay assemblies wired to perform practically any switching functions. Employing perforated tape for switching control, the test set applies operating and test conditions to terminals of the wired assembly. Indicator lamps pin-point terminals which fail to meet test conditions and, in most cases, indicate the nature of the trouble. This automatic test set is the subject of this paper. The particular set to be described was designed for testing relay circuits having up to 64 connecting block terminations. The design principles may be applied to testing larger assemblies up to practical limits of test set size and the switching principles could be used for testing other types of wired assemblies.

Table I. Available Terminal Testing Conditions

Condition No.	Reader Relays Operated	Terminal Relays Operated	Terminal Condition Desired
0*			Open check
1	*D*0, *D*1	*A*, *B*	Ground
2	*D*0, *D*2	*A*, *C*	200-ohm ground
3	*D*1, *D*2	C	Ground check
4	*D*0, *D*4	*B*, C	Battery
5	*D*1, *D*4	*A*, *B*, *C*	Common jack
6	*D*2, *D*4	*B*	Battery check
7	*D*0, *D*7	*A*	Individual jack

* Condition 0 is applied to any terminal not having conditions 1 to 7 and is not affected by the *D* group reader relays.

Test Sets, General

A brief discussion of the types of manually operated sets used to test wired relay assemblies will help to show the advantages of the automatic set. First, a manual set requires many cross-connections that vary for each different type of wired relay circuit to be tested. Since the circuits may be entirely different, one from another, each type of relay circuit tested has different circuit conditions wired to the connecting blocks. To bring the desired test set condition to the terminals of the wired assembly, cross-connections must be made at the test set that may number as many as 100. This is a time-consuming setup procedure and is a source of potential operator error. Second, practically every step in the progress of a test is controlled by manual operation of switches. Third, the operator verifies wiring accuracy by observing signal lamps which light or extinguish as each switch is operated. Fourth, the test man must refer to an instruction between each step of the test.

These are all major disadvantages as they all present potential sources of operator error. The automatic set avoids these disadvantages. With this automatic test set, progress of a test is controlled by relays which perform switching operations according to a sequence set by a perforated paper tape. The test continues automatically. When trouble is encountered, the set stops and indicates the location of the trouble on signal lamps. Because it is quickly adaptable to different wired relay assemblies, it has been called a Universal equipment test set.

Universal Equipment Test Set and Perforated Tape

Fig. 1 shows in block diagram form the main components of the Universal equipment test set. The tape is of specially prepared paper 3 inches wide, perforated with embossments in a saw-tooth fashion, with patterns of holes that can be read by the reading pins of an automatic message accounting reader. When placed in the tape reader, the embossments are on the underside of the tape. A selection of 28 embossments are possible across one line of tape. Fig. 2 shows a section of perforated tape demonstrating a complete line of twenty-eight holes and a

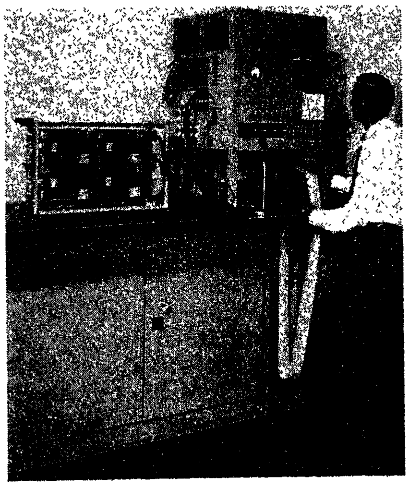

Fig. 3. The Universal equipment test set with unit under test

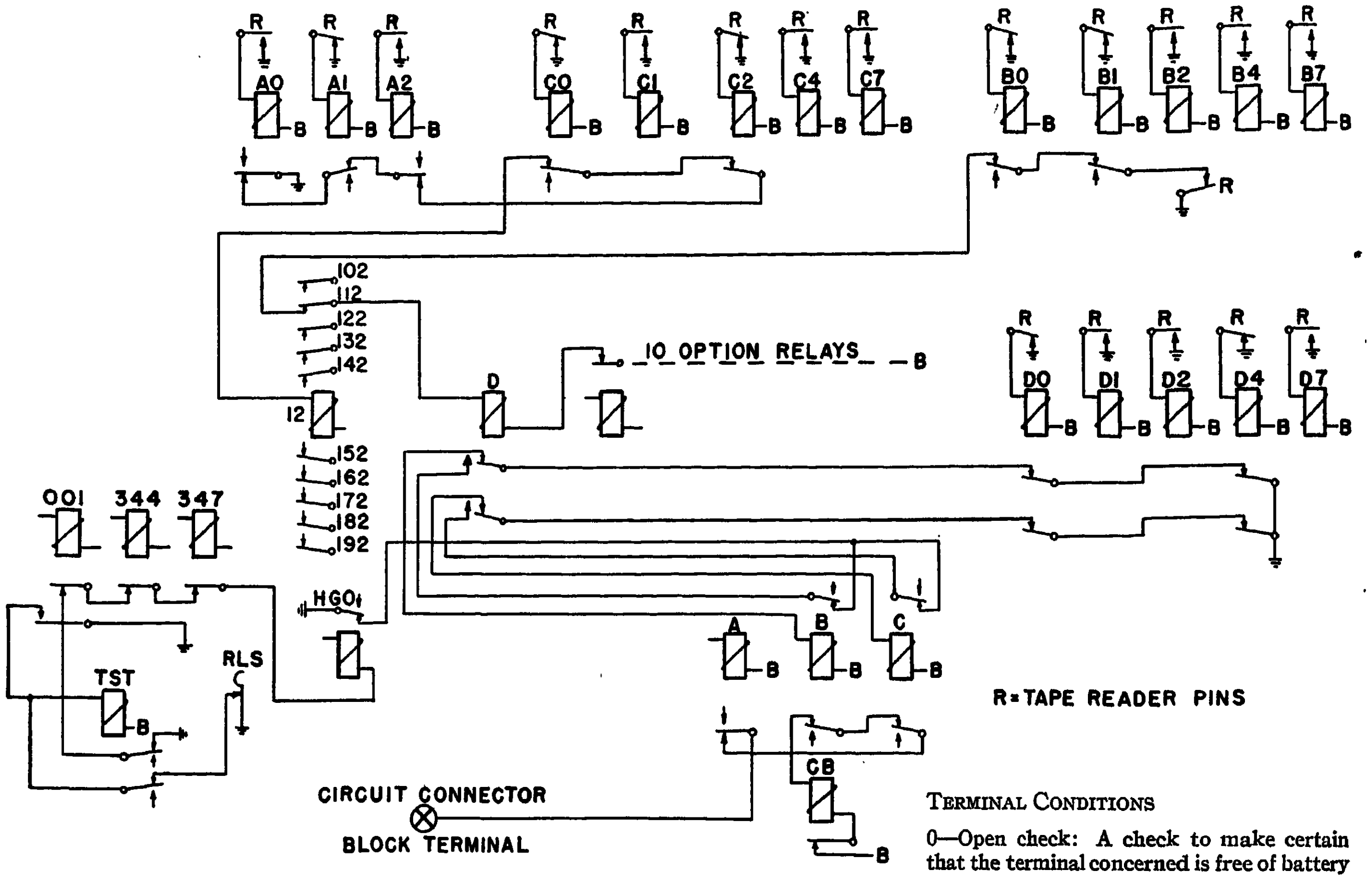

Fig. 4. Functional schematic of terminal selection and terminal condition selection circuit

compressed section of test perforations. The perforations, as shown in Fig. 2, are divided into six groups, *A* to *F*. Group *A* has three positions for the perforations and groups *B* to *F* have five positions each. Perforating a single position in the *A* group represents the numeral 0, 1 or 2. Perforating all positions in the *A* group represents the numeral 3. Perforations positions in groups *B* to *F* (there are 5 positions per group) are given values 0, 1, 2, 4 and 7 respectively. Two, and only two, perforations are provided in each of groups *B* to *F*. The values of any two perforated holes, properly selected, can be added to result in any numeral from 1 to 9. The numeral 0 is obtained by adding 4 and 7. The significance of the numerical values will be apparent later.

The Tape Reader

The tape reader steps the tape at a rate of 16 steps per second. Between each step, 28 sensing pins descend to the tape in the same saw-tooth pattern shown in Fig. 2. When a hole permits a pin to pass through the tape, a pair of twin contacts close, to provide ground potential to complete a circuit path. If no hole is found, the contacts remain open as the pin strikes the paper. Reader relays, so called since they operate directly from the reader-pin closed contacts, are provided, one for each perforation position. They are designated *A*0, *A*1, *A*2, *B*0, *B*1, *B*2, *B*4, *B*7, *C*0 to *C*7 and *D*0 to *D*7. The *E* and *F* digits require no reader relays. They are used only to light display lamps which connect directly to the reader-pin contacts.

Terminal Condition Selection Relays

Test set terminations are connected to the unit under test through fixtures that contact the unit connecting block terminals. To each of these terminations is connected a set of four relays designated *A*, *B*, *C* and *D*. By the proper pattern of holes in the *A*0 to *A*2, *B*0 to *B*7 and *C*0 to *C*7 tape groups, any desired terminal of the connecting block can be selected to receive the test condition prepared by its set of terminal condition selection relays *A*, *B* and *C*. By a pattern of holes in the *D*0-*D*7 tape group, which produce the condition number, relays *A*, *B* and *C* can be operated in any one of eight combinations to provide one of eight conditions required for testing. These eight conditions are shown in Table I. The following will clarify the use of the terminal conditions.

Terminal Conditions

0—Open check: A check to make certain that the terminal concerned is free of battery or ground potential.

1—Ground: Connects direct ground from the test set to a unit terminal.

2—Ground check: A check to determine that ground potential is received by the test set from the circuit under test.

3—200-ohm ground: Connects a 200-ohm resistance ground from the test set to a unit terminal.

4—Battery: Connects direct battery from the test set to a unit terminal.

5—Common jack: Connects unit terminals to a pin jack for patching in special conditions or to form a loop between two or more terminals by connecting them to the common pin jack simultaneously.

6—Battery check: A check to determine that a battery potential is received by the test set from the circuit under test.

7—Individual jack: Connects a circuit terminal to an individual pin jack assigned to each connecting block terminal, for patching in special conditions or to present an open circuit to the terminal if desired.

Trouble Circuit

The terminal conditions are used to set up, within the circuit to be tested, circuit conditions that will verify agreement of the circuit with manufacturing drawings. For instance, ground will be connected by means of condition 1 to a connecting block terminal of the relay unit which carries a wire to one terminal of a relay coil that has battery on the far end of the coil. Terminal condition 2 is connected to another connecting block terminal that connects to a relay spring-make combination of that relay with ground on one spring. Thus, a relay of the unit, has been energized, and means provided for checking that the relay has operated, and for checking that the relay coil and relay spring combination are connected to the proper connecting block terminal. The actual verification check is not made, however, until a check line, to be described later, is perforated on the tape. As the *A*, *B* and *C* relays are operated, they are locked up until the *D* relay operates to introduce another condition or until a release-all combination is punched in the *A*0 to *A*2, *B*0 to *B*7 and *C*0 to *C*7 groups on the tape. When the check line is introduced by perforating the numbers 0, 1 and 2 in the *A* tape group, 0 and 4 in the *B* tape group and 0 and 1 in the *C* tape group (no. 341), the test set hesitates for 2 reader cycles (2/16 seconds). In this time, the TBL (trouble) relay is introduced to determine if terminal condition 2 is satisfied. If ground does not come back from the test set over the proper terminal, the TBL relay operates. At the same time, condition 0 is checked on all connecting block terminals not affected by conditions 1 or 2. If potential is returned to the set from any terminal which should be an open circuit, the TBL relay operates and stops the test.

To every connecting block terminal of the unit is connected four lamps with the terminal identification stamped on the lamp caps. In one group, labeled "In Use *G*," a lamp showing the terminal number will light if ground is expected back to the test set, but is missing. A second group, labeled "In Use *B*" will act the same where battery is involved. A third group of lamps labeled "Open *G*" and a fourth group labeled "Open *B*" will light, respectively, if ground or battery is present on any terminal not involved in the test that is in effect. These lamps point directly to the terminals that are in trouble and they aid in determining the nature of the trouble. The check line tape perforations are introduced at frequent intervals to narrow the field to be searched when trouble is encountered.

Using the Test Set

Fig. 3 shows a view of a test set designed for testing a relay unit having a maximum of 64 connecting block terminals. The cabinet to the right contains the control keys, indicating lamps, rheostats, pin jacks for special conditions, and cable connecting sockets. Below this cabinet is seen the perforated tape reader. In the enclosed cabinet under the table top are mounted the switching relays, capacitors, and resistors. A relay unit is seen connected to the test set by fixtures and conducting cable.

To start the test, the perforated test tape is fed into the tape reader. The reader pins first find a pattern of perforations known as the lead pattern. The lead pattern insures that the tape is properly aligned and feeding correctly into the tape reader. From the lead pattern, the tape perforations lead directly into the test pattern. Referring to Fig. 4, assume that the test will start with the placement of 48-volt negative battery on terminal 11 of terminal strip group no. 2. The perforations in the tape *A* group determine the 10's digit of the terminal number, the tape *B* group determines the unit's digit of the terminal number and the tape *C* group determines the desired terminal group or the terminal strip number. Thus, to find the desired terminal, the tape *A* group will have a perforation in the *A*-1 position, the tape *B* group will be perforated in the *B*-0 and *B*-1 positions, and the tape *C* group will be perforated in the *C*-0 and *C*-2 positions. The *D* tape position at this point determines the terminal condition to be placed on the selected terminal, which in this case

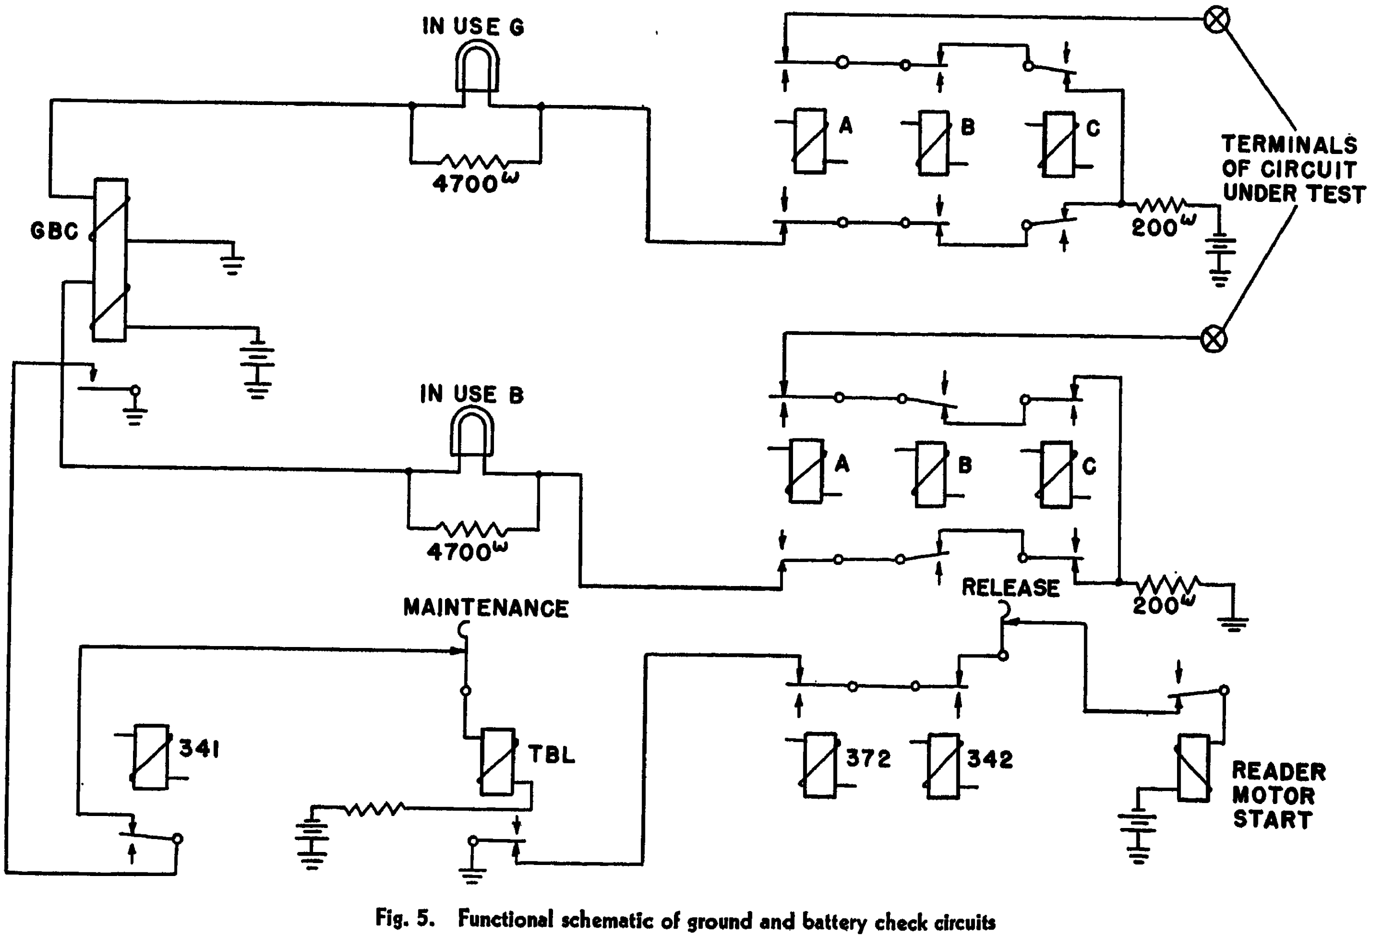

Fig. 5. Functional schematic of ground and battery check circuits

is condition 4 for −48-volt battery from the test set. The *D* group perforations, therefore, are *D*-0 and *D*-4. Thus, as the reader pins descend to the tape, they will find entrance through holes, registering the number 112,401 as the first line of the test pattern. The 01 represents the line identification and is not shown as a part of Fig. 4. Reader relays, corresponding in designation to the perforation designations, will operate directly from ground on the contacts of the reader pins that find perforations in the tape.

Referring to Fig. 4, the *A* and *C* tape groups select first the no. 12 relay representing the terminal 10's digit and the terminal strip number. Through one of the No. 12 relay make contacts, the tape *B* group selects the terminal identified by the units digit and operates the *D* relay associated with the terminal condition selection relays *A*, *B* and *C* associated with that terminal. The operation of the *D* relay closes a path to operate the *A*, *B* and *C* relays in a combination in accordance with the *D*0 and *D*4 perforations which in this case operates relays *B* and *C*, with *A* remaining normal. Operating relays *B* and *C* places battery on the relay circuit connecting block terminal. The *B* and *C* relays then lock and the *D* relay releases.

In similar manner, potentials are applied to other circuit-connecting block terminals to operate relays within the circuit under test. To check that the relays have operated, and to check that the wiring of the relay spring combinations are correctly connected, battery or ground potential is connected under tape control to the circuit terminals that are connected to the spring combinations. This potential from within the circuit is to be looked for at the test set when the check line is introduced on the tape. The check interval is introduced by presenting a tape line perforated in positions *A*0, *A*1 and *A*2, *B*0 and *B*4, and *C*0 and *C*1, or 341-XXX. At the check line, the *D*, *E* and *F* tape groups represent a test line identifying number. During this interval the TBL relay is connected into the circuit and a check is made by the test set to determine if the terminal conditions, set up by the terminal condition selection relays, are satisfied where potential is expected back from the relay circuit under test. At the same time, a check is made to determine that no potential is present on any terminal that should present an open circuit. Figs. 5 to 9 show typical examples of how the TBL relay is connected, to detect incorrect conditions.

Should the TBL relay remain normal, the conditions that the test set is looking for are satisfied and the test continues automatically. Should the TBL relay operate, it releases the reader clutch that advances the perforated tape and the test stops instantly. At that time, display lamps on the test set light to indicate the nature and location of the trouble. A set of lamps, giving the entire tape entry, light with every step of the tape, and if the tape stops in a check line this set of lamps indicates the serial number of the tape line of perforations. With each tape is provided a list of numbers that serve as a decoder for the perforated tape. Referring to this number list at the stopping or trouble point in the test, the test man can determine what test conditions were imposed after the last successful check line, and thus find aid in dealing with trouble.

Referring to Fig. 5, the TBL relay operates from contacts of an operated GBC (Ground battery check) relay, if either expected ground or expected battery from a predetermined connecting block terminal fails to appear. If ground is expected, on a circuit terminal, condition 3 on the test tape prepares the test set to receive it. If it appears, that ground will shunt out the ground winding of the GBC relay and prevent it from

appears on any terminal that should be free of potential. Since the terminal condition selection relays are unoperated if not involved in the immediate test, their normally closed contacts are connected in series between their circuit terminal and the OC relay winding at all times. It will be recalled that the check position carries over two steps of the reader. On the first step the OCG (open-circuit ground) relay, unoperated, completes the path across its break contacts to detect unwanted ground. Should no ground be detected it operates and in turn operates the OCB (open-circuit battery) relay to check for unwanted battery. Should either potential be present, the open-*G* or open-*B* lamp, carrying the terminal number, will light.

Referring to Fig. 7, the TBL relay will operate if battery or ground is found on the circuit unit framework, which is left purposely floating. An FG (frame ground) or FB (frame battery) lamp will light in case of an error. Relays with the designation *P* on the relay core are of the polarized variety. That is, they are sensitive to the direction of the current through their windings.

Certain relay circuits are equipped with a grounded 10-ohm resistor used as a very important holding ground in the telephone system. Referring to Fig. 8, the TBL relay will operate from an unbalanced wheatstone bridge circuit and 10*G* lamp will operate if the resistance is incorrect or missing.

If none or only two relays operate in the *A* tape groups or if any but 2 out of 5 reader relays of the *B*, *C*, or *D* tape groups operate, it is a signal that the perforated tape is defective and the TBL relay will operate. Fig. 9 illustrates this feature.

The test cannot proceed until the trouble is cleared, after which the start key is used to resume the test.

Special Conditions

In a shop test, it is not always possible to check automatically all conditions which might affect wiring accuracy, partly because of the circuit design and partly because associated circuits are missing. Therefore, where necessary 342XXX line is inserted on the tape which stops the test set tape reader and lights the SP lamp on the test set panel. The last three digits of the 342XXX line will show the actual sequence number of the perforated tape line. The test set operating instruction, provided with every circuit, tells the test man what special verification to make at that position of the test.

Special circuits not regularly used but which are made available at pin jacks to be patched to the individual jack (Table I, condition 3) or the common jack, (condition 5) when required, are:

1. Ground, −24 volts d-c, −48 volts d-c, 88 volts 20 cycles per second with −48 volts d-c superimposed, 105 volts 20 cycles per second, +130 volts d-c, −130 volts d-c.
2. Five lump resistances of 10,000; 20,000; 30,000; 40,000; and 50,000 ohms respectively.
3. Two 0–9,999 ohm resistance decades.
4. Seven calibrated rheostats 0–500, 0–1,000, 0–2,500, 0–3,500, 0–5,000, 0–8,500, 0–10,000 ohms respectively.
5. Five 90-ohm battery circuits.
6. Battery or ground potential under control of a switch.
7. Tip, ring and sleeve of a telephone jack.
8. Interval timing circuit.
9. 10-ohm ground checking circuit.
10. 1,000 cycles per second source.
11. Transmission measuring circuit.

Options

An option consists of wiring or apparatus, or a combination of both in a circuit, used in addition to a standard circuit to provide variable conditions as required by special telephone traffic conditions. Wherever provided, such options must be tested and the perforated test tape for each circuit includes the tests for all options as well as the main circuit, in their proper sequence. Provisions are made to include on a tape as many as nine options under control of nine switches on the test set panel. With all of the nine option switches in the off position, all options on a tape may be by-passed. Although the tape reader must pass over every line of perforations, the switch will supply a circuit, under control of the appropriate entry on the tape, to ignore tests of that option. With any option switches 1 to 9 in the on position, that numbered option is automatically included as a test feature.

Maintenance

One of the advantageous features of this test set is simplification of maintenance. The *A*, *B*, *C*, and *D* relays (256 in all, or 1 set for each of the 64 terminals) are identically wired, and the OC, OCB, OCG, and GBC relays; (28 in all) are also identically wired. Thus, of a total of 384 relays in a test set, 320 fall in two groups of identically wired relays. This makes easier a good understanding of the circuit functions. A tape is provided for maintenance use in rapidly checking the entire test circuit. This tape not only places conditions on the test set to cause it to operate, but also places simulated defective conditions to make certain that the test set will stop and indicate, properly, such conditions.

Testing Instructions

A set of testing instructions(IMI), in addition to the perforated tape, is provided by the engineer to the tester covering each different circuit to be tested. This instruction includes information for test set preparation, for action to be taken when the test set is stopped for a special condition and a complete number list of the tape perforations. Each line of perforations on a tape is represented by a 6-digit number. As explained heretofore, these numbers represent a phase of test set preparation determined by the tape group, *A*0 to *A*2, *B*0 to *B*7, *C*0 to *C*7, and sometimes, *D*0 to *D*7, in which they are located, plus the arrangement of the test set switching circuit. The test man, acquainted with the numbering significance and plan of perforations can, at a glance, determine how far the test has progressed, and what tests have gone on before. Referring to his chart Table I, which is quickly memorized, he can determine from the number list *D* tape group what conditions have been imposed since the last successful check line, as well as the unit terminal (*A*, *B*, and *C* tape groups) upon which the condition was imposed. At each check line is included identification of the relays that should be operated at that time. This information is given to aid in locating trouble conditions.

Conclusion

This test set is coming into extended use for testing wired relay units. The fact that lighted lamps indicate not only the nature of the trouble but pin-point the terminals to which the wires are connected that are in trouble, is of course, a great aid in finding the trouble.

The Use of Electric Network Analyzers for Pipe Network Analysis

ROBERT E. STEPHENSON
ASSOCIATE MEMBER AIEE

J. R. EATON
MEMBER AIEE

THE determination of fluid-flow and pressure drop in complicated pipe networks such as gas or water distribution systems presents many problems similar to those encountered by the electrical engineer in the study of transmission and distribution networks. As the network analyzer has proved to be a very great help to the electrical engineer in his studies, it seems reasonable that similar techniques utilizing similar analyzers would be of considerable value in the analysis of pipe networks. Several investigators have reported methods for applying network analyzer techniques to gas or water distribution problems, some using special handling of conventional analyzers and others using special analyzers built solely for fluid-flow problems.

This paper presents a newly developed method for adapting conventional a-c or d-c network analyzers to pipe network problems. It has the advantage of requiring a minimum of slide rule computations and provides a degree of accuracy of results comparable to those attained in studies of electric systems made on the same analyzer.

Comparison of Fluid Flow and Electric Flow Networks

A comparison of the basic relations pertaining to fluid flow and to electric flow in networks demonstrates that the two systems are very similar in certain respects but quite different in one important aspect. It might be stated that Kirchhoff's laws apply in both systems. In a fluid flow network the algebraic sum of the pressure drops around any closed loop must be equal to zero, whereas the algebraic sum of the flow into any pipe junction must total zero. Because of these similarities of the two systems, it is logical that in studying pipe systems by means of electric networks, the pressure drop in the gas systems should be represented by voltage drop in the electric system while flow in the fluid system is represented by current in the electric system. When this relationship is adopted, the topology of the fluid system is maintained in the electric system which represents it.

The one important difference between the fluid and the electric systems is in the relationship between flow and pressure drop which, (for incompressible flow) is of the form given in equation 1

$$Q=K_gP^n \qquad (1)$$

Paper 53-410, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2-6, 1953. Manuscript submitted February 16, 1953; made available for printing August 21, 1953.

The authors acknowledge the valuable help and assistance given by J. B. Ward, H. W. Hale, and D. L. Johnson, all of Purdue University, in performing the experimental work connected with this development.

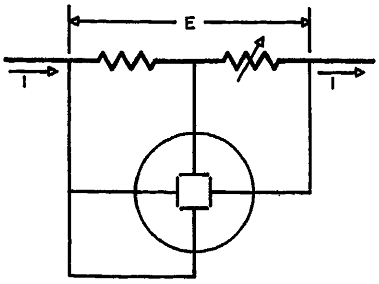

Fig. 1. Basic connections

where

Q = the flow through a particular pipe section
K_g = constant of proportionality
P = pressure drop or head-loss through a particular pipe section
n = a constant having the value 0.5 for gas flow and the value 0.54 for water flow

This equation is in contrast to the behavior of electric circuit elements in which current and voltage drop are related as indicated in equation 2

$$I=GE \tag{2}$$

where

I = the current through a particular element
E = the voltage drop across the element
G = the conductance of the element

In representing a pipe network by a topologically similar electric network, the first two characteristics of the fluid flow system are inherently maintained by the electric network. For an electric network to perform in a fashion identically analogous to the pipe network, it would be necessary to have current flow in each circuit element related to voltage drop across that circuit element by the relation

$$I=K_eE^n \tag{3}$$

Rewriting this equation as
$I=(K_eE^{n-1})E$

it is evident that this relationship may be attained if

$$G=K_eE^{n-1} \tag{4}$$

which states that the conductance of each circuit element of the electric network must change in value with changes in voltage drop across that section. The automatic adjustment to fit this equation requires elements whose conductance is a nonlinear function of the voltage impressed. On the other hand, manual adjustment of linear elements may be made to achieve the same result, provided a convenient method is available for indicating the proper adjustment.

Method of Adjusting *E-I* Relationship

When displayed on rectangular coordinates, a plot of the E versus I relationship of a linear conductance is a straight line through the origin, the slope being dependent on the value of the conductance. A similar plot of the *E-I* relationship where the conductance is varied according to equation 4 will be a parabola if n has a value of 0.5 (as for gas flow) or an approximate parabola if n has a value of 0.54 (as for water flow).

The relation between E and I for the variable conductance element can be exhibited on a cathode-ray oscillograph by producing a deflection along one axis proportional to current, and a deflection along the other axis proportional to voltage. If the conductance of the circuit element is adjusted either automatically or manually, in such a fashion that E and I follow the relation shown in equation 3, the figure shown on the cathode-ray oscillograph will be a section of a parabola with the zero signal position of the beam coincident with the origin. It follows, therefore, that if a parabola of proper shape is drawn on the face of a cathode-ray oscillograph, proper adjustment of a resistor in accordance with equation 3 will be indicated when the oscillograph beam coincides with the plotted line.

If, on the other hand, linear resistive elements are connected as shown in Fig. 1, and carry sinusoidal alternating current, the trace on the cathode-ray oscillograph will be a straight inclined line passing through the origin of the plotted line. The slope of this luminous straight line trace will be governed by the resistance (or conductance) of the element. The correct nonlinear relationship between current and voltage will be indicated when the end of this straight luminous trace coincides with the plotted line.

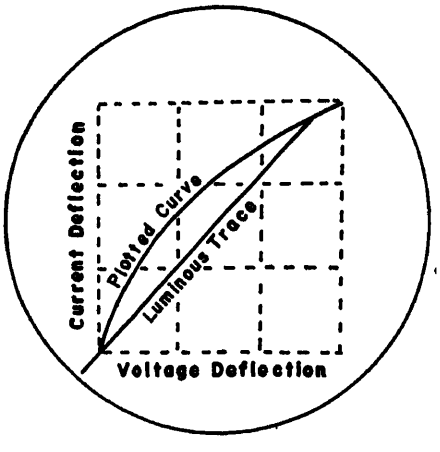

Fig. 2. View of the indicator screen

Proper adjustment of the resistance of the circuit element can be used to change the slope of the luminous trace and bring it into a position where the end of the trace coincides with the plotted line. This condition is illustrated in Fig. 2.

If the linear circuit element carries direct current, the beam will appear as a stationary spot, changing position only when voltage and current or circuit adjustment are changed.

The installation of an attenuator between the circuit element terminals and the oscillograph amplifiers makes possible the use of the same parabola on the oscillograph in the adjustment of different circuit elements having different values of K_e. Proper connection of the oscillograph to the network-analyzer metering circuits makes possible the transfer of the oscillograph and potentiometer combination to the various line elements of the network, the switching being accomplished by means of the conventional analyzer-metering selector system.

Circuitry

The success of the oscilloscope method of adjusting circuit elements is dependent on establishing a convenient method of switching the indicating circuit from one analyzer element to another, and conveniently adapting it to necessary changes to take into account the differences in pipe sections represented. A complete diagram of the indicating equipment for connection in proper relation to the analyzer metering circuits is shown in Fig. 3. Points *F* and *G* connect across the terminals of the analyzer master voltmeter, while terminals *H* and *J* are connected in series with the master ammeter. As a result, selector switching of the master instruments carries along the indicating equipment necessary for resistance adjustment.

As indicated in Fig. 3, the master instruments are isolated from the oscilloscope by means of transformers T_1 and T_2. It is possible that, when applying this method to some analyzers, better results would be obtained by replacing these transformers with isolating amplifiers. The particular analyzer to which this circuit was adapted is one in which currents may be as high as 3 amperes and voltages as high as 200 volts. As a result, the burden imposed by the indicating network was not of great importance but might be of considerable significance on analyzers utilizing smaller base voltages and currents.

To make the parabola drawn on the oscillograph representative of current and voltage relations in a pipe of any length and diameter, an appropriate attenuator, herein designated as a pipe potentiometer, is inserted between the isolating transformer and the terminals of the oscilloscope. This potentiometer must be of the linear precision type which may be set by dial indication to any desired ratio. Since the adjusting indicator may be used to adjust analyzer elements across which voltage may be of high or low value, and the current through it may be of high or low value, it is necessary to have in the circuit a means of changing the sensitivity of the instrument. This is accomplished by the gang-operated switches in both the voltage and current circuits. It should be noted that if the change of switch position in the current circuit reduces the vertical deflection of the oscilloscope trace to some fraction of its former value, say one-third, the corresponding change in the potential circuit must cause a reduction of deflection on the horizontal plates by a factor of $(1/3)1/n$.

The calibration of the completed oscilloscope circuit is accomplished by setting up a special test circuit on the analyzer and assuming for this circuit a particular value K_e. The current through this element, the voltage across it, and its resistance are then adjusted to values consistent with the assumed K_e. With an arbitrarily selected value of the setting of the pipe potentiometer, the gain controls of the cathode-ray oscilloscope are adjusted to bring the oscillograph spot in coincidence with the parabola. These oscillograph controls are then left undisturbed and the metering equipment switched to any other selected analyzer unit with the pipe potentiometer set to the appropriate value for that unit. Adjustment of the resistance of that particular unit may then be made to bring it into proper current and voltage relationship as indicated by the oscilloscope.

In conducting studies of fluid flow systems it is frequently necessary to represent loads of prescribed outflow. To represent such loads it is necessary to have appropriate circuits in the electric network through which current may be maintained at a constant value. These constant current loads are attainable on some anzlyzers equipped with electronic current control systems. On the conventional a-c network analyzer the flow of a particular value of current may be indicated continuously by means of the load circuit meters as shown in Fig. 4. Here a load circuit is connected in series with an ordinary line unit. By making any necessary adjustments in the line unit it is possible to keep the meter of the load unit reading at constant value, which insures constant load current.

Derived Constants

In equation 1, the constant K_g is indicated as being dependent on the size and length of the particular pipe selection in question. To represent this particular pipe section by a resistor in which current and voltage are related as shown in equation 3, it is necessary to find a correlation betwen K_g and K_e. Let a given flow Q_1 be represented by a current I_1 such that

$$Q_1=AI_1$$

Further, let a pressure P_1 be represented by a particular voltage E_1 such that

$$P_1=BE_1$$

Applying these relationships to equation 1, it follows that

$$K_e=\frac{K_gB^n}{A} \qquad (5)$$

As mentioned in a preceding section, the pipe potentiometer is set to some arbitrary value, and calibration is made in a circuit element having a known value of K_e. If this known value is K_{e1} and the potentiometer setting is X_1, then the potentiometer setting X_n for any other value of K_{en} will be

$$X_n=X_1\frac{(K_{e1})}{K_{en}} \qquad (6)$$

Flow of Compressible Fluid

It is shown in the literature that the flow of compressible fluid through a pipe section may be represented by an equation similar to equation 1, but with P replaced by Pa where

$$Pa=\frac{P_1^2-P_2^2}{2}$$

where P_1 is upstream pressure and P_2 is downstream pressure in absolute units. As it may be readily shown that the sum of the Pa's around a closed loop must equal zero, it is evident that the compressible fluid problem may be handled as far as the network analyzer is concerned, by the same methods as have been described for incompressible fluid flow. It is necessary only to handle all computations and manipulations in terms of Pa. When all network analyzer adjustments have been made and readings taken, Pa readings are converted to pressure values.

Examples

It might seem, at first glance, that it would be an almost hopeless task to make cut-and-dried adjustments of the many circuit elements representing a multipipe system. However, experience has shown that three to five successive series of consecutive manipulations are sufficient to bring the network into proper adjustment setting. As the adjustment of each individual unit, to bring it into proper current and voltage relationship, requires but a few seconds, the adjustment of a network by this method is accomplished with reasonable speed.

In Appendix I is shown an example of a 16-pipe 4-mesh system. From the cross section and length of each pipe section, a determination was made of K_g, K_e, and the pipe potentiometer setting. The results of a study by the network analyzer method can be compared with a similar study made by conventional slide rule methods, see Figs. 5 and 6. It may be noted that the results are in good agreement indicating that the network analyzer determination is well within the range of accuracy required for engineering studies.

Obviously, the network analyzer method of study has increasing advantage over the conventional methods when the number of pipe sections, number of loads, and number of loops is large. This method has been applied to rather large pipe networks with satisfactory results.

Conclusions

1. Network analyzers may be readily adapted to the solution of fluid flow problems involving complicated pipe networks.
2. The flow relations at junctions and the pressure relations around closed loops are properly represented by electric circuits because of the conformity of the electric circuit to Kirchhoff's laws.
3. An electric system set up to represent a pipe system will be topologically similar to the pipe system.
4. A method has been presented for quickly and easily relating the flow of current in each analyzer unit to the voltage across it so that current and voltage relations are similar to the flow and pressure drop relations applying to fluid flow in pipes.
5. The accuracy of the network analyzer method is equivalent to that obtained by slide rule calculations.

Table I. Measurements and Potentiometer Settings for Pipes

Pipe No.	Length	Diameter	K_g	K_e	X	Calculated Flow 1,000 Cubic Feet per Hour	Measured Flow 1,000 Cubic Feet per Hour

11	8,000	8	9,100	0.024	5.83	130	134
12	6,000	10	21,200	0.056	2.50	300	292
13	5,000	20	121,000	0.24	0.58	1,000	1,010
14	4,000	6	6,500	0.0172	8.13	113	104
15	5,000	12	34,000	0.090	1.56	250	260
16	10,000	16	41,200	0.109	1.28	750	750

The potentiometer settings X were found using the relationship

$$X_n=X_a\frac{K_{ea}}{K_{en}}$$

The smallest K_{ea} was found and the corresponding Xa was chosen arbitrarily as being equal to 10. All other potentiometer settings X_n were then calculated.

After the network has been adjusted, the current and voltage distribution was measured. Since 1 ampere represented 1,000,000 cubic feet per hour, the current reading could be converted to thousands of cubic feet per hour by multiplying the current in amperes by 1,000. Likewise, since 100 volts represented a Pa of 700, the voltage drops could be multiplied by 7 to obtain the equivalent Pa. With the Pa thus obtained for each pipe, the actual pressure could be found at all points if it were known at one point. The gauge pressure was specified as 35 pounds per square inch at point A. All other pressures could then be calculated, since

$$Pa=\frac{(P_1+P_2)}{2}(P_1-P_2)$$

Knowing Pa from the preceding work, and calling $P_1=(35+15)=50$ pounds per square inch absolute P_2 could be found. The results of the network analyzer solution are shown in Fig. 6.

6. The time requirements for network analyzer solutions of fluid flow problems are favorable to the method, particularly in complicated pipe systems with many closed loops.

Appendix I. Analysis of an Intermediate Pressure Gas System

The complete solution of an intermediate pressure gas system by this newly developed method, as well as by conventional calculation, is given in the following material.

A map showing system layout, pipe lengths, pipe diameters, loads, supply pressures and pipe numbers is given in Fig. 5, along with the solution of pressure and flow distribution, as obtained by slide rule calculation. The slanted numerals above the flow arrows designate flows in thousands of cubic feet per hour. The vertical numerals under the flow arrows designate the *Pa* drop in each section. The gauge pressure is indicated at each junction by the numbered flag. The network analyzer solution is given in Fig. 6.

Table I shows the length, diameter, K_g, K_e, and X (potentiometer setting) for each pipe with flows obtained by each method.

K_g was obtained using a gas flow computing slide rule.

K_e was obtained using the relationship of equation 5.

In this case, 1,000,000 cubic feet of gas per hour corresponded to 1 ampere giving

$$A=\frac{10^6}{1}=10^6$$

Also 7 units of *Pa* corresponded to 1 volt, giving

$$B=\frac{7}{1}=7$$

Therefore

$$K_e=K_g\frac{\sqrt{7}}{10^6}=K_g\times 10^{-6}\sqrt{7}$$

Based on these relationships, the current in amperes in any element would be interpreted as a flow in millions of cubic feet per hour in the corresponding pipe section. Likewise a voltage drop in volts would be interpreted as a *Pa* drop seven times as large numerically.

An Analysis of an Analogue Solution Applied to the Heat Conduction Problem in a Cartridge Fuse

A. E. GUILE
NONMEMBER AIEE

E. B. CARNE
ASSOCIATE MEMBER AIEE

Synopsis: The general equation of heat conduction for a wire heated by an electric current and contained in an insulating cartridge filled with powder cannot be solved by analytical methods. In this paper, two approximate solutions are obtained; the first, obtained by an analytical method, assumes that radial heat loss from the wire is negligible; the second assumes that the parameters of the wire, filler, and cartridge remain constant at some average value, so that the equation can be solved by an analogue method. The analogue is described and the results obtained are checked against those calculated by assuming no radial heat loss, the circuit of the analogue being modified to eliminate the elements representing that loss. The magnitudes of the various errors associated with the analogue are determined as far as possible. The range of fusing current over which the analytical solution with no radial heat loss gives a good approximation to the correct temperature distribution is examined, and found to cover most of the region which is important in fuse operation. The temperature distributions obtained are used to determine the distribution of axial and radial losses along the length of a particular wire. From this the variation of losses with fusing current is obtained, and the range of current over which heat losses are negligible is determined.

WHEN CURRENT flows in a conductor, energy is generated according to the well-known equation

$$\frac{dU}{dt}=i^2R \tag{1}$$

where

U = energy generated
i = instantaneous current flowing in conductor
R = instantaneous resistance of conductor

If the current be assumed to be constant, and the resistance to vary with temperature θ in a linear manner, the rate of heat generation may be represented graphically, as in Fig. 1. Suppose that the rate of heat loss to the environment varies with temperature as shown by curve A, and let curve B and curve C represent the rates of heat generation appropriate to two currents, I_B and I_C $I_B>I_C$, then the conductor will remain in the solid state when carrying a current I_C, but will melt and break up if the magnitude be increased to I_B. The current at which the wire just melts is known as the minimum fusing current for the combination (wire and environment). Currents such as I_B will be referred to as fusing currents.

In studying fuse behavior, a knowledge of the distribution of temperature

Paper 53-411, recommended by the AIEE Computing Devices and Switchgear Committees and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Kansas City, Mo., November 2–6, 1953. Manuscript submitted March 10, 1953; made available for printing September 8, 1953.

A. E. GUILE is with the Queen Mary College, University of London, London, England, and E. B. CARNE is with Remington Rand, Inc., South Norwalk, Conn.

The work described was performed in the Electrical Engineering Department of Queen Mary College. The authors would like to acknowledge the advice and encouragement given by Prof. W. J. John, and by Dr. H. Tropper and W. B. Diamond. Mr. Carne would like to thank the Governors of Queen Mary College and the Senate of the University of London for financial support.

The section headed "Solution of Equation with Constant Parameters by Analogy" is a summary of part of a thesis presented by E. B. Carne to the University of London in fulfillment of the requirements for the degree of Doctor of Philosophy.

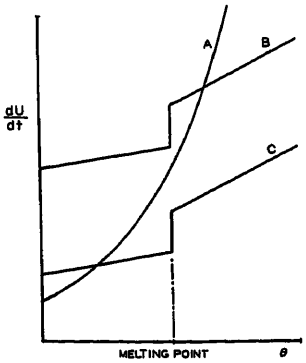

Fig. 1. Definition of fusing current. Curve A represents the rate of heat loss from the wire to environment. Curves B and C are the rates of heat generation appropriate to two currents I_B and I_C, $I_B > I_C$. The conductor will remain in the solid state when carrying a current I_C, but will melt and break up if the current be I_B

along the element is of great importance.[1] If the distribution has the form of *A* in Fig. 2, it is probable that the element will break at one point near the center of the wire. In a high-voltage a-c circuit, or in a lower voltage d-c circuit, this may lead to the formation of a stable, single arc, and the liberation of a considerable amount of energy with consequent unsatisfactory operation of the fuse, and unnecessary prolongation of the fault. On the other hand, if the temperature distribution is as shown in Fig. 2(*B*) a substantial length of the element melts and breaks up at the same time, and the fault current is ruptured with comparative ease. Because of the small diameter wires normally employed as fuse elements, and the fairly rapid heating which occurs, any attempt to determine the temperature distribution experimentally involves considerable difficulty. This paper presents a more general approach by approximate solutions of the general equation of heat conduction for the element.

The particular system to which these principles are applied was one which could be constructed easily in the laboratory from material at hand, and which was well within the range of the testing facilities available. Details of its construction are shown in Fig. 3, while the appropriate physical parameters for the materials used are given in Table I. The normal rated working current of such a fuse would be of the order of 10 amperes. If

k_0, k_1, k_2 = thermal conductivity of wire, filling powder, cartridge
c_0, c_1, c_2 = specific heat of wire, filling powder, cartridge
m_0, m_1, m_2 = density of wire, filling powder, cartridge
[illegible]adius of wire
r_1 = inner radius of cartridge
r_2 = outer radius of cartridge
A_0 = cross-sectional area of wire
K_0 = electric conductivity of wire
I_0 = current flowing through wire
(h_c+h_r) = combined coefficient of heat loss by convection and radiation from the outer surface of the cartridge[2]
$2L$ = total length of fuse element
J = Joule's equivalent
θ = excess temperature, ambient as datum
z = axial co-ordinate
t = time from commencement of current flow

then the equation of heat conduction for the system of Fig. 3 is

$$k_0A_0\frac{\partial^2\theta}{\partial z^2}+2\pi r_0k_1\left.\frac{\partial\theta}{\partial r}\right|_{r=r_0(+)}+\frac{I_0^2}{JA_0K_0}=A_0c_0m_0\frac{\partial\theta}{\partial t} \quad (2)$$

where the quantity

$$\left.\frac{\partial\theta}{\partial r}\right|_{r=r_0(+)}$$

is to be determined from

$$k\left[\frac{\partial^2\theta}{\partial z^2}+\frac{\partial^2\theta}{\partial r^2}+\frac{1}{r}\frac{\partial\theta}{\partial r}\right]=cm\frac{\partial\theta}{\partial t} \quad (3)$$

with conditions

(a) $r_0 \leqslant r \leqslant r_2$
(b) $k=k_1$ $c=c_1$ $m=m_1$ when $r_0<r<r_1$
(c) $k=k_2$ $c=c_2$ $m=m_2$ when $r_1<r<r_2$
(d) $\dfrac{\theta}{(h_c+h_r)}+k_2\left.\dfrac{\partial\theta}{\partial r}\right|_{r=r_2(-)}=0$
(e) $t=0$ $\theta=0$ for all z and r $-L<z<+L$
(f) $z=\pm L$ $\theta=0$ for all r and t

The initial and boundary conditions for equation 2 are

(g) $t=0$ $\theta=0$ for all z $-L<z<+L$
(h) $z=\pm L$ $\theta=0$ for all t

A general solution is not practicable. A solution for infinitely long wires has been given by Schubert,[3] but is not suitable for the investigation of temperature distribution, since it neglects axial heat flow which gives rise to the characteristic distributions shown in Fig. 2. Provided certain assumptions are made, however, two approximate solutions can be obtained, one analytical, the other from an analogue. The analytical solution involves the assumption of no radial heat loss and that the thermal parameters of the wire are constant. This neglect of radial heat loss is justifiable in the important practical case of very rapid heating, such as occurs on short circuit. The analogue is based on the assumption that the wire and filler parameters remain constant at some average value, as the temperature rises. The analytical method will be presented first and will be followed by a consideration of the analogue.

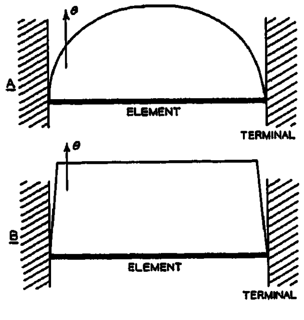

Fig. 2. Idealized temperature distribution diagrams for fuse wires. If the distribution is as shown at A, the wire will probably break up at one point near the center; if the distribution is as shown at B, a considerable length of the element will melt and break up at the same time

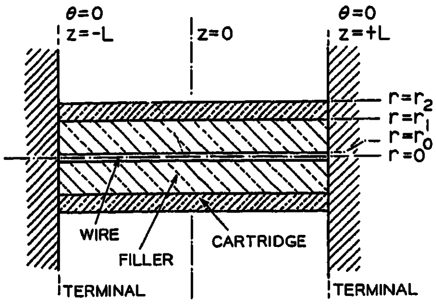

Fig. 3. Details of the construction of the test fuse

Solution of Equation Neglecting Radial Heat Flow

If radial heat losses can be neglected, and the thermal parameters of the wire may be treated as constant, equation 2 becomes

$$k_0A_0\frac{\partial^2\theta}{\partial z^2}+\frac{I_0^2}{JA_0}\rho_0(1+\alpha\theta)=A_0c_0m_0\frac{\partial\theta}{\partial t} \quad (4)$$

where

$\rho_0(1+\alpha\theta)$ = the resistivity of the wire, assumed to vary linearly with temperature

with conditions

(a) $t=0$, $\theta=0$ for all z $-L<z<+L$
(b) $z=\pm L$, $\theta=0$ for all t
(c) $z=0$, $\partial\theta/\partial z=0$ for all t

Rewriting equation 4 and putting

$$a^2=\frac{k_0}{m_0c_0};\quad q=\frac{I_0^2\rho_0}{Jr_0^4\pi^2m_0c_0}$$

gives

$$a^2\frac{\partial^2\theta}{\partial z^2}+q(1+\alpha\theta)=\frac{\partial\theta}{\partial t} \quad (5)$$

Using the transformation

$$\Theta(z,p)=p\int_0^\infty \epsilon^{-pt}\theta(z,t)dt$$

equation 5 becomes

This has the solution

$$\Theta=\frac{q}{(p-q\alpha)}-\frac{q\cosh\dfrac{z\sqrt{(p-q\alpha)}}{a}}{(p-q\alpha)\cosh\dfrac{L\sqrt{(p-q\alpha)}}{a}} \qquad (7)$$

Inverting with the aid of a table of transform-pairs and a few simple properties of the Laplace transformation gives the solution for θ as

$$\theta=\frac{4q}{\pi}\sum_{s=1}^{\infty}\frac{(-1)^s}{(2s-1)}\frac{\cos\dfrac{m_s z}{a}}{(q\alpha-m_s^2)}\times\left\{1-\epsilon^{(q\alpha-m_s^2)t}\right\} \qquad (8)$$

where

$$m_s=\frac{\pi a(2s-1)}{2L}$$

Solution of Equation with Constant Parameters by Analogy

THEORETICAL CIRCUIT AND EQUATIONS OF ANALOGUE

Consider the circuit shown in Fig. 4 where

$$R=R_0\Delta x;\; C=C_0\Delta x;\; i=i_g\Delta x;\; R_1=\frac{v\Delta y}{2\pi y\Delta x};$$
$$R_2=\frac{v\Delta x}{2\pi y\Delta y};\quad R_3=\frac{\eta 2\pi y_2}{\Delta x};\quad C_1=\gamma 2\pi y\Delta x\Delta y$$

and

$v=v_1,\quad \gamma=\gamma_1,\quad y_0<y<y_1$
$v=v_2,\quad \gamma=\gamma_2,\quad y_1<y<y_2$

The quantities, $R_0C_0i_g\eta v_1v_2\gamma_1$ and $\gamma_2$are constants.

It can be shown that, in Limit ($\Delta x\rightarrow0$, $\Delta y\rightarrow0$) and provided $(i/y)(\Delta^2V/\Delta y)\rightarrow0$, the differential equation for this system is

$$\frac{1}{R_0}\frac{\partial^2V}{\partial x^2}+\frac{2\pi y_0}{v}\left.\frac{\partial V}{\partial y}\right|_{y=y_0(+)}+i_g=C_0\frac{\partial V}{\partial t} \qquad (9)$$

where V represents the voltage developed in the mesh, and the quantity

$$\left.\frac{\partial V}{\partial y}\right|_{y=y_0(+)}$$

is to be determined from

$$\frac{1}{v}\left[\frac{\partial^2V}{\partial x^2}+\frac{\partial^2V}{\partial y^2}+\frac{1}{y}\frac{\partial V}{\partial y}\right]=\gamma\frac{\partial V}{\partial t} \qquad (10)$$

which has as a boundary condition

(a) $\dfrac{V}{\eta 2\pi y_2}+\dfrac{2\pi y_2}{v}\left.\dfrac{\partial V}{\partial y}\right|_{y=y_2(+)}=0$

By suitable connections, the conditions

(b) $t=0$, $V=0$ for all x and y $-S\leqslant x\leqslant S$
(c) $x=\pm S$, $V=0$ for all y and t $y_0\leqslant y<\infty$

can be impressed on the system, so that the circuit of Fig. 4 can serve as an electrical analogy of the thermal system of the simple cartridge fuse already described, provided the electrical and thermal parameters of the fuse are not dependent on temperature.

TRANSFORMING SYSTEM PARAMETERS

In transforming values from one system to the other, effective use can be made of the principle of similarity to reduce the time scale of the electric system as compared with the thermal system. For the sake of generality, suppose the scales of length and time in the two systems to be connected by the relations

$$\xi x_E=x_T \qquad (11)$$

$$\mu t_E=t_T \qquad (12)$$

where the subscripts E and T denote the electric and thermal systems respectively. Further, suppose that the potential quantities be given by

$$\zeta P_E=P_T \qquad (13)$$

and, finally, suppose that each term of the thermal equations be multiplied by a fourth coefficient ω. By comparing terms it can be shown that

$$R_0=\frac{\xi^2}{\omega\zeta}\frac{1}{k_0A_0} \qquad (14)$$

$$C_0=\frac{\omega\zeta}{\mu}A_0c_0m_0 \qquad (15)$$

$$i_g=\frac{\omega I_0^2}{JA_0K_0} \qquad (16)$$

$$v=\frac{\xi^2}{\omega\zeta}\frac{1}{k} \qquad (17)$$

where $v=v_1$ when $k=k_1$
and $\quad v=v_2$ when $k=k_2$

$$\gamma=\frac{\omega\zeta}{\mu}cm \qquad (18)$$

where $\gamma=\gamma_1$ when $c=c_1$, $m=m_1$
and $\quad \gamma=\gamma_2$ when $c=c_2$, $m=m_2$

$$\eta=\frac{1}{\xi^2\zeta\omega(h_c+h_r)4\pi^2y_2^2} \qquad (19)$$

The coefficients $\xi\zeta\mu$ and ω can be defined within the limitations of equations 11

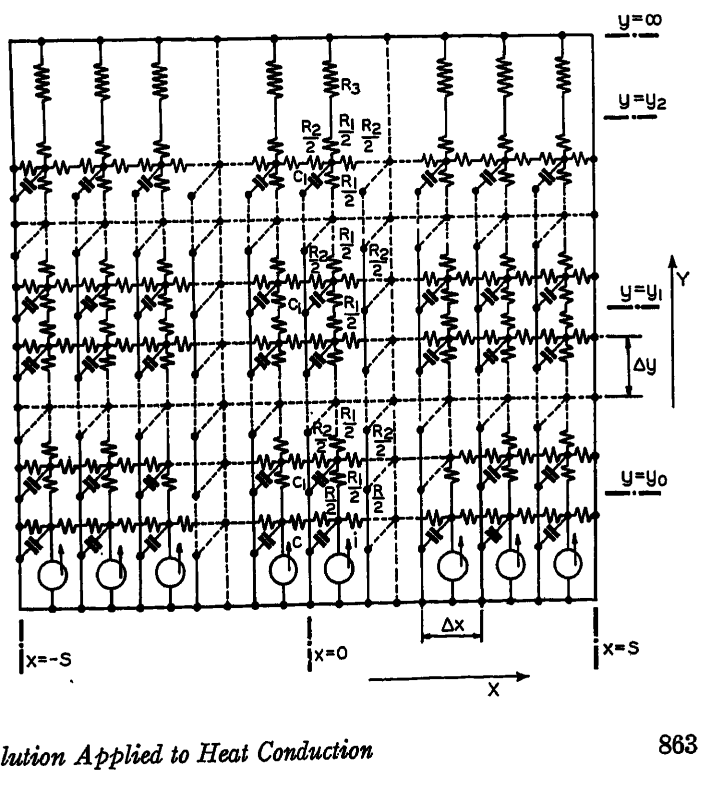

Fig. 4. Theoretical circuit of analogue

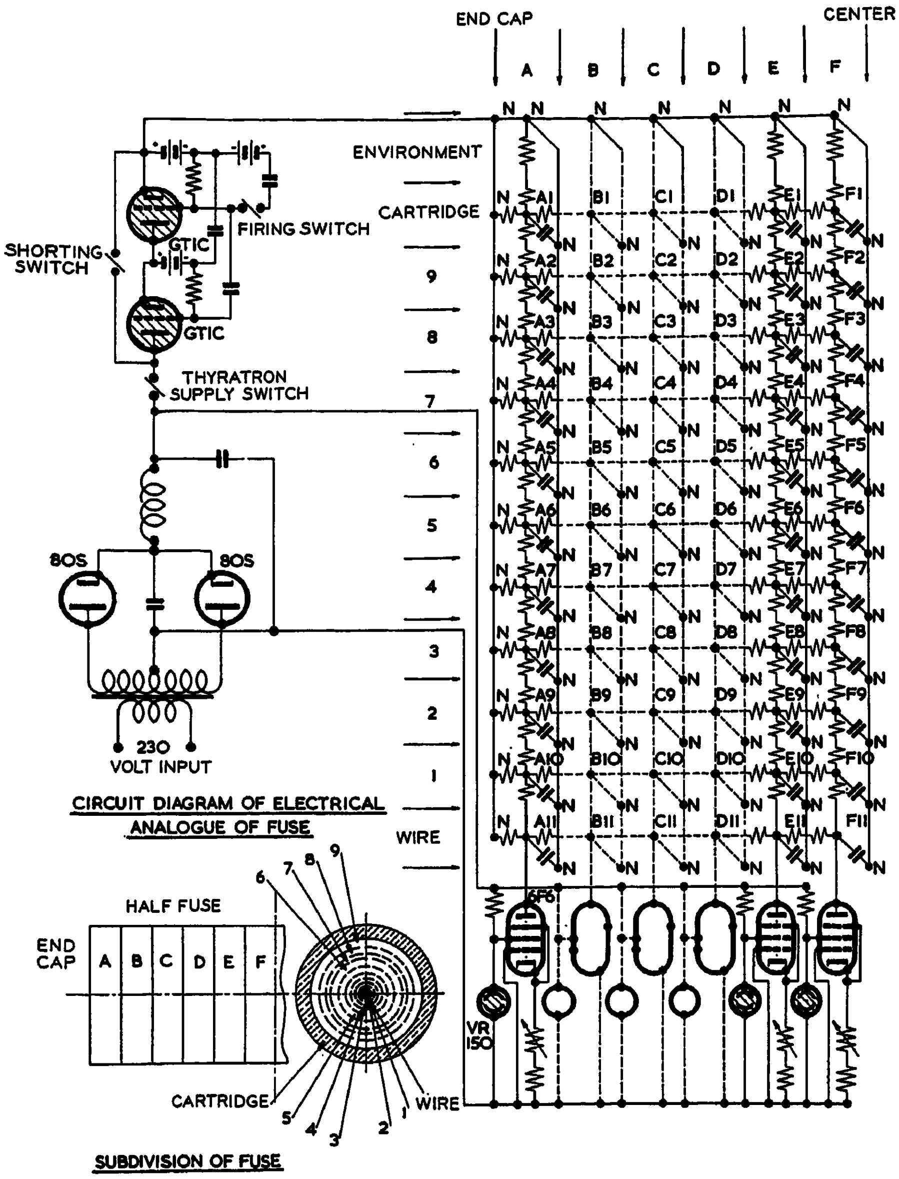

Fig. 5. Practical circuit of analogue

through 19 so as to obtain convenient magnitude relations between the thermal and electrical parameters.

THE ANALOGUE CURRENT

Supposing the fusing current is sinusoidal, then the analogue current will be given by

$$i_g=\frac{\omega I_p^2}{2JA_0K_0}(1-\cos 2\mu pt) \qquad (20)$$

where I_p = peak value of current. This is equivalent to two terms, one a d-c term of magnitude

$$\frac{\omega I_{rms}^2}{JA_0K_0}$$

and an a-c term of frequency $2\mu f$ where $f=p/2\pi$ is the frequency of the fusing current. On inserting numerical values into the design equations 14–19, it is apparent that the response of the analogue mesh to a 50 cycles per second alternating current is essentially that of a simple capacitance. Suppose this capacitance be denoted by C, then the voltage developed by the current of equation 20 is

$$V=\frac{\omega I_p^2}{2JA_0K_0C}\left[t_B-\frac{\sin 2\mu pt_B}{2\mu p}\right]$$

The maximum value of the alternating term is $1/2\mu p$ so that, if $t_B>>1/2\mu p$, i.e., $t_T>>1/2p$, only the d-c component of the current is significant. For 50 cycles per second fuse service this requires that $t_T>>1/628$ second. Provided that this condition is fulfilled, the response will be the same for alternating or direct current, and the mesh may be supplied with current of step-function shape and of magnitude

$$i_g=\frac{\omega I^2}{JA_0K_0}$$

where

I = actual magnitude of current (d-c)
= rms value of current (a-c)

A PRACTICAL CIRCUIT

The thermal fields are symmetrical about a cross-section normal to the longitudinal axis, and through the center of the fuse. The temperature on both sides of this plane will be the same, and there will be no heat flow across it. As far as the electrical system is concerned, this implies that the two halves may be separated one from the other, and the analogue circuit need only represent one half of the complete fuse.

The analogue circuits are true replicas of the thermal system only if they are characterized by continuously distributed parameters. In general, such circuits are difficult to build, and are easily disturbed by the introduction of measuring probes. Fortunately, approximate solutions can be obtained by the use of a finite number of lumped elements, the accuracy of the response increasing with the fineness of the subdivision. In the final assessment, this degree of subdivision is primarily dependent on considerations of economic cost and constructional time, and the analogue as constructed comprised 72 sections, the half-fuse in the electrical model being divided into six lateral discs and 12 longitudinal cylinders. A diagram of the analogue, and of the method of subdivision is given in Fig. 5.

The mesh is fed at six points by type *6F6* pentode valves working as constant current sources. Parallel stabilization of the screens is provided by type *VR150* glow-discharge tubes, and a step-function of current is generated by suddenly switching on the voltage to the anodes of the generators. Two *GT1C* thyratrons

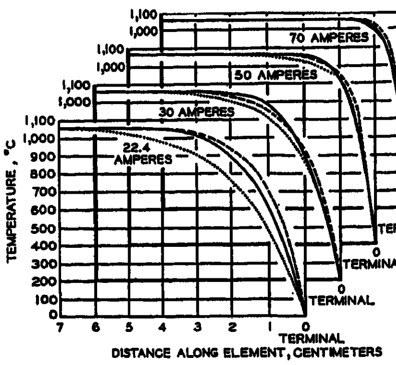

Fig. 6. A comparison of the temperature distributions obtained from the analytical solution and from the analogue, for various fusing currents

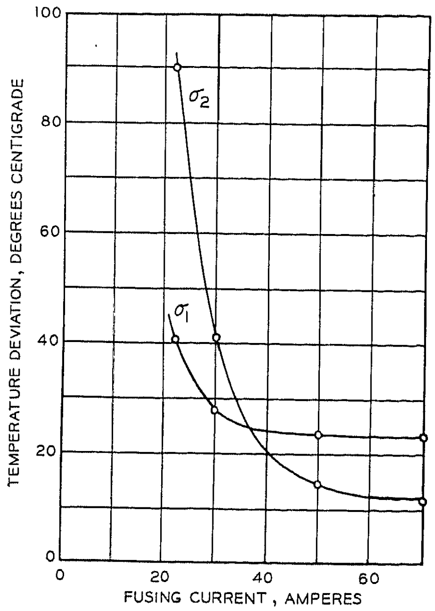

Fig. 7. The deviation between the analytical and analogue solution. σ_1 represents the deviation between the analytical system and the analogue modified so as to eliminate radial losses. σ_2 is the deviation between the analytical system and the complete analogue

are used in the switching circuit because it was found that one valve sometimes broke down before the triggering pulse was generated by closing the firing switch. The voltage rise at any mesh point is recorded by an oscilloscope,[4] the single-stroke time base being initiated by the applied signal, and a complete voltage (and therefore temperature) distribution diagram is built up by scanning each node in turn.

A number of tests were made on the analogue. The results of those significant to this paper are shown in Fig. 6.

Comparison of Analytical and Analogue Solutions

ERRORS INHERENT IN ANALOGUE

The response of the analogue will differ from that required to reproduce equation 2 because

1. The resistivity of the wire is represented by a constant average value.

2. The continuous thermal system is represented by a number of lumped circuits.

3. The analogue current magnitude has to be set up, and the tolerance on the values of analogue components kept as small as possible.

4 The analogue voltage response is measured by an oscilloscope.

5. The specific heat, thermal conductivity, and density of the wire, filling material and cartridge, and the coefficient of heat transfer from the outer surface of the cartridge to the ambient temperature are represented by average values.

6. The end terminals of the system are considered as infinite planes held at the ambient temperature.

7. In the case of an alternating fusing current, the fusing time must be very much greater than 0.0016 second.

COMPARISON OF ANALOGUE RESPONSE AND CALCULATED RESULTS TO ASSESS THE ACCURACY OF THE ANALOGUE

Temperature Distribution Errors in Analogue

The analogue was used to obtain temperature distribution curves with various fusing currents, for the case where radial heat flow was excluded. These curves are shown in Fig. 6 together with the curves obtained for the same currents by calculation from equation 8. Since both sets of curves represent the same case, a direct comparison between them can be made, any differences being due to errors in the analogue.

In this comparison, error 7 does not arise, since both solutions refer to a d-c fusing current; error 6 is common to both systems, and in any case is known experimentally to be small for terminals of appreciable size; error 5 is also common to both systems, and can be neglected in comparison with error 1, since the variation of specific heat and thermal conductivity of copper up to melting temperature is only of the order of 20 per cent, whereas the resistivity of copper increases by some 500 per cent over the same temperature range. The significant errors in this comparison are therefore 1, 2, 3, and 4.

The deviation (σ_1) between these two distributions has been calculated as follows: let

θ_1 = temperature rise given by the analogue at some point in the wire

θ_2 = temperature rise given by equation 8 at the same point in the wire for the same fusing current

and suppose the values of θ_1 and θ_2 are noted at n points along the wire length, then

$$\sigma_1 = \sqrt{\left\{\frac{1}{n}\sum_{n} (\theta_1 - \theta_2)^2\right\}}$$

i.e., the root mean square deviation in temperature. The magnitude of this deviation is plotted against fusing current in Fig. 7. It can be seen that, as the current decreases, the deviation increases from a constant value at high currents of approximately 20 degrees centigrade (C), i.e., 2 per cent of melting temperature, to about 50 C at the minimum fusing current.

Fig. 6 shows that the analogue gives too great a value of temperature rise near the terminals. This results from error 1 since, in the design of the analogue, a resistivity has been assumed for the fuse wire, which is the mean of the values at 20 C and 1,083 C. For high fuse currents, the greater part of the wire reaches melting temperature at the same time (e.g. 80 per cent for 70 amperes), and the use of this mean value along the whole length is justified. As the fusing time increases, the temperature distribution becomes less uniform and the use of this average resistivity produces too large a value of heat generation near the terminals so that the temperature there is too high.

The constant deviation of 20 C at high fusing currents suggests that, since error 1 becomes small in this region, this error of 2 per cent must be due to errors 2, 3, and 4 which are not dependent upon fusing current. Hence error 1 rises from zero at high currents to about 3 per cent at minimum fusing current, while the sum of errors 2, 3, and 4 remains constant at 2 per cent.

It will be assumed that this information on the errors can be used to correct the readings of the complete analogue when both radial and axial heat losses are included. The justifications for this are that the variation of the parameters of the filling powder and cartridge is very small and that the error resulting from the use of lumped circuits representing the filler will be much less than that for the wire, because of the greater number of circuits.

From these figures it therefore seems that the uncorrected analogue readings give the temperature distribution quite closely for currents above minimum fusing current (20 amperes). The fact that minimum fusing current is given as 20 amperes by the complete analogue and 5 amperes by the analogue with radial flow excluded, modifies somewhat the direct

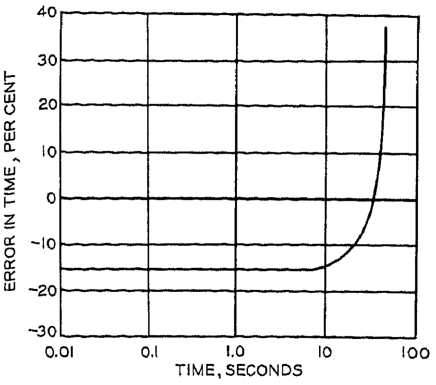

Fig. 8. The time error resulting from the use of an average resistivity

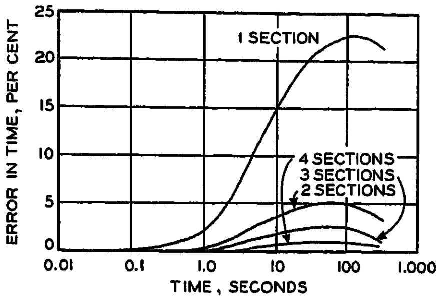

Fig. 9. The time error resulting from representing a continuously distributed system by a finite number of lumped sections

application of the deviations given by Fig. 7 to the complete analogue for very low currents. An upper current limit exists to the use of the analogue in the case of an alternating fusing current, since the thermal time must be very much greater than 0.0016 second so that heating effect of a step function of current in the analogue shall correspond to that of an alternating fusing current. For currents giving fusing times of this order, the temperature distribution will, however, be substantially rectangular, so that the range of the analogue is sufficient to cover those fusing currents in which the uneven temperature distribution will affect the breakup.

To determine temperature distributions for currents at or below the minimum fusing value, grading of the currents injected at the analogue wire nodes will take account of the variation of resistivity along the length, and reduce error 1. Comparison of the rise in temperature of an actual wire at a current just above the minimum fusing current as measured by the over-all increase in resistance shows good agreement with the resistance increase predicted by the analogue, until oxidation of the wire becomes appreciable just before the element melts.

Time Response Errors of the Analogue

Although the main purpose in constructing the analogue has been achieved insofar as the analogue readings closely represent the correct temperature distribution, the time response can also be examined. The errors inherent in the analogue will affect the time required to raise any point on the wire to a given temperature and, in particular, the time to raise the center of the wire to melting point.

The errors which contribute to this are again 1, 2, 3, and 4, of which the first two will now be examined in some detail.

Time Error Due to the Assumption of Average Resistivity—Error 1. If in equation 4, $\rho_0(1+\alpha\theta)$ is replaced by ρ_{av} (the average resistivity of solid copper between 20 C and 1083 C) as was done in the analogue, then instead of equation 8, the expression for the temperature rise is

$$\theta=\frac{4q_1}{\pi}\sum_{s=1}^{\infty}\frac{(-1)^s}{(2s-1)}\cos\left(\frac{m_s z}{a}\right)\times \frac{1}{m_s^2}\{\epsilon^{-m_s^2 t}-1\} \qquad (21)$$

where

$$q_1=\frac{I_0^2\rho_{av}}{Jr_0^4\pi^2c_0m_0}$$

If the time taken for the center of the wire to reach melting temperature given by equation 21 is compared with that given by equation 8 for the same current, then any difference is due to the assumption of average resistivity. This time error is shown plotted against time in Fig. 8. Until the minimum fusing current is approached, this error is constant at −15.5 per cent. The reason for this can be seen by considering a copper wire heated through a temperature rise of θ C with no heat losses, for the two cases (a) and (b)

(a) $\rho=\rho_{av}$
(b) $\rho=\rho_0(1+\alpha\theta)$

In case (a)

$$\frac{I_0^2\rho_{av}L}{A_0}\,dt=c_0A_0L\,d\theta$$

from which

$$\int_0^t \frac{I_0^2}{A_0^2}\,dt=\frac{c_0\theta}{\rho_{av}}=7.86\times 10^8 \qquad (22)$$

when $\theta=1063$ C.

In case (b)

$$\frac{I_0^2\rho_0(1+\alpha\theta)L}{A_0}\,dt=c_0A_0L\,d\theta$$

from which

$$\int_0^t \frac{I_0^2}{A_0^2}\,dt=\frac{c_0}{\rho_0\alpha}\log_\epsilon(1+\alpha\theta)=9.30\times 10^8 \qquad (23)$$

when $\theta=1063$ C.

$\int_0^t \frac{I_0^2}{A_0^2}\,dt$ is the current heat integral given by Gibson[5] and is independent of length.

Thus, owing to the assumption of an average resistivity, the error in the time required to raise the center to melting temperature is

$$\frac{7.86-9.30}{9.30}=-15.5 \text{ per cent}$$

for high fusing currents where the losses are negligible.

The minimum fusing current given by equation 8 is 4.11 amperes for 29 British Standard Wire Gauge (SWG) copper wire, whereas equation 21 gives 5.05 amperes. (Since both neglect radial heat loss, neither represents a practical condition.) Hence as the current is reduced and approaches 5.05 amperes, the error must change sign and grow rapidly in magnitude as shown in Fig. 8.

Time Error due to Representing the Fuse by a Finite Number of Analogue Sections—Error 2. This error has been examined by representing the half length of fuse by circuits having one, two, three and four sections, and analyzing their transient responses. The times given by these circuits for various currents to raise the center of the wire to melting temperature, were compared with the times given by equation 21. An average resistivity is assumed in both cases so that any time error is due to the finite number of analogue sections. Fig. 9 shows how this time error varies with the fusing time and the number of sections. It can be seen that the analogue with its six sections does not have an appreciable time error resulting from this in any part of the fusing current range.

The time range in which the analogue was used was 0.08 to 1.2 seconds and in this range the errors result from:

1. Assumption of an average resistivity.
3. Setting up the analogue.
4. Measurement.

The error attributable to the first assumption amounts to −15.5 per cent in this range. The errors recorded by the analogue in excess of this are given in Table II; they must result from the inaccuracy of setting up and measurement.

Table II. Errors in Excess of Those Attributable to Assumption of Average Resistivity

Fuse Current, Amperes	Calculated Time, Seconds	Analogue Time, Seconds	Analogue Time Error, Seconds	Time Error, Per Cent
22.44	1.63	1.67	+0.04	2.45
30	0.912	0.88	−0.032	3.5
40	0.513	0.54	+0.027	5.25
50	0.328	0.33	+0.002	0.6
60	0.228	0.24	+0.012	5.23

The complete analogue predicts times to reach melting temperature which show very good agreement with those recorded in actual tests for times of the order of, or less than, 1 second. For times greater than this, the analogue predicts times 30 per cent to 40 per cent greater than the actual prearcing times. This is probably because of oxidation of the wire which accelerates the breakup in the practical case.

Range of Application of the Analytical Solution

In many of our problems it has been more convenient to calculate the temperature distribution than to set up the analogue, and it is therefore necessary to know over what range the approximation of no radial heat flow gives reasonable results, i.e., over what range equation 8 can be used.

This can be shown by comparison between the temperature distributions obtained from equation 8 and those given by the complete analogue, when the latter are corrected for the errors discussed. The rms deviation (σ_2) in temperature between the distributions obtained from the complete analogue and those calculated from equation 8 is plotted against fusing current in Fig. 7. It will be seen that above about 1.5 times minimum fusing current, the deviation is less than 4 per cent of melting temperature. The analytical solution therefore gives a good approximation to the correct temperature distribution for fuse currents above about 1.5 times minimum fusing current. As will be seen later, however, the times for the center to reach melting temperature predicted by this equation, are true only for fusing times smaller than a few hundredths of a second, where radial loss is indeed negligible.

Analysis of Axial and Radial Heat Losses in a Simple Cartridge Fuse

In any element of the fuse wire, the heat generated is expended in raising the temperature of the wire and supplying the radial and axial heat losses.

If there are no losses, equation 23 holds. This gives the value of the current-heat integral as 9.30×10^8 for a copper element at melting temperature. Consider the case of a fusing current of 70 amperes. The time required to raise the wire center to melting temperature calculated from equation 8 is 0.1677 second, and

$$\int_0^t \frac{I_0^2}{A_0^2}\,dt=\frac{70^2\times0.1677}{9.4^2\times10^{-8}}=9.30\times10^8$$

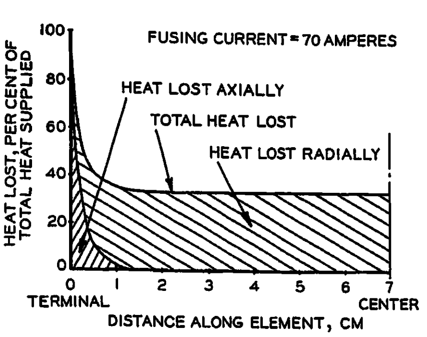

Fig. 10. The distribution of axial and radial losses along the fuse wire for a fusing current of 70 amperes

There is therefore no axial heat loss from an element at the center of the wire. Inspection of the temperature distribution with no radial loss in Fig. 6 shows constant temperature over a distance of about 5.5 cm from the center. Consequently there can be no axial heat loss in this region. Fig 6 also shows that the introduction of radial loss modifies the temperature distribution in such a way that this region decreases to 5 cm from the center. The time required for the center of the wire to reach melting temperature is 0.25 second. Hence, assuming no radial loss, 70 amperes raises 5 cm to melting temperature in 0.1677 second; with radial loss, 70 amperes raises 5 cm to melting temperature in 0.25 second, so that, in this region

$$\frac{\text{radial energy lost}}{\text{energy stored in wire}+\text{radial energy lost}}=\frac{0.25-0.1677}{0.25}=33\text{ per cent}$$

Again Fig. 6 shows that within 0.25 cm of the terminals the temperature distribution given by the analogue is unchanged by the addition of radial flow. At 0.2 cm from the terminals, 70 amperes raises the temperature by 440 C in 0.1677 seconds when radial flow is neglected. Equation 23 shows that if there is no loss 70 amperes raises the temperature by 440 C in 0.104 second.

Hence

$$\frac{\text{axial energy lost}}{\text{energy stored in wire}+\text{axial energy lost}}=\frac{0.1677-0.104}{0.1677}=38\text{ per cent}$$

At the fuse terminal, the axial heat loss will account for 100 per cent of the heat supplied. From calculations such as these, it is possible to estimate the variation of axial heat loss along the wire. The distribution is shown in Fig. 10.

When radial loss is included, 70 amperes raise the temperature of a point 0.2 cm from the terminals by 440C in 0.25 second; therefore

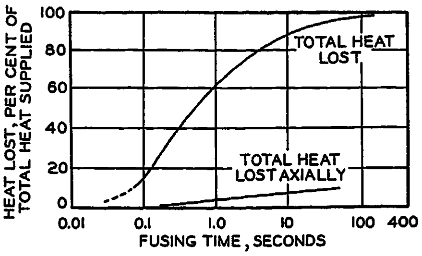

Fig. 11. The variation of the total heat lost with fusing time

$$\frac{\text{total energy lost}}{\text{energy stored in wire}+\text{total energy lost}}=\frac{0.25-0.104}{0.25}=58.4\text{ per cent}$$

The variation of the total heat lost along the wire is plotted in Fig. 10. The difference between this curve and the curve representing the distribution of axial heat loss gives the proportion of the heat lost by radial flow.

If this process is repeated for various fusing currents, and the mean values of the heat losses for the whole fuse element, expressed as a percentage of the total heat input, are determined, a curve of the variation of the losses against fusing time may be drawn. This is done in Fig. 11. The curve shows a total loss of 15 per cent at a heating time of 0.1 second, and agrees with the suggestion[6] that heat losses are negligible below 0.016 second.

Conclusions

The analogue described is capable of predicting the temperature distribution along the element of a cartridge fuse with a fair degree of accuracy over a range of fusing currents extending from minimum fusing current up to about five times minimum fusing current, i.e., about ten times the normal rated current.

For currents above about 1.5 times minimum fusing current, the temperature distribution may be calculated to a fair degree of accuracy on the basis of no radial heat loss. The fusing times given by this calculation are incorrect however except for very short fusing times where the radial loss is in fact negligible: for the fuse considered the time must be less than a few hundredths of a second for the radial and axial losses to be negligible.

The methods used are of quite general application, although the specific remarks made apply only to the particular size of cartridge fuse described at the beginning of the paper. It is possible to predict certain trends, knowing that the axial loss depends on the square of the wire diameter, and that the radial loss depends principally upon the diameter alone, but these should not be pressed to extremes.

No Discussion

LATE DISCUSSION

The following closure was received too late to be included with the paper.

Sensitivity and Output Formulas for the Resistance Bridge

Author's closure of paper 53-1 by Philip M. Andress, published in Communication and Electronics, May 1953, pp. 213–16.

Philip M. Andress: Dr. Harris and Dr. Wenner have mentioned in their discussion that it may be more convenient to consider galvanometer sensitivity in terms of available electromotive force and available current rather than current in the coil. This is certainly true in the calculation of steady-state deflections where the damping or the time response for specified precision of reading is to be considered. In the case of a dynamic or transient state, the ideas may have even greater significance affecting the design as well as the circuit application of the galvanometer.

To illustrate one useful application of the idea, we may consider the following statement: To reduce the response of a galvanometer by a given ratio without changing the damping, both the available electromotive force and the available current must be reduced by this ratio.

For example, assume it is desired to reduce sensitivity by 10 to 1 where the source resistance is 1,000 ohms. There are two possible L-sections. In the first, the series resistance is toward the source and serves to reduce the available current. This calls for 9,000 ohms since it raises the resistance looking toward the source by a factor of 10 to 1. According to the rule, it is then necessary to reduce the electromotive force by the same ratio and this is done by shunting to restore the original resistance of 1,000 ohms. The required parallel resistance to accomplish this is 1,111 ohms.

In the second method, the available electromotive force is reduced first by shunting to 100 ohms. This calls for a parallel resistance of 111.1 ohms. According to the rule, the available current must also then be reduced by the 10-to-1 factor. Hence the L is completed by adding a series resistance of 900 ohms on the galvanometer side.

It will be noted that a considerable amount of juggling of algebraic expressions is eliminated by this method, also that the calculation is entirely independent of the galvanometer characteristics. The deflection is reduced precisely by 10 to 1, yet there is no change in damping.

Addendum: The particular formulas for w, y, and z given in Table I of the paper, Auxiliary Equations 6, 7, and 8, apply where the input branch connects the junction of arms X and A with the junction of arms B and R.

Erratum: The title of Table I was listed incorrectly. It should read "Bridge Sensitivity and Output Formulas."

Under**, item 2 of the footnotes for Table I, delete $+A$ from the expression for z. If $L=\infty$, $z=[X+RC/(C+G)]/T$.

Analysis of a Series Circuit Containing a Nonlinear Capacitor, A Mathematical. Pipes ..238-42; disc. 242

Analysis of an Analogue Solution Applied to the Heat Conduction Problem in a Cartridge Fuse, An. Guile, Carne....................861-7

Analytical Operations, An Application of Magnetic Amplifier Circuits to Perform Multiplication and Other. Finzi, Mathias....................455-61

Analyzer, A New Design 60-Cycle A-C Network. Davidson, Koll....................141-5

Analyzer for Magnetic Amplifier Cores, A Permeability. Siskind....................572-6

Analyzer for Magnetic Amplifiers, A Transient. Smith....................461-5

Analyzer, The Solution of Sturm-Liouville Problems by D-C Network. Swenson....................811-13

Analyzers for Pipe Network Analysis, The Use of Electric Network. Stephenson, Eaton....................857-61

Apparatus for NTSC Color Television, Transmitting Terminal. Burr....................26-33

Application of Boolean Algebra to the Design of Electronic Switching Circuits, An. Washburn...380-8

Application of Electric and Acoustic Impedance Measuring Techniques to Problems in Diathermy. Schwan, Carstensen....................106-10

Application of Magnetic Amplifier Circuits to Perform Multiplication and Other Analytical Operations, An. Finzi, Mathias....................455-61

Applications of Integral Equations to the Solution of Nonlinear Electric Circuit Problems. Pipes....................445-50

Applications of Recorded Machine Announcements, Telephone System. Bennett....................478-83

Asymmetry of the Resonance Curves, Effects of Harmonics on the Frequency of Oscillation as Well as on the. Mostafa....................309-14

Automatic Call Recording and Accounting in the SATT System. Ostline....................56-62

Automatic Computing Equipment, Solutions of Boundary-Value Problems on. Verzuh........813-21

Automatic Control System with Provision for Scanning and Memory, An. Young................392-5

Automatic Synchronizer, Cathode-Ray Synchroscope and. Ahmed................217-22; disc. 222

Automatic Testing of Wired Relay Circuits. Hanson....................850-7

Automatic Transfer Function Measuring and Recording System, An. Ehret, Hochschild, Embree, Grogan.................664-9; disc. 669

B

Band-Pass Filters, Maximum Impedance Transformations in. O'Donnell, Williams.........110-13

Basic Concepts in the Analysis of Stationary Electric Circuits. Spence, Cahn........617-23; disc. 623

(Basic Sciences) A Capacitively Coupled Field Mapper for 2-Dimensional Distributed Source Field Problems. Gilbert, Gilbert..........345-9; disc. 349

(Basic Sciences) A Graphical Method for Flip-Flop Design. Johnston, Ratz..................52-60

(Basic Sciences) A Mathematical Analysis of a Series Circuit Containing a Nonlinear Capacitor. Pipes..........................238-42; disc. 242

(Basic Sciences) Analysis of a Comb Filter Using Synchronously Commutated Capacitors. LePage, Cahn, Brown..............................63-8

(Basic Sciences) Applications of Integral Equations to the Solution of Nonlinear Electric Circuit Problems. Pipes..................................445-50

(Basic Sciences) Block-Diagram Solutions for Vacuum-Tube Circuits. Stout...................561-7

(Basic Sciences) Dielectric Breakdown of Sulfur Hexafluoride in Nonuniform Fields. Works, Dakin..........................682-7; disc. 687

(Basic Sciences) Electron-Ion Recombination at Low Pressures. Borowitz....................430-5

(Basic Sciences) Flow of Energy in D-C Machines. Hawthorne............................438-45

(Basic Sciences) Fluorine-Containing Gaseous Dielectrics. Camilli, Plump.................93-102

(Basic Sciences) Mathematical Descriptions of Core Losses. Hale, Richardson.............495-501

(Basic Sciences) New Method for the Optimum Design of Permanent Magnets Subjected to Demagnetizing Effects. Ziegler..............253-62; disc. 262

(Basic Sciences) Nondestructive Testing of Insulation. Brancato...................202-05; disc. 205

(Basic Sciences) Polyethylene Terephthalate—Its Use as a Capacitor Dielectric. Wooley, Kohman, McMahon..............................33-7

(Basic Sciences) Production of Unipolar Air with Radium Isotopes. Martin..................771-6

(Basic Sciences) Propagation Mechanism of Impulse Corona and Breakdown in Oil. Liao, Anderson.........................641-7; disc. 647

(Basic Sciences) Some Fluorinated Liquid Dielectrics. Bashara...............................79-85

(Basic Sciences) Stressed Ferrites Having Rectangular Hysteresis Loops. Williams, Sherwood, Goertz, Schnettler...............................531-7

(Basic Sciences) Temperature Fields in Electrical Coils: Numerical Solutions. Schneider..........768-71

(Basic Sciences) The First-Order Behavior of Separable Oscillators. dePackh...................450-5

(Basic Sciences) The Influence of a Transverse Magnetic Field on an Unconfined Glow Discharge. McBee, Dow......................229-37; disc. 237

(Basic Sciences) The Permeability of Silicon-Iron at Very Low Flux Densities. Both..656-61; disc. 661

(Basic Sciences) The Rayleigh Method in Network Calculations. Schott, Heilfron..............89-93

Behavior of Separable Oscillators, The First-Order. dePackh................................450-5

Billing of AMA Toll Messages, Mechanized. Slade...................175-82; disc. 182

Block-Diagram Solutions for Vacuum-Tube Circuits. Stout....................................561-7

Boolean Algebra to the Design of Electronic Switching Circuits, An Application of. Washburn....380-8

Boundary-Value Problems on Automatic Computing Equipment, Solutions of. Verzuh.........813-21

Breakdown of Sulfur Hexafluoride in Nonuniform Fields, Dielectric. Works, Dakin........682-7; disc. 687

Bridge for Admittance Determinations of Highly Conducting Materials at Low Frequencies, Wheatstone. Schwan, Sittel...................114-21

Bridge, Sensitivity and Output Formulas for the Resistance. Andress...........213-16; disc. 216, 868

Broadcast Network, Development of Television Service Standards and Application to Design of a Television. Reed.........................838-50

C

Cable, A Nonarmored Submarine Telegraph. Lawton Hutchins.....................153-6; disc. 156

Cable in the Telegraph Industry, Wire and. Markley............................298-308; disc. 308

Calculations, The Rayleigh Method in Network. Schott, Heilfron.........................89-93

Call Recording and Accounting in the SATT System, Automatic. Ostline......................56-62

Capacitively Coupled Field Mapper for 2-Dimensional Distributed Source Field Problems, A. Gilbert, Gilbert.......................345-9; disc. 349

Capacitor, A Mathematical Analysis of a Series Circuit Containing a Nonlinear. Pipes..238-42; disc. 242

Capacitor Dielectric, Polyethylene Terephthalate—Its Use as a. Wooley, Kohman, McMahon.....33-7

Capacitors, Analysis of a Comb Filter Using Synchronously Commutated. LePage, Cahn, Brown..63-8

Capacitors in Power Systems with Rectifier Loads. Schmidt...............................14-17

Capacitors, The Effect of Minor Constituents in High Dielectric Constant Titanate. Coffeen....704-09

Card Conversion in the AMA System, Principles of Tape-to-. Groth........................42-52

Carrier Systems, Co-ordination of M1 and N1 Telephone. Smith, Cornell, Jerome..........517-20

Carrier Systems, The Control of Noise and Crosstalk on N1. Aikens, Thaeler...........605-10; disc. 610

Carrier Technique, Railroad Communications Using High-Power. Hansen, Dean, Mullins.............................785-90; disc. 790

Carrier Telephone Deviation Regulator, Type-N. Perkins, Mahoney......................757-62

Carrier Telephone, Program Transmission Over Type-N. Case, Kerney.......................791-5

Carrier Telephone, Type-ON. Fracassi, Kahl..713-21

Cartridge Fuse, An Analysis of an Analogue Solution Applied to the Heat Conduction Problem in a. Guile, Carne............................861-7

Cathode—A Review, The Nickel Base Indirectly Heated Oxide. Bounds, Hambleton.............102-06

Cathode-Ray Synchroscope and Automatic Synchronizer. Ahmed................217-22; disc. 222

Changer Used as Nonsynchronous Tie Between A-C Power Systems, Electronic Frequency. Winograd............................263-72; disc. 272

Characteristics of FTL Type No. 20-B UHF Television Transmitter, Technical. Bradburd........555-61

Circuit Containing a Nonlinear Capacitor, A Mathematical Analysis of a Series. Pipes.............................238-42; disc. 242

Circuit Problems, Applications of Integral Equations to the Solution of Nonlinear Electric. Pipes...445-50

Circuitry Upon the Operating Hysteresis Loops, The Influence of Magnetic Amplifier. Lord.....721-8

Circuits, Automatic Testing of Wired Relay. Hanson..............................850-7

Circuits, Basic Concepts in the Analysis of Stationary Electric. Spence, Cahn........617-23; disc. 623

Circuits, Block-Diagram Solutions for Vacuum-Tube. Stout..................................561-7

Circuits Containing Iron-Cored Inductances, Oscillatory. Mostafa, El-Shishini.......:.......274-83

Circuits in the 4A Toll Crossbar Switching System, Transistors and Their. Mallery..........388-92

Circuits, The Diode Matrix as a Component in Relay Switching. Bush.......................833-8

Circuits, The Map Method for Synthesis of Combinational Logic. Karnaugh......593-8; disc. 598

Circuits to Perform Multiplication and Other Analytical Operations, An Application of Magnetic Amplifier. Finzi, Mathias.........................455-61

Civil Defense, Communications for. Armstrong.......................................315-26

Coast Area, Microwave as Applied to Railroad Operation in the Gulf. Thomas..............800-04

Coaxial System—Amplifiers, L3. Morris, Lovell Dickinson....505–17
Coaxial System—Equalization and Regulation, L3. Ketchledge, Finch....414–30
Coaxial System—Television Terminals, L3. Rieke, Graham....541–51
Coaxial System, The L3. Elmendorf, Ehrbar, Klie, Grossman....395–413
Code Digital Quantizer, A Progressive. Raasch....567–71
Coils: Numerical Solutions, Temperature Fields in Electrical. Schneider....768–71
Color Kinescope, The RCA 3-Gun Shadow-Mask. Law....134–40
Color Television, Transmitting Terminal Apparatus for NTSC. Burr....26–33
Comb Filter Using Synchronously Commutated Capacitors, Analysis of a. LePage, Cahn, Brown....63–8
Combinational Logic Circuits, The Map Method for Synthesis of, Karnaugh....593–8; disc. 598
(Committee Report) Water Cooling Systems of Mercury-Arc Rectifiers. (53–288)....465–75
(Communication) A Subscriber Toll Dialing Tape Reader. Blashfield....17–21
(Communication) Automatic Call Recording and Accounting in the SATT System. Ostline....56–62
(Communication) Automatic Testing of Wired Relay Circuits. Hanson....850–7
(Communication) Co-ordination of M1 and N1 Telephone Carrier Systems. Smith, Cornell, Jerome....517–20
Communication Facilities Serving Power Stations and Substations, Protection of Wire. Alexander....587–91; disc. 591
(Communication) Heat Dissipation from Toll Transmission Equipment. Coy....762–8
(Communication) L3 Coaxial System—Amplifiers. Morris, Lovell, Dickinson....505–17

Indicator, Generator Stator Copper Temperature. Brownlee, Brown..........676-8; disc. 678
Inductances, Oscillatory Circuits Containing Iron-Cored. Mostafa, El-Shishini..........274-83
Inductive D-C Load, Saturable Reactors with. Storm: Part II. Transient Response......182-90; disc. 191
Industrial Electronic Equipment, Reliability in. Cook...........351-60
Industrial Vacuum Tubes Having Thoriated-Tungsten Filaments, High-Power. Ayer..........121-5
Industry, Use of Radio and Radar in the Petroleum. Rust..........796-800
Industry, Wire and Cable in the Telegraph. Markley...........298-308; disc. 308
Influence of a Transverse Magnetic Field on an Unconfined Glow Discharge, The. McBee, Dow...........229-37; disc. 237
Influence of A-C Reactance on Voltage Regulation of 6-Phase Rectifiers. Witzke, Kresser, Dillard...........244-52; disc. 252
Influence of Magnetic Amplifiers Circuitry Upon the Operating Hysteresis Loops, The. Lord.....721-8
Instability of Self-Saturating Magnetic Amplifiers Using Rectangular Loop Core Materials, An. Batdorf. Johnson..........223-7; disc. 227
Installation, Load-Dropping Tests on a Large Ignitron Rectifier. Pope, Dillard, Marcum...........164-72; disc. 172
(Instruments) A Commutatorless D-C Tachometer. Eckels, Peck..........625-8; disc. 628
(Instruments) A Permeability Analyzer for Magnetic Amplifier Cores. Siskind..........572-6
(Instruments) Correction of Frequency Errors in Wattmeters. Freeman..........679-81; disc. 681
Instruments for Simplified Quality-Control Measurements, Integrating. Longenecker..........375-80
(Instruments) Generator Stator Copper Temperature Indicator. Brownlee, Brown.....676-8; disc. 678
(Instruments) Preliminary Development of a Magnettor Current Standard. Felch, Potter..........524-31
Insulation, Nondestructive Testing of. Brancato...........202-05; disc. 205
Insulation Resistance, A Universal Meter for Measuring Voltages at High Impedances, Micromicroamperes, and. Clark, Watson, Mergner.......551-5
Integral Equations to the Solution of Nonlinear Electric Circuit Problems, Applications of. Pipes...........445-50
Integrating Instruments for Simplified Quality-Control Measurements. Longenecker..........375-80
Interference, The Measurement of Random Monochrome Video. Barstow, Christopher......735-41
Intertoll Telephone Trunks, Transmission Design of. Huntley..........670-6; disc. 676
Ion Recombination at Low Pressures, Electron-. Borowitz..........430-5
Iron at Very Low Flux Densities, The Permeability of Silicon-. Both..........656-61; disc. 661
Iron-Cored Inductances, Oscillatory Circuits Containing. Mostafa, El-Shishini..........274-83
Isotopes, Production of Unipolar Air with Radium. Martin..........771-6

J

Joint Use of Wood Pole Lines with Increasing Line Voltage, Some Aspects of. Bloecker, Bullard...........709-12

K

Kinescope, The RCA 3-Gun Shadow-Mask Color. Law..........134-40

L

L3 Coaxial System—Amplifiers. Morris, Lovell, Dickinson..........505-17
L3 Coaxial System—Equalization and Regulation. Ketchledge, Finch..........414-30
L3 Coaxial System—Television Terminals. Rieke, Graham..........541-51
L3 Coaxial System, The. Elmendorf, Ehrbar, Klie, Grossman..........395-413
Layers by Electromagnetic and Ultrasonic Diathermy, Heating of Fat-Muscle. Schwan, Carstensen, Li..........483-8
Level Compensator for Telephotograph Systems, A. Jones, Phelps..........537-41
Lines with Increasing Line Voltage, Some Aspects of Joint Use of Wood Pole. Bloecker, Bullard...........709-12
Liouville Problems by D-C Network Analyzer, The Solution of Sturm-. Swenson..........811-13
Liquid Dielectrics, Some Fluorinated. Bashara...79-85
Load-Dropping Tests on a Large Ignitron Rectifier Installation. Pope, Dillard, Marcum...........164-72; disc. 172
Loads, Capacitors in Power Systems with Rectifier. Schmidt..........14-17
Logic Circuits, The Map Method for Synthesis of Combinational. Karnaugh......593-8; disc. 598
Loop Core Materials, An Instability of Self-Saturating Magnetic Amplifiers Using Rectangular. Batdorf. Johnson..........223-7; disc. 227
Loops of Several Core Materials Employed in Magnetic Amplifiers, Dynamic Hysteresis. Lord.......85-8
Loops, Stressed Ferrites Having Rectangular Hysteresis. Williams, Sherwood, Goertz, Schnettler......531-7
Loops, The Influence of Magnetic Amplifier Circuitry Upon the Operating Hysteresis. Lord......721-8
Losses, Mathematical Descriptions of Core. Hale, Richardson..........495-501
Low Flux Densities, The Permeability of Silicon-Iron at Very. Both..........656-61; disc. 661
Low Pressures, Electron-Ion Recombination at. Borowitz..........430-5

M

Ml and Nl Telephone Carrier Systems, Co-ordination of. Smith, Cornell, Jerome..........517–20
Machine Announcements, Telephone-System Applications of Recorded. Bennett..........478–83
Machine Constants for Rectifiers, Equivalent. Dortort..........435–8
Machines, Flow of Energy in D-C. Hawthorne..438–45
Magnetic Amplifier Circuitry Upon the Operating Hysteresis Loops, The Influence of. Lord....721–8
Magnetic Amplifier Circuits to Perform Multiplication and Other Analytical Operations, an Application of. Finzi, Mathias..........455–61
Magnetic Amplifier Cores, A Permeability Analyzer for. Siskind..........572–6
Magnetic Amplifier for Synchros, A. Van Allen..........749–56; disc. 756
Magnetic Amplifiers, A Transient Analyzer for. Smith..........461–5
(Magnetic Amplifiers) Dielectric Amplifiers. Penney, Horsch, Sack..........68–79
Magnetic Amplifiers, Dynamic Hysteresis Loops of Several Core Materials Employed in. Lord...85–8
Magnetic Amplifiers, Fast Response with. Scorgie..........741–9
Magnetic Amplifiers, Flux Preset High-Speed. House..........728–35
Magnetic Amplifiers Using Rectangular Loop Core Materials, An Instability of Self-Saturating. Batdorf, Johnson..........223–7; disc. 227
Magnetic Amplifiers with Square-Loop Core Materials, Theory of. Storm..........629–37; disc. 637
Magnetic Cores, Nondestructive Sensing of. Buck, Frank..........822–30
Magnetic Field on an Unconfined Glow Discharge, The Influence of a Transverse. McBee, Dow..........229–37; disc. 237
Magnetic Tape Recording, Synchronized. Ranger..........581–6
Magnets Subjected to Demagnetizing Effects, New Method for the Optimum Design of Permanent. Ziegler..........253–62; disc. 262
Magnettor Current Standard, Preliminary Development of a. Felch, Potter..........524–31
Map Method for Synthesis of Combinational Logic Circuits, The. Karnaugh..........593–8; disc. 598
Mapper for 2-Dimensional Distributed Source Field Problems, A Capacitively Coupled Field. Gilbert, Gilbert..........345–9; disc. 349
Materials at Low Frequencies, Wheatstone Bridge for Admittance Determinations of Highly Conducting. Schwan, Sittel..........114–21
Materials, Theory of Magnetic Amplifiers with Square-Loop Core. Storm..........629–37; disc. 637
Mathematical Analysis of a Series Circuit Containing a Nonlinear Capacitor, A. Pipes..........238–42; disc. 242
Mathematical Descriptions of Core Losses. Hale, Richardson..........495–501
Matrix as a Component in Relay Switching Circuits, The Diode. Bush..........833–8
Maximum Impedance Transformations in Band-Pass Filters. O'Donnell, Williams..........110–13
Measurement of Random Monochrome Video Interference, The. Barstow, Christopher......735–41
Measurements, Integrating Instruments for Simplified Quality-Control. Longenecker..........375–80
Measuring and Recording System, An Automatic Transfer Function. Ehret, Hochschild, Embree, Grogan..........664–9; disc. 669
Mechanism of Impulse Corona and Breakdown in Oil, Propagation. Liao, Anderson....641–7; disc. 647
Mechanized Billing of AMA Toll Messages. Slade..........175–82; disc. 182
(Medicine) The Elements of Electrocardiographic Theory. Frank..........125–34
Memory, An Automatic Control System with Provision for Scanning and. Young..........392–5
Mercury-Arc Rectifiers, Water Cooling Systems of. (Committee Report)..........465–75
Meter for Measuring Voltages at High Impedances, Micromicroamperes, and Insulation Resistance, A Universal. Clark, Watson, Mergner......551–5
Meter, 40- to 4,000-Microwatt Power. Lange....492–4
Method for Flip-Flop Design, A Graphical. Johnston, Ratz..........52–60
Method for the Optimum Design of Permanent Magnets Subjected to Demagnetizing Effects, New. Ziegler..........253–62; disc. 262
Method for Treating Electron Tubes When Used as Superregenerative Detectors, A New. Mostafa, El-Shishini:
  Part I. Superregenerative Circuits Under No-Signal Condition..........207–13
  Part II. Superregenerative Circuits Under Signal conditions..........283–9
  Part III. Experimental Investigation of Superregenerative Circuits..........290–7
Method in Network Calculations, The Rayleigh. Schott, Heilfron..........89–93
Micromicroamperes, and Insulation Resistance, A Universal Meter for Measuring Voltages at High Impedances. Clark, Watson, Mergner......551–5
Microvoltages, Accurate Radio-Frequency. Selby..........158–63; disc. 163
Microwatt Power Meter, 40- to 4,000-. Lange....492–4
Microwave as Applied to Railroad Operation in the Gulf Coast Area. Thomas..........800–04
Microwave-Radio Routes, Path Testing for. Campbell..........326–34
Mid-Frequency Range, Electron-Tube Voltmeter Concepts in the. Hoadley..........501–04
Million-Watt Naval Communication Transmitter, A. Walter..........369–74
Million Watt Navy Transmitter, Frequency Generating Equipment for. Robertson..........475–7
Miniature Compandor for General Use in Wire and Radio Communication Systems, A. Boxall, Caruthers..........804–11
Monochrome Video Interference, The Measurement of Random. Barstow, Christopher..........735–41
Multiplication and Other Analytical Operations, An Application of Magnetic Amplifier Circuits to Perform. Finzi, Mathias..........455–61

N

N1 Carrier Systems, The Control of Noise and Crosstalk on. Aikens, Thaeler..........605–10; disc. 610
Nl Telephone Carrier Systems, Co-ordination of Ml and. Smith, Cornell, Jerome..........517–20
National Political Conventions, Television Coverage of the. Ralston, Wickline..........1–14
Naval Communication Transmitter, A. Million-Watt. Walter..........369–74
Navy Transmitter, Frequency Generating Equipment for Million Watt. Robertson..........475–7
Network Analyzer, A New Design 60-Cycle A-C. Davidson, Koll..........141–5
Network Analyzer, The Solution of Sturm-Liouville Problems by D-C. Swenson..........811–13
Network Analyzers for Pipe Network Analysis, The Use of Electric. Stephenson, Eaton........857–61
Network Calculations, The Rayleigh Method in. Schott, Heilfron..........89–93
Network, Development of Television Service Standards and Application to Design of a Television Broadcast. Reed..........838–50
New Jersey Turnpike—A Unique Highway Communication System, The. Godley, Neubauer, Marsh..........360–9
Nickel Base Indirectly Heated Oxide Cathode—A Review, The. Bounds, Hambleton........102–06
Noise and Crosstalk on Nl Carrier Systems, The Control of. Aikens, Thaeler..........605–10; disc. 610
Nonarmored Submarine Telegraph Cable, A. Lawton, Hutchins..........153–6; disc. 156
Nondestructive Sensing of Magnetic Cores. Buck, Frank..........822–30
Nondestructive Testing of Insulation. Brancato..........202–05; disc. 205
Nonlinear Capacitor, A Mathematical Analysis of a Series Circuit Containing a. Pipes..........238–42; disc. 242
Nonlinear Electric Circuit Problems, Applications of Integral Equations to the Solution of. Pipes..........445–50
Nonsynchronous Tie Between A-C Power Systems, Electronic Frequency Changer Used as. Winograd..........263–72; disc. 272
Nonuniform Fields at Radio Frequencies, The Electric Strength of Air in. Whitehead, Birx, Miller..520–4
NTSC Color Television, Transmitting Terminal Apparatus for. Burr..........26–33
Nuclear Power Plant Control Considerations. Schultz..........22–6
Null-Type Recorder with Balancing Amplifier Which Provides Damping and Suppresses the Quadrature Component, A-C. Williams, Payne..........611–15; disc. 615
Numerical Solutions, Temperature Fields in Electrical Coils. Schneider..........768–71

O

Oil-Immersed 110-Kv 440-Kw Rectifier Unit for Resnatron Plate Supply. Featherstone, Ling, Cartwright..........145–51; disc. 151
Oil, Propagation Mechanism of Impulse Corona and Breakdown in. Liao, Anderson...641–7; disc. 647
Optimum Design of Permanent Magnets Subjected to Demagnetizing Effects, New Method for the. Ziegler..........253–62; disc. 262
Oscillation as Well as the Asymmetry of the Resonance Curves, Effects of Harmonics on the Frequency of. Mostafa..........309–14
Oscillators, The First-Order Behavior of Separable. dePackh..........450–5
Oscillatory Circuits Containing Iron-Cored Inductances. Mostafa, El-Shishini..........274–83
Output Formulas for the Resistance Bridge, Sensitivity and. Andress..........213–16; disc. 216, 868
Oxide Cathode—A Review, The Nickel Base Indirectly Heated. Bounds, Hambleton..........102–06

P

Path Testing for Microwave-Radio Routes. Campbell..........326–34
Permeability Analyzer for Magnetic Amplifier Cores, A. Siskind..........572–6
Permeability of Silicon-Iron at Very Low Flux Densities, The. Both..........656–61; disc. 661
Permanent Magnets Subjected to Demagnetizing Effects, New Method for the Optimum Design of Ziegler..........253–62; disc. 262
Petroleum Industry, Use of Radio and Radar in the. Rust..........796–800
Pipe Network Analysis, The Use of Electric Network Analyzers for. Stephenson, Eaton..........857–61
Plant Control Considerations, Nuclear Power. Schultz..........22–6
Plastic, Forcing Function Generator Employing Conductive. Norman..........576–81
Plate Supply, Oil-Immersed 110-Kv 440-Kw Rectifier Unit for Resnatron. Featherstone, Ling, Cartwright..........145–51; disc. 151
Pole Lines with Increasing Line Voltage, Some Aspects of Joint Use of Wood. Bloecker, Bullard....709–12
Political Conventions, Television Coverage of the National. Ralston, Wickline..........1–14
Polyethylene Terephthalate—Its Use as a Capacitor Dielectric. Wooley, Kohman, McMahon....33–7
Power Meter, 40- to 4,000-Microwatt. Lange....492–4
Power Plant Control Considerations, Nuclear. Schultz..........22–6
Power Stations and Substations, Protection of Wire Communication Facilities Serving. Alexander..........587–91; disc. 591
Power Systems, Electronic Frequency Changer Used as Nonsynchronous Tie Between A-C. Winograd..........263–72; disc. 272
Power Systems with Rectifier Loads, Capacitors in. Schmidt..........14–17
Preliminary Development of a Magnettor Current Standard. Felch, Potter..........524–31
Principles of Tape-to-Card Conversion in the AMA System. Groth..........42–52
Problems by D-C Network Analyzer, The Solution of Sturm-Liouville. Swenson..........811–13
Problems on Automatic Computing Equipment, Solutions of Boundary-Value. Verzuh..........813–21
Problems to Consider in Applying Selenium Rectifiers. Gramels..........488–92
Production of Unipolar Air with Radium Isotopes. Martin..........771–6
Program Transmission Over Type-N Carrier Telephone. Case, Kerney..........791–5
Progressive Code Digital Quantizer, A. Raasch.567–71
Propagation Mechanism of Impulse Corona and Breakdown in Oil. Liao, Anderson.....641–7; disc. 647
Protection of Wire Communication Facilities Serving Power Stations and Substations. Alexander..........587–91; disc. 591
Pulse Response Characteristics of Rectangular-Hysteresis-Loop Ferromagnetic Materials. Wylen..........648–55; disc. 655

Q

Quadrature Component, A-C Null-Type Recorder with Balancing Amplifier Which Provides Damping and Suppresses the. Williams, Payne..........611–15; disc. 615
Quality-Control Measurements, Integrating Instruments for Simplified. Longenecker........375–80
Quantizer, A Progressive Code Digital. Raasch..........567–71

R

RCA 3-Gun Shadow-Mask Color Kinescope, The. Law..........134–40
Radar in the Petroleum Industry, Use of Radio and. Rust..........796–800
(Radio) A Million-Watt Naval Communication Transmitter. Walter..........369–74
Radio and Radar in the Petroleum Industry, Use of. Rust..........796–800
